Michael Lehrke and Nikolaus Marx

Department of Internal Medicine I (Cardiology), University Hospital, RWTH Aachen University, Aachen, Germany

Key points

- People with diabetes have an increased risk of developing ischaemic heart disease.
- Glucose lowering is important for the prevention of microvascular disease in diabetes, but has only moderate effects on the prevention of macrovascular complications.
- Individuals with diabetes and high or very high cardiovascular risk, including those with atherosclerotic cardiovascular disease, should be treated with sodium–glucose cotransporter 2 inhibitors and/or glucagon-like peptide 1 receptor agonists with proven cardiovascular benefit.
- Lowering low-density lipoprotein (LDL) cholesterol is highly effective in lowering cardiovascular event risk in people with diabetes; the LDL cholesterol goal in individuals with type 2 diabetes and very high cardiovascular risk and also in those with long-standing type 1 diabetes or end-organ damage is ≤ 55 mg/dl (1.4 mmol/l).
- Arterial hypertension should be treated to achieve a blood pressure of $\leq 140/80$ mmHg in people with diabetes, aiming for a systolic blood pressure of 130 mmHg and lower if tolerated, but not below 120 mmHg.
- Aspirin may be considered on an individualized basis in those at high cardiovascular risk.

Epidemiology

Ischaemic heart disease is by far the leading cause of death in people with diabetes [1]. Approximately one-third of all individuals with diabetes have atherosclerotic cardiovascular disease. Understanding the pathophysiological links between diabetes and coronary heart disease and gaining a thorough knowledge of the therapeutic options to prevent ischaemic heart disease in people with diabetes are therefore of the utmost importance.

In a 1998 landmark study [2], Haffner et al. reported that individuals with diabetes without previous myocardial infarction were at the same risk of future ischaemic heart disease events as someone with a prior myocardial infarction, but no diabetes. This observation had a major impact on clinical practice and established the concept of treating diabetes as a coronary heart disease risk equivalent. Indeed, in the current European Society of Cardiology (ESC) prevention guidelines, a similar aggressive approach to lipid lowering is recommended for those with type 2 diabetes and very high cardiovascular risk (>3 risk factors or end-organ damage), as recommended for those with established cardiovascular disease [3].

Pathophysiological perspective

Although diabetes as a clinical entity is diagnosed when glucose or glycated haemoglobin (HbA_{1c}) rises above internationally recognized thresholds, metabolic abnormalities that are associated with atherosclerosis in general, and with ischaemic heart disease in particular, typically exist for years or decades before diabetes becomes manifest [4, 5]. In the sequence of events that eventually leads to the

development of diabetes, insulin resistance is an early feature. This in turn is the key pathophysiological mechanism behind the metabolic syndrome, a cluster of metabolic abnormalities including elevated glucose, dyslipidaemia, visceral obesity, and elevated blood pressure, all of which are independently linked to the development of atherosclerotic disease [4, 5]. Type 2 diabetes becomes manifest only when β -cell failure develops on the background of pre-existing insulin resistance; that is, when the demand for insulin supply caused by insulin resistance can no longer be fulfilled [4]. The atherogenic environment of multiple cardiovascular risk factors associated with the metabolic syndrome has by then typically existed for years, if not decades. From this, it is clear that cardiovascular prevention must not be delayed till the stage of established diabetes, but should take place much earlier.

As glucose levels increase during the transition from metabolic syndrome to type 2 diabetes, the cardiovascular risk becomes progressively higher. In addition to the atherogenic metabolic syndrome risk factors, elevated glucose concentrations, through oxidative stress, can cause additional harm to the endothelium [6]. Importantly, however, glucose is not the main driving force for ischaemic heart disease, as glucose-lowering strategies have been largely disappointing with respect to reducing macrovascular disease. This is an important difference in comparison with the paramount role of elevated glucose for diabetic microangiopathy, which is directly caused by elevated glucose [7].

This pathophysiology applies to type 2 diabetes, which is particularly closely linked to cardiovascular disease, but type 1 diabetes is also associated with an increased cardiovascular risk [8]. However, the timespan between the onset of diabetes and the development of ischaemic heart disease is much longer in type 1 diabetes than in type 2 diabetes. In addition to direct glucotoxicity,

impairment of kidney function is an important mechanism linking type 1 diabetes to ischaemic heart disease risk.

Given the strong association of diabetes and cardiovascular disease, people with diabetes should be screened for the presence of atherosclerotic cardiovascular disease and heart failure, while those with heart failure or atherosclerotic cardiovascular disease should be screened for diabetes.

How can cardiovascular risk be reduced in people with diabetes?

Cardiovascular risk categorization

Recent guidelines, such as the 2019 ESC guidelines on pre-diabetes, diabetes, and cardiovascular disease, suggest classifying individuals according to their cardiovascular risk [3]. Very high-risk individuals are those with diabetes and established cardiovascular disease, as well as those with target-organ damage such as left ventricular hypertrophy or chronic kidney disease. In addition, those with diabetes and three or more major risk factors are also considered to be at very high risk, based on the observation that multiple risk factors in diabetes increase the risk, for example, for cardiovascular death [3]. People in the high-risk category are those with a diabetes duration of 10 years or longer without target-organ damage plus any additional risk factors. Finally, younger people (those with type 1 diabetes aged <35 years or type 2 diabetes aged <50 years) with a diabetes duration of <10 years and without other risk factors are considered at moderate risk. The American Diabetes Association (ADA)/European Association for the Study of Diabetes (EASD) consensus report uses comparable approaches to classify individuals and stratify therapeutic strategies and goals based on these categories.

Glucose lowering

Given that diabetes is diagnosed when glucose is elevated, glucose normalization seems to be of relevance for cardiovascular risk reduction in people with diabetes. However, numerous intervention trials addressing cardiovascular risk modification by lowering of glucose have shown no benefit.

The UK Prospective Diabetes Study (UKPDS) enrolled more than 4000 individuals with newly diagnosed type 2 diabetes [9]. Among other interventions, intensified glucose lowering was compared with conventional treatment, with participants followed for over 10 years. Although the incidence of microvascular diabetes complications was significantly reduced with intensive glucose-lowering therapy, macrovascular events, in particular myocardial infarction, stroke, and peripheral arterial disease, were not significantly reduced, although there was a non-significant trend towards a lower myocardial infarction incidence in those with intensive glucose management.

Importantly, three further trials, Action to Control Cardiovascular Risk in Diabetes (ACCORD), Action in Diabetes and Vascular Disease: Preterax and Diamicron-MR Controlled Evaluation (ADVANCE), and the Veterans Affairs Diabetes Trial (VADT), also did not show a reduction in macrovascular diabetes events with more aggressive glucose lowering [10–12].

In ADVANCE [11], more than 11 000 participants with type 2 diabetes were randomized to intensive glucose management, with the aim of lowering HbA_{1c} below 6.5% (48 mmol/mol) versus standard glucose management according to country guidelines. During a follow-up period of five years, a combined macro- plus

microvascular endpoint was significantly reduced by 14%, but macrovascular events were not reduced.

Interestingly, however, when longer time periods were observed, a benefit of more intense glucose lowering has emerged in some studies. In UKPDS, a 10-year post-trial follow-up revealed significant reductions in myocardial infarction among individuals whose glucose was lowered more aggressively during the trial [13]. In ADVANCE, however, a long-term follow-up did not show a benefit with regard to major vascular events [14], whereas in VADT there was a reduction of macrovascular events after 10 years, but this was not sustained after 15-year follow-up [15].

In people with type 1 diabetes, the Diabetes Control and Complications Trial (DCCT) did not show a significant reduction in macrovascular events during the original study period [16], but a long-term follow-up reported a significant reduction in macrovascular events over a period of 17 years [17].

In the ACCORD trial [10], contrary to expectation, mortality was higher in participants receiving more intense glucose lowering. This suggests that overly aggressive glucose lowering can cause harm in people with diabetes, possibly through weight gain and increased risk for hypoglycaemia. Hypoglycaemia is a severe stressor leading to an adrenergic and inflammatory response and has been linked to increased risk of cardiovascular events [18]. Furthermore, repolarization abnormalities of the heart occur in response to hypoglycaemia with the potential for malignant arrhythmia. Although this provides a rationale for the increased mortality observed in the ACCORD trial, causality has not been proven. Other studies using insulin or sulfonylurea, both hypoglycaemia-prone medications, have not reported increased cardiovascular risk despite an increased occurrence of hypoglycaemia during the trials, questioning direct causality [19, 20]. However, hypoglycaemia impairs life quality and should be avoided whenever possible.

Meta-analysis of interventional glucose-lowering trials have identified subgroups of individuals deriving macrovascular benefit from intensive glucose management. Importantly, these were younger persons with lower HbA_{1c}, early stages of diabetes, and absence of micro- or macrovascular disease [21]. As a consequence, individualized HbA_{1c} treatment goals have been recommended, which should consider existing comorbidities, life expectancy, and individual preference [3]. The ADA recommends an HbA_{1c} of <7.0% (53 mmol/mol) for the prevention of diabetes complications [22].

The general lack of effect of HbA_{1c} reduction on cardiovascular risk shifted attention to the cardiovascular benefit of individual glucose-lowering drugs and drug classes. When a 2008 meta-analysis of the study programme of rosiglitazone, a peroxisome proliferator-activated receptor-γ (PPAR γ) agonist, suggested that the drug caused cardiovascular harm, the US Food and Drug Administration (FDA) mandated that cardiovascular outcome trials of all new anti-diabetes drugs should be undertaken to demonstrate that the drug did not increase cardiovascular risk [23]. As a consequence, a multitude of cardiovascular endpoint trials have been performed, which have reshaped the evidence of diabetes therapy in those with high and very high cardiovascular risk. Sodium-glucose cotransporter 2 (SGLT-2) inhibitors and glucagon-like peptide 1 (GLP-1) receptor agonists have emerged as two drug classes that improve cardiovascular outcomes independent of HbA_{1c} (Chapters 35 and 36). In addition, dipeptidyl peptidase 4 (DPP-4) inhibitors, sulfonylureas, and basal insulin provide cardiovascular safety in treatment periods up to 6.3 years.

The concept of metformin as the first-line therapy in people with type 2 diabetes has recently been challenged in the 2019 ESC

guidelines on diabetes, pre-diabetes, and cardiovascular diseases. Evidence for the use of metformin derived from the UKPDS trial, in which a subgroup of 342 obese individuals with newly diagnosed diabetes treated with metformin had a 39% risk reduction of myocardial infarction and 36% risk reduction in total mortality [24]. The subgroup design with small sample size, a limited number of events, and selected baseline characteristics, however, precludes a generalization of these findings. This has led the ESC to recommend SGLT-2 inhibitors or GLP-1 receptor agonists as new first-line therapy in those with diabetes and high or very high cardiovascular risk, while metformin was only recommended as first-line therapy in those with moderate cardiovascular risk, resembling the UKPDS population [3]. By contrast, the ADA/EASD still recommend metformin as first-line therapy for most people with type 2 diabetes.

Cardiovascular risk reduction has also been demonstrated for pioglitazone. In the Prospective Pioglitazone Clinical Trial in Macrovascular Events (PROACTIVE), 5238 people with type 2 diabetes and macrovascular disease were randomized to either pioglitazone 45 mg daily or placebo [25] and followed up for three years. The primary endpoint of PROACTIVE was broad, including, in addition to death, non-fatal myocardial infarction and stroke, three-point major adverse clinical event (MACE), acute coronary syndrome, leg amputation, coronary revascularization, and revascularization of peripheral arteries. With regard to the primary endpoint, the risk reduction with pioglitazone was non-significant; however, when the more clinically relevant secondary endpoint of three-point MACE was considered, a significant 16% event reduction was observed with pioglitazone compared with placebo. Similar results were found in the Insulin Resistance Intervention after Stroke (IRIS) trial, in which 3876 individuals with pre-diabetes were treated with pioglitazone versus placebo following an ischaemic neurological event. Pioglitazone significantly reduced three-point MACE by 24% [26].

The Outcome Reduction with Initial Glargine Intervention (ORIGIN) trial randomized people to insulin glargine or standard care and showed neither a decrease nor increase in total cardiovascular events or ischaemic heart disease events with insulin glargine [19].

Following the 2018 FDA recommendations, several cardiovascular safety trials were published. Four large cardiovascular outcome trials compared DPP-4 inhibitors with placebo. DPP-4 inhibitors increase the serum levels of native GLP-1 by inhibiting the cleaving enzyme DPP-4. In all of these trials (Saxagliptin Assessment of Vascular Outcomes Recorded in patients with diabetes mellitus–Thrombolysis In Myocardial Infarction [SAVOR-TIMI 53] with saxagliptin vs placebo [27]; Examination of Cardiovascular Outcomes with Alogliptin versus Standard of Care [EXAMINE] with alogliptin vs placebo [28]; Trial Evaluating Cardiovascular Outcomes with Sitagliptin [TECOS] with sitagliptin vs placebo [29]; and Cardiovascular and Renal Microvascular Outcome Study with Linagliptin [CARMELINA] with linagliptin vs placebo [30]), the cardiovascular safety of DPP-4 inhibitors was confirmed, but none of the agents tested reduced cardiovascular events for three-point MACE (SAVOR-TIMI 53, EXAMINE, CARMELINA) or four-point MACE (TECOS). Notably, in one of the trials (SAVOR-TIMI 53), saxagliptin increased the risk for hospitalization for heart failure, an effect that was not seen with any of the other agents, suggesting that this is not a class effect but related to the compound itself or a chance finding [27].

The Cardiovascular Outcome Study of Linagliptin vs Glimepiride in Type 2 Diabetes (CAROLINA) directly compared the DPP-4 inhibitor linagliptin with the sulfonylurea glimepiride in respect to cardiovascular outcomes in people with relatively early type 2 diabetes and cardiovascular risk factors or established atherosclerotic cardiovascular disease. No difference in cardiovascular safety was observed between the two drugs despite glimepiride causing more hypoglycaemia (37.7% vs 10.6%) [20].

Sodium-glucose cotransporter 2 inhibitors

SGLT-2 inhibitors inhibit glucose reabsorption in the proximal tubal, thus leading to glucosuria and lowering of blood glucose levels. Four placebo-controlled cardiovascular outcome trials examined the effect of SGLT-2 inhibitors on the three-point MACE endpoint. Empagliflozin in the Empagliflozin cardiovascular outcome event trial in type 2 diabetes mellitus patients–Removing Excess Glucose (EMPA-REG) OUTCOME trial [31] and canagliflozin in the Canagliflozin Cardiovascular Assessment Study (CANVAS) trial significantly reduced three-point MACE [32]. In addition, canagliflozin significantly reduced three-point MACE in people with diabetes and nephropathy (Evaluation of the Effects of Canagliflozin on Renal and Cardiovascular Outcomes in Participants with Diabetic Nephropathy [CREDENCE] trial) [33]. Dapagliflozin Effect on CardiovascuLAR Events (DECLARE) examined the effect of dapagliflozin versus placebo in people with diabetes and did not find a significant reduction of three-point MACE, most likely due to the lower risk population; approximately 60% of participants did not have cardiovascular disease but did have multiple risk factors [34]. However, all three agents showed a significant reduction of the combined endpoint of hospitalization for heart failure or cardiovascular death, suggesting that the beneficial effect of SGLT-2 inhibitors is most likely mediated through a reduction of heart failure-related events (Chapter 50). This has been confirmed by the Dapagliflozin and Prevention of Adverse Outcomes in Heart Failure (DAPA-HF) trial, which showed that dapagliflozin led to a reduction of the combined endpoint of worsening of heart failure or cardiovascular death versus placebo in people with heart failure with reduced ejection fraction (HF_{EF}), with or without diabetes [35]. In addition, in the EMPA-REG OUTCOME trial, empagliflozin significantly reduced all-cause mortality compared to placebo [31].

In the Cardiovascular Outcomes Following Ertugliflozin Treatment in Type 2 Diabetes Mellitus Participants with Vascular Disease (VERTIS CV) trial [36], ertugliflozin was compared with placebo in 8238 individuals with type 2 diabetes and established cardiovascular disease. This turned out to be the only SGLT-2 inhibitor cardiovascular outcome trial to miss its primary superiority endpoint of cardiovascular death. Hospitalization for heart failure, however, occurred less frequently in the ertugliflozin group (hazard ratio [HR] 0.70; 95% confidence interval [CI] 0.54 to 0.090) [36]. In the randomized, placebo-controlled DApagliflozin and Prevention of Adverse outcomes in Chronic Kidney Disease (DAPA-CKD) trial, the effects of dapagliflozin on morbidity and mortality were studied in people with chronic kidney failure (mean estimated glomerular filtration rate [eGFR] of 43 ml/min/1.73 m²). The trial was performed in a population of people both with and without diabetes. Dapagliflozin, compared to placebo, led to a significant reduction in the primary composite endpoint of sustained ≥50% eGFR decline, end-stage kidney disease, renal or cardiovascular death, as well as hospitalization for heart failure [37].

In the most recent meta-analysis of SGLT-2 inhibitor cardiovascular outcome trials [38, 39], relative risk reductions for MACE, cardiovascular death, hospitalization for heart failure, and chronic kidney disease progression were estimated to be 10%, 15%, 32%, and 38%, respectively. For MACE, the benefit was only significant in those with established atherosclerotic cardiovascular disease. In contrast, hospitalization for heart failure was reduced in individuals both with and without atherosclerotic cardiovascular disease, and with or without heart failure.

Glucagon-like peptide 1 receptor agonists

Eight large cardiovascular outcome trials with GLP-1 receptor agonists have been published in full so far. Two of these trials confirmed cardiovascular safety by showing non-inferiority versus placebo, while in six trials a reduction of cardiovascular endpoints has been observed [40].

Confirmation of cardiovascular safety but no reduction of cardiovascular risk was shown in the Evaluation of Lixisenatide in Acute Coronary Syndrome (ELIXA) [41] and the Exenatide Study of Cardiovascular Event Lowering (EXSCEL) [42]. In ELIXA, people with a recent acute coronary syndrome were randomized to lixisenatide or placebo and followed over a median of 2.1 years. Lixisenatide was non-inferior to placebo, but did not show a reduction in the primary endpoint of three-point MACE [41]. EXSCEL examined the effect of extended-release exenatide versus placebo in more than 14 000 individuals and showed a non-significant trend towards reduction of three-point MACE with an HR of 0.91 (95% CI 0.83 to 1.0). Exenatide reduced all-cause mortality with an HR of 0.86 (95% CI 0.77 to 0.97), but based on the hierarchical statistical analysis plan, this result has to be considered hypothesis generating [42].

Six other trials with GLP-1 receptor agonists showed a reduction in cardiovascular endpoints. Liraglutide Effect and Action in Diabetes: Evaluation of cardiovascular outcome Results (LEADER) assessed the effect of liraglutide versus placebo over a median follow-up of 3.8 years and showed that liraglutide treatment not only reduced three-point MACE, but also led to a significant reduction in cardiovascular death and all-cause mortality [43]. In the Trial to Evaluate Cardiovascular and Other Long-Term Outcomes with Semaglutide in Subjects with T2DM (SUSTAIN-6), once-weekly injectable semaglutide significantly reduced three-point MACE over a median follow-up of 2.1 years with a significant relative risk reduction of 27% ($p = 0.02$). This effect of three-point MACE was mainly driven by a significant reduction of stroke and a trend towards a reduced incidence of myocardial infarction [44]. Albiglutide, another GLP-1 receptor agonist currently not marketed, was tested versus placebo in HARMONY OUTCOMES. Over a median follow-up of 1.6 years, albiglutide led to a significant 22% reduction of three-point MACE and a 25% relative risk reduction of myocardial infarction [45]. The effect of dulaglutide, a long-acting GLP-1 receptor agonist, on cardiovascular events was assessed in Researching cardiovascular Events with a Weekly INcretin in Diabetes (REWIND) versus placebo. Over a median follow-up of 5.7 years, a significant reduction of three-point MACE as well as a significant reduction of stroke was observed in those treated with dulaglutide [46]. The Peptide Innovation for Early Diabetes Treatment (PIONEER-6) trial assessed the effect of oral semaglutide in a phase 2 study versus placebo and over a median follow-up of 1.3 years, this GLP-1 receptor agonist did not reduce three-point MACE, but led to a 51% relative reduction of cardiovascular death [47]. In addition, oral semaglutide reduced all-cause mortality. Effect of Efpeglenatide on Cardiovascular Outcomes

(AMPLITUDE-O) investigated cardiovascular outcomes of the exendin-based weekly GLP-1 receptor agonist efpeglenatide. During a treatment period of 1.81 years, efpeglenatide reduced MACE significantly by 27%, independent of SGLT-2 inhibitor use, which was prescribed present in 15% of the population [48]. In all of these trials, only albiglutide significantly reduced hospitalization for heart failure, while the effect on heart failure hospitalization was neutral in the other trials.

These GLP-1 receptor agonist cardiovascular outcome trials differ with respect to the population examined, ranging from established cardiovascular disease in all individuals enrolled in ELIXA and HARMONY, to the population in REWIND where only 31% had established cardiovascular disease, while the remainder were included based on multiple risk factors. One of the questions arising from these cardiovascular outcome trials with GLP-1 receptor agonists is whether the beneficial effects seen are only present in those with established cardiovascular disease, or whether people with type 2 diabetes and multiple risk factors might benefit to a similar extent. A recent meta-analysis published by Masiko et al. suggests that there is no difference in benefit of GLP-1 receptor agonists on three-point MACE between people with or without cardiovascular disease, indicating consistent benefits not only in individuals with established cardiovascular disease, but also importantly in those with multiple risk factors in the absence of clinically apparent cardiovascular disease.

These trials have had a major impact on recent guidelines. The 2019 ESC guidelines on diabetes and cardiovascular disease recommend the use of a GLP-1 receptor agonist with proven cardiovascular benefit in individuals at high or very high cardiovascular risk. This group includes individuals with multiple risk factors or atherosclerotic cardiovascular disease (very high risk or those with a single risk factor) [3]. The ADA/EASD guidelines suggest prescribing these agents for individuals with established cardiovascular disease and those at high risk of cardiovascular disease [49].

Lipid management

Lipids play an essential role in the development of ischaemic heart disease, and therefore are a central target in preventive cardiology, in particular in people with diabetes (Chapter 48). Lipid metabolism in people with diabetes is characterized by hypertriglyceridaemia, low high-density lipoprotein (HDL) cholesterol, and small dense low-density lipoprotein (sdLDL) particles. The absolute levels of LDL cholesterol do not differ between people with and without type 2 diabetes [43].

Owing to insulin resistance, free fatty acids are released from adipose tissue and used by the liver to synthesize triglyceride-rich very low-density (VLDL) particles. Lipases hydrolyse triglycerides from VLDL particles, creating intermediate-density lipoprotein (IDL) particles and finally low-density lipoprotein (LDL) particles, which return to the liver by LDL receptor binding and secretion of cholesterol in the form of bile acids. Mediated by the enzyme cholesteryl ester transfer protein (CETP), triglyceride-rich lipoproteins are exchanged for cholesterol from LDL and HDL particles. LDL and HDL particles thus lose cholesterol and receive triglycerides in turn. These triglycerides are then removed by the action of hepatic lipase, rendering both LDL and HDL smaller and denser. Smaller HDL particles are more rapidly cleared by the kidney, which explains the low HDL cholesterol of individuals with type 2 diabetes; sdLDL particles are particularly atherogenic and explain in part why people with diabetes already at moderate LDL cholesterol levels are at a high risk of cardiovascular events.

Epidemiological and genetic studies confirm triglyceride-rich lipoproteins and their remnant particle as important contributors to cardiovascular disease [50]. Most triglycerides are carried by VLDL and VLDL remnants, with the latter being cholesterol enriched and sufficiently small to penetrate the vessel wall. Each triglyceride-rich lipoprotein and LDL carries one apolipoprotein B (ApoB). Circulating ApoB therefore indicates the number of atherogenic lipoproteins, while non-HDL cholesterol (total cholesterol minus HDL cholesterol) summarizes the atherogenic cholesterol content [51]. Both measures are used to guide lipid therapy [52]. While ApoB can substitute for the use of LDL cholesterol, non-HDL cholesterol is considered a secondary therapeutic target after reaching sufficient LDL cholesterol lowering. Despite the relevance of triglyceride-rich lipoproteins for atherosclerotic disease, cardiovascular risk reduction can most efficiently be reached by LDL cholesterol lowering, most likely reflecting the smaller particle size and efficacy in penetrating the arterial wall [52]. A large meta-analysis enrolling over 18 600 people with diabetes from 14 randomized trials of statins showed that for every 1 mmol LDL cholesterol reduction, the risk of myocardial infarction was reduced by 22%, which was not significantly different from the 19% event reduction achieved with the same amount of LDL reduction in individuals without diabetes [44]. The more LDL cholesterol is reduced, the better for cardiovascular risk reduction [45], and this holds true for individuals with and without diabetes and/or elevated triglyceride levels [53]. The absolute benefit of LDL cholesterol lowering is most pronounced in those with high baseline cholesterol, in addition to high cardiovascular risk.

The ESC guidelines recommend that all individuals with diabetes be treated to an LDL cholesterol target of <2.6 mmol/l (100 mg/dl). This should be intensified in individuals with high cardiovascular risk (no end-organ damage but diabetes duration ≥10 years and any additional risk factor) to an LDL cholesterol target of <1.8 mmol/l (<70 mg/dl). Additional intensification is recommended in case of very high risk (with target-organ damage, or at least three major risk factors, or early onset of type 1 diabetes with duration >20 years) to an LDL cholesterol target of <1.4 mmol/l (55 mg/dl) and a secondary target of non-HDL cholesterol of <2.2 mmol/l (85 mg/dl).

Low-density lipoprotein cholesterol lowering

LDL cholesterol lowering should primarily be achieved with statin therapy, which lowers LDL cholesterol by 30–50%. Individuals not reaching LDL cholesterol targets with maximal tolerated statin therapy should receive additional ezetimibe treatment, which lowers LDL cholesterol by 15–20% [52, 54]. Subgroup analysis of the IMPROved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) trial suggested that people with diabetes benefited particularly from LDL cholesterol lowering with ezetimibe [55]. Lowering of LDL cholesterol with a statin or with additional ezetimibe treatment thus has proven efficacy in reducing cardiovascular events, in particular in those with diabetes.

Escalation of therapy can also be reached by proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibition. Currently two PCSK9-directed monoclonal antibodies (evolocumab and alirocumab) are available, each resulting in additional LDL cholesterol lowering of 50–60% in individuals with or without diabetes [56, 57]. Both antibodies reduced cardiovascular risk by 15% in high-risk individuals with established cardiovascular disease [58, 59]. A comparable efficacy was found in people with and without diabetes, while absolute risk reduction was more pronounced in

individuals with diabetes, reflecting their greater baseline risk [60]. Further inhibition of PCSK9 can be achieved with small interfering RNA molecules that inhibit hepatic protein synthesis. Inclisiran is currently being developed for subcutaneous application every six months, with additional LDL cholesterol lowering of approximately 50% in individuals on statin therapy [61]. Novel therapies for LDL cholesterol reduction further include bempedoic acid. This pro-drug is metabolized to a competitive inhibitor of adenosine triphosphate (ATP)-citrate lyase, depleting intracellular cholesterol content with LDL receptor induction and subsequent LDL cholesterol lowering of 15–30% [62]. The Cholesterol Lowering via Bempedoic acid, an ACL-inhibiting Regimen (CLEAR) Outcomes study is evaluating the cardiovascular efficacy of bempedoic acid in 12 600 statin-intolerant individuals who were intolerant of statins and is expected to report in 2023 (NCT02993406).

Treatment of hypertriglyceridaemia

Treatment of hypertriglyceridemia simultaneously reduces ApoB and non-HDL cholesterol and should primarily be achieved by lifestyle and dietary interventions. Pharmacotherapy can be performed with fibrates or nicotinic acid, both reducing triglycerides by 20–50% [63]. Randomized trials found that fibrates and nicotinic acid lowered cardiovascular risk in the pre-statin area [64], but this was not replicated in more recent trials providing statin background therapy [65–67]. An important limitation of these trials, however, is that inclusion of participants was not limited to those with elevated triglyceride or low HDL cholesterol. Subgroup analysis suggests that fibrates may lower cardiovascular risk in people with elevated triglycerides or low HDL cholesterol despite concomitant statin therapy [68]. The Pemafibrate to Reduce Cardiovascular Outcomes by Reducing Triglycerides in Patients with Diabetes (PROMINENT) trial, which recruited 10 497 statin-treated persons with type 2 diabetes and high triglycerides, did not show a reduction of the combined primary efficacy end point (non-fatal myocardial infarction, ischaemic stroke, coronary revascularization, or death from cardiovascular causes) by pemafibrate compared to placebo [69].

Lowering of triglycerides can also be achieved with high-dose omega-3-fatty acids (>2 g/d). Lower-dose omega-3-fatty acids (1 g/d) have not been found to reduce cardiovascular risk [64]. High-dose icosapent ethyl (4 g/d) importantly reduced cardiovascular events (three-point MACE) by 26% (HR 0.74; 95% CI 0.65 to 0.83) in 8179 statin-treated high-risk individuals with elevated triglycerides, with similar reductions in those with or without diabetes [70]. These results were not confirmed in the Statin Residual Risk Reduction with EpaNova in High Cardiovascular Risk Patients with Hypertriglyceridaemia (STRENGTH) trial; treatment with a combination of omega-3 fatty acids (eicosapentaenoic acid and docosahexaenoic acid; 4 g/d) did not reduce cardiovascular risk in >13 000 individuals with high cardiovascular risk [71]. Additional studies are consequently needed to evaluate the cardiovascular benefit of high-dose omega-3-fatty acids in people with high triglyceride levels.

Novel triglyceride-lowering therapies include strategies to reduce ApoC-III and angiopoietin-like protein 3 (ANGPTL-3), which have both been linked to cardiovascular risk in genetic studies [72, 73]. ApoC-III travels with triglyceride-rich lipoproteins and inhibits lipoprotein lipase [74]. The antisense oligonucleotide volanesorsen reduces triglyceride levels by approximately 80% and was recently approved by the European Medical Agency for the treatment of familial chylomicronaemia syndrome [75]. Adverse

events include thrombocytopaenia and flu-like symptoms [75]. ANGPTL-3 impairs VLDL clearance and HDL particles by inhibition of lipoprotein and endothelial lipase activity. Reduction of ANGPTL-3 has been obtained with a monoclonal antibody (evinacumab) and antisense oligonucleotide (IONIS-ANGPTL-3-LRx), both of which reduce triglycerides by 60–70% and LDL cholesterol by 20–30% [76, 77].

Targeting high-density lipoprotein cholesterol

HDL cholesterol is a strong negative predictor of cardiovascular risk. Still, neither genetic nor pharmacological interventions have found that modification of HDL levels reduces cardiovascular risk [78]. HDL is a complex molecule comprising multiple lipoproteins and recent evidence suggests that HDL composition and functionality determine cardiovascular risk rather than particle number. This mostly refers to the capacity of HDL to guide reverse cholesterol transport, which is initiated by ApoA-1 serving as an acceptor for the cellular cholesterol [79]. New early therapeutic avenues include recombinant HDL or ApoA-1 particles in addition to lecithin-cholesterol acyl transferase (LCAT) activators.

Blood pressure management

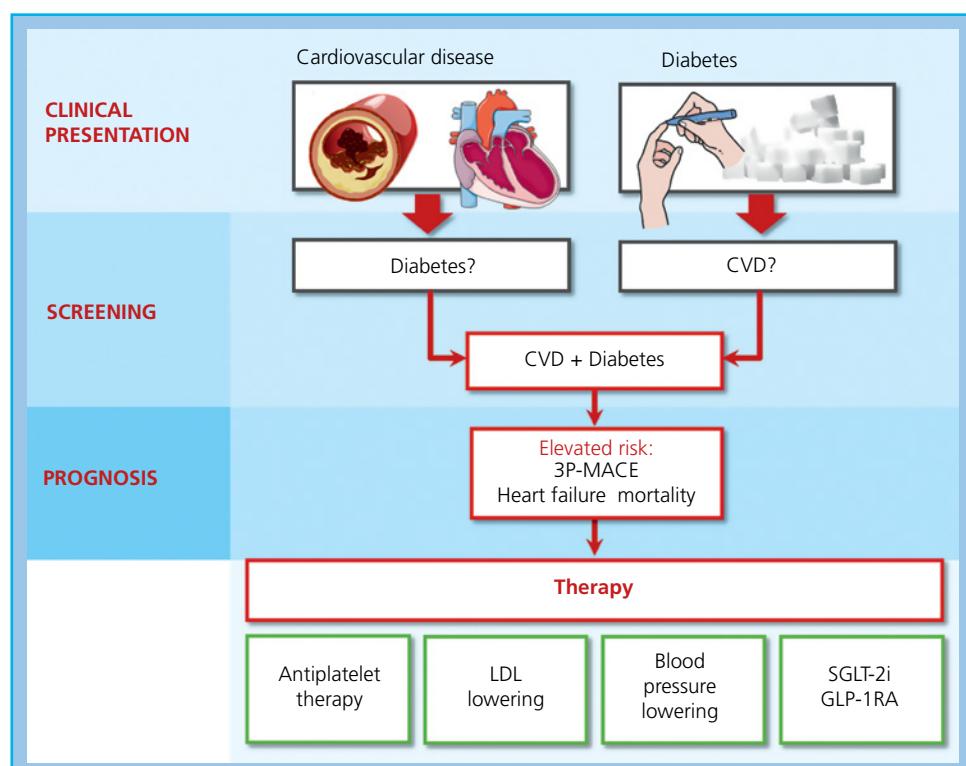

Blood pressure and the management of hypertension in people with diabetes are discussed in more detail in Chapter 47 [80]. The 2018 ESC Guidelines for the Management of Arterial Hypertension recommend a blood pressure target of $\leq 140/80$ mmHg in people with diabetes. Provided that treatment is well tolerated, treated systolic blood pressure targets of < 130 mmHg should be considered because of the benefits for stroke prevention. Achieved systolic blood pressure values of < 120 mmHg should be avoided [80].

In the blood pressure arm of the ACCORD trial, 4700 individuals with type 2 diabetes were randomized to a systolic blood pressure target < 120 mmHg or standard therapy with a systolic blood

pressure target of < 140 mmHg [81]. Mortality and ischaemic heart disease were not reduced by more aggressive blood pressure lowering, but stroke events fell by 47%. More intense therapy, however, was associated with more arrhythmic events, hypokalaemia, and hypotension, and so this aggressive treatment target cannot be generally recommended. Another study found that in people with diabetes and established ischaemic heart disease, overly intense blood pressure lowering led to an increased mortality risk. In individuals with systolic blood pressure below 110 mmHg, mortality was significantly increased compared with those with systolic blood pressure between 125 and 130 mmHg [82]. In the VADT [83], a significant increase in cardiovascular event risk was observed when the diastolic blood pressure was lowered to < 70 mmHg. For people with diabetes at high risk of cardiovascular events, in particular for those with established coronary artery disease, extremely low blood pressure targets therefore do not appear warranted.

Aspirin and anticoagulation

For many years it has been largely accepted that aspirin therapy should be employed only in secondary prevention, because of the risk-to-benefit ratio when used in primary prevention. In the newly reported A Study of Cardiovascular Events iN Diabetes (ASCEND) trial [84] of aspirin 100 mg/d against placebo in 15 480 individuals with diabetes, but without CVD, a 12% reduction in cardiovascular outcomes with a 4% bleeding risk was observed, results similar to previous meta-analyses and smaller datasets [85]. These data led to the recommendation that aspirin at a dose of 75–160 mg/d is recommended as secondary prevention in persons with diabetes. Treatment with a P2Y12 receptor blocker (ticagrelor or prasugrel) and aspirin is recommended for individuals with diabetes and acute coronary syndrome for one year, and in those who undergo percutaneous cardiac intervention or coronary artery bypass grafting.

In the Cardiovascular Outcomes for People Using Anticoagulation Strategies (COMPASS) trial of 27 395 individuals with stable atherosclerotic cardiovascular disease [86], the combination of low-dose aspirin (100 mg daily) plus low-dose rivaroxaban (2.5 mg twice daily) was significantly superior to aspirin alone in preventing myocardial infarction, stroke, or cardiovascular death. In a subgroup of 7240 individuals, of whom 44% had diabetes, followed for 23 months, there was a significant reduction in major limb events (HR 0.54), leading to the recommendation that the combination of rivaroxaban and aspirin should be considered in individuals with diabetes and lower-extremity arterial disease.

Overall, cardiovascular risk reduction in individuals with diabetes and ischaemic heart disease is mainly based on four pillars, and

the implementation of evidence-based therapies is of the utmost importance to improve the prognosis of these individuals [87] (Figure 49.1).

Multimodal therapy of cardiovascular risk factors in type 2 diabetes

Treatment of people with type 2 diabetes requires multimodal management of cardiovascular risk factors. The effectiveness of this approach was demonstrated in the Steno-2 study, in which intensified intervention of blood glucose, blood pressure (use of renin-angiotensin system blockers), aspirin, and lipid-lowering agents led to a 59% reduction of cardiovascular events and a 46% reduction of mortality during a follow-up period of 13.3 years [88].

- Diabetes is associated with elevated risk for the development of heart failure.
- Hyperglycaemia, lipotoxicity, inflammation, and abnormal myocardial metabolism contribute to the underlying pathophysiology of heart failure development in diabetes.
- People with comorbid heart failure and diabetes have worse outcomes, including functional status, hospitalization, and mortality, compared with those with heart failure without diabetes.
- Several risk scores are available to estimate the risk of developing heart failure among people with diabetes.
- Clinical trials of sodium–glucose cotransporter 2 (SGLT-2) inhibitors initially demonstrated consistent benefits for heart failure prevention and

later revealed improved cardiovascular outcomes among people with prevalent heart failure.

- The beneficial effects of β -blockers, renin–angiotensin system inhibitors, mineralocorticoid receptor antagonists, and SGLT-2 inhibitors for managing heart failure with reduced ejection fraction are consistent among people irrespective of diabetes status.
- Several factors should be considered when selecting anti-diabetes medications, including the risk of developing heart failure, history of heart failure, and left ventricular ejection fraction.

The relationship between diabetes and heart failure is well-recognized [1]. Dating back to the nineteenth century, diabetes was primarily considered a metabolic disorder characterized by hyperglycaemia, and its cardiovascular complications were just starting to be acknowledged. Growing evidence suggested that cardiovascular disease developed over time in this population, but excess mortality observed in diabetes limited the evaluation of long-term complications. Survival of people with diabetes was extended after the discovery and development of insulin, which facilitated the investigation of long-term diabetes-related complications. In 1954, Lundbaek reported abnormalities in the myocardium of older people with diabetes [2]. A landmark study was published in 1972 by Rubler et al. detailing the post-mortem findings of four individuals with diabetes-related complications without coexisting hypertensive, valvular, and congenital heart disease [3]. The term diabetic cardiomyopathy was used to describe the abnormalities in myocardial structure and function observed in people with diabetes in the absence of alternative causes. The contribution of diabetes to heart failure risk was further supported by epidemiological evidence from the Framingham Heart Study, demonstrating that diabetes was associated with heart failure risk after accounting for cardiovascular disease risk factors [4].

Contemporary studies confirmed and extended the findings from prior investigations examining the link between diabetes and heart failure. The epidemiology for both conditions has evolved significantly, and their impact on one another compounds the growing burden of diabetes and heart failure. Among people with heart failure, the presence of diabetes is associated with a worse

prognosis compared with those without diabetes [5]. Similarly, in people with diabetes, the presence versus absence of heart failure is associated with adverse outcomes [5]. These comorbid diseases not only contribute to the prognosis of each other, but therapies targeting these conditions influence one another. Cardiovascular outcome trials of medications used to manage hyperglycaemia in diabetes revealed safety concerns such that certain agents increased the risk of hospitalization for heart failure while others improved outcomes [6]. The purpose of this chapter is to describe the overlapping epidemiology, pathophysiology, outcomes, and treatment options for diabetes and heart failure. Type 2 diabetes accounts for most diabetes cases and will be the focus of the chapter.

Two epidemics: diabetes and heart failure**Epidemiology of diabetes and heart failure**

The worldwide prevalence of diabetes increased from 285 million in 2009 to 425 million in 2017 [7]. In 2019, diabetes affected 463 million people worldwide, with projected growth to 700 million by 2045. The diagnostic criteria for diabetes has been updated over the years, but this is unlikely to explain the dramatic increase in its burden. In the USA, diabetes affects more than 10% of the population and pre-diabetes, a condition of hyperglycaemia below diagnostic thresholds for diabetes, affects approximately one-third of adults [8]. In mid-life, at age 45 years, the lifetime risk of progression from pre-diabetes to diabetes is 74% [9]. Among individuals

born in 2000 in the USA, the lifetime risk for developing diabetes is 33% in men and 39% in women [10].

Similar alarming trends have been observed in the burden of heart failure. The global prevalence of heart failure is ~12% [11]. The lifetime risk of developing heart failure is high, at ~24–27% at 45 years of age [12]. Across heart failure subtypes, the lifetime risk of heart failure with preserved ejection fraction (HFpEF) was similar among people with and without diabetes at 10–12%. In contrast, the lifetime risk of heart failure with reduced ejection fraction (HFrEF) was 60% higher in people with versus without diabetes (11.6% vs 7.4%). The older population accounts for approximately three-quarters of heart failure hospitalizations [13, 14]. The burden of heart failure has grown in the setting of declining incidence, suggesting improved survival with this chronic condition. Among people with diabetes, heart failure incidence has decreased compared to those without diabetes among older individuals [15]. The availability and use of effective preventive therapies for heart failure in diabetes may be contributing to the declining incidence of heart failure [16]. Furthermore, diabetes and heart failure commonly coexist, and the prevalence of one is higher when the other is present. For example, the prevalence of diabetes among people hospitalized with heart failure is more than 40%, which is nearly four times that observed in the general population [17]. From 2005 to 2014, the prevalence of diabetes in both heart failure subtypes appeared stable in the community [18]. Similarly, the prevalence of heart failure in diabetes is up to 20%, which is approximately four times the rate observed in the community [19]. These excess rates of coexisting diabetes and heart failure suggest interrelated pathophysiology between two cardiometabolic diseases.

Diabetes is a risk factor for heart failure and subclinical abnormalities

In the Framingham Heart Study, the risk of developing heart failure was 2–5 times higher among adults with versus without diabetes [4]. The elevated risk of heart failure observed in diabetes persisted after accounting for differences in risk factors. Unlike atherosclerotic cardiovascular diseases such as myocardial infarction, the risk of heart failure remains elevated despite control of risk factors, including haemoglobin A_{1c} (HbA_{1c}), low-density lipoprotein cholesterol, blood pressure, albuminuria, and smoking, compared with adults without diabetes [20]. The residual risk of heart failure is greatest in young adults, emphasizing the importance of developing novel and sustainable heart failure-prevention strategies.

Heart failure develops over a series of several intermediate high-risk phenotypes. The presence of diabetes is associated with these subclinical cardiac abnormalities, including chronic myocardial injury and adverse cardiac remodelling [21, 22]. Across the glycaemic spectrum, hyperglycaemia is associated with greater left ventricular mass, and worse left ventricular systolic and diastolic function [21, 22]. The subtle, subclinical abnormalities in cardiac structure and function among people with diabetes identify an intermediate at-risk stage in the pathway to heart failure development that is often referred to as diabetic cardiomyopathy in the literature. While there is no consensus regarding its definition, recent epidemiological studies have used echocardiographic evidence of left ventricular hypertrophy, diastolic dysfunction, or elevated natriuretic peptide levels to define diabetic cardiomyopathy. The burden of diabetic cardiomyopathy in the community ranges from 12% to 67%, depending on the criteria used for its definition [23]. Presence of diabetic cardiomyopathy is independently associated with an increased risk of heart failure development, even in the

absence of other cardiovascular risk factors. Thus, diabetic cardiomyopathy identifies a potentially reversible intermediate stage in the development of heart failure and may be a potential target for therapeutic intervention. To this end, results from studies evaluating the role of different pharmacotherapies in preventing heart failure hospitalization among individuals with diabetic cardiomyopathy are awaited.

Diabetes and other heart failure risk factors

People with diabetes commonly have several comorbid cardiovascular disease risk factors, and this multimorbidity contributes to the excess risk of adverse outcomes, including heart failure (Figure 50.1). Hypertension, obesity, dyslipidaemia, and kidney disease are common conditions found in people with diabetes [24].

Hypertension

Hypertension is one of the commonest risk factors observed in diabetes, with comorbid rates of ~80% (Chapter 47) [24]. Both diseases exert adverse effects on the myocardium and lead to coronary artery disease, further exacerbating myocardial ischaemia and maladaptive cardiac remodelling [25]. The multiplicative effects of hypertension and diabetes may be explained by several mechanisms:

- Differential vascular remodelling is observed in hypertension (eutrophic) and diabetes (hypertrophic), which may lead to amplified atherosclerosis and myocardial ischaemia.
- Impaired coronary flow reserve leads to heart failure, and hypertension and diabetes may synergistically worsen functional circulation [26]. Endothelial dysfunction is observed in each disease separately, but together there is a worsening of coronary flow reserve through mechanisms independent of endothelial dysfunction.
- The sympathetic tone may be exacerbated by two triggers in hypertension and diabetes, leading to neurohormonal dysregulation, cardiac remodelling, and heart failure.

Dyslipidaemia

An abnormal lipid profile is observed in approximately three-quarters of individuals with diabetes (Chapter 48) [24]. People with diabetes have a typical pattern of low high-density lipoprotein cholesterol and elevated triglyceride levels, which is termed diabetes-related dyslipidaemia [27]. The dyslipidaemia in diabetes likely

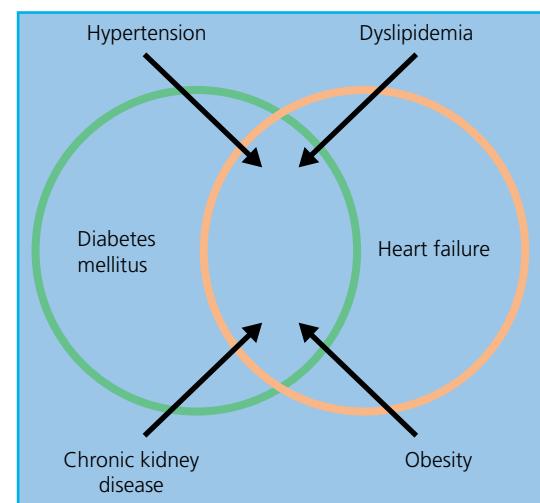

Figure 50.1 Overlapping epidemiology of diabetes, heart failure, and shared risk factors.

contributes to the risk of heart failure through multiple pathways. Dyslipidaemia may have a direct impact on heart failure risk, as low high-density lipoprotein cholesterol and elevated non-high-density lipoprotein cholesterol are associated with excess heart failure risk after accounting for risk factors, including myocardial infarction [28]. Additionally, diabetes-related dyslipidaemia is particularly pro-atherogenic, leading to coronary atherosclerosis, ischaemic heart disease, and downstream risk of heart failure.

Chronic kidney disease

Diabetes is the leading cause of chronic kidney disease, and each condition affects the other (Chapter 44) [29]. Diabetes-related kidney disease is based on chronic kidney disease, assessed by glomerular filtration rate and albuminuria, paired with clinical evidence of diabetes. Albuminuria reflects endothelial dysfunction and is associated with subclinical cardiac abnormalities such as left ventricular thickness, diastolic dysfunction, and elevated natriuretic peptide levels [30, 31]. These high-risk intermediate phenotypes observed with chronic kidney disease and diabetes likely contribute to the high risk of heart failure development when both conditions are present [32].

Obesity

The relationship between obesity, defined by a body mass index (BMI) of at least 30 kg/m², and heart failure is related to the effect of excess body mass on cardiac remodelling plus comorbid cardiovascular disease risk factors [33, 34]. A major driver of heart failure risk in obesity may be comorbid metabolic dysregulation. The elevated heart failure risk observed with higher measures of overall obesity, abdominal obesity, and fat mass appears to be related to comorbid risk factors [35, 36]. There is a suggestion that a metabolically healthy obese phenotype may not have an increased risk for developing heart failure. Compared with individuals with normal weight and metabolic syndrome, those with overweight and obesity but no metabolic syndrome had a lower risk of developing heart failure [37]. Similarly, among an older population, higher BMI levels were associated with the risk of heart failure, particularly in those with diabetes [38]. Taken together, there appears to be a synergistic effect between obesity and diabetes for the risk of developing heart failure.

Pathophysiology of heart failure in diabetes

Several pathophysiological mechanisms underlie the development of heart failure in diabetes, contributing to a vicious cycle (Figure 50.2). In diabetes, impaired glucose handling observed systemically follows a similar pattern in the heart. There is a shift

in the substrate used to generate energy within the myocardium, with a relative increase in the oxidation of free fatty acids compared with glucose [39]. The alterations in cardiac metabolism are related to changes in the source of energy substrates and abnormal mitochondrial oxidative processes. Glucose uptake into the myocardium is reduced in diabetes due to a reduction in proteins that facilitate transport [40]. Additionally, fatty acid transport is enabled by the availability of transporters. The increased availability and free fatty acid oxidation further inhibit glucose oxidation. The shift in substrate utilization is necessary to meet the metabolic demands of the heart, but this process is maladaptive. To produce the same amount of adenosine triphosphate, oxidation of fatty acids versus glucose consumes more oxygen and increases myocardial oxygen consumption. Inefficient oxygen utilization leads to hypoxia and a vulnerable substrate at high risk for injury in the setting of ischaemia. The high burden of ischaemic heart disease in diabetes coupled with abnormal cardiac metabolism may partly explain the increased risk of heart failure observed in people with diabetes. Additionally, the delivery of fatty acids to the heart may exceed its oxidative needs, leading to an oversupply of lipids and lipotoxicity [41]. The deposition of lipids into the myocardium can lead to myocardial injury, inflammation, and adverse cardiac remodelling [42]. People with diabetes have greater triglyceride content within the myocardium than individuals without diabetes [43, 44]. This myocardial triglyceride content was associated with subclinical diastolic dysfunction, a known risk factor for heart failure development [45].

Hyperglycaemia can have impacts on heart failure risk both directly and indirectly. Elevated circulating glucose levels can lead to non-enzymatic glycation of lipids, proteins, and nucleic acids, resulting in advanced glycation end-products. Advanced glycation end-products can directly impact cardiac structure and function by modifying extracellular protein cross-linking, resulting in impaired relaxation and diastolic dysfunction [46]. The vascular system can also be affected by advanced glycation end-products, with resulting coronary atherosclerosis contributing to downstream heart failure risk. Hyperglycaemia also exacerbates neurohormonal activation, with upregulation of the renin–angiotensin system and greater adverse cardiac remodelling [42]. Therapies for managing HFrEF target this axis in people with and without diabetes. Finally, there is significant overlap in the epidemiology of diabetes with other cardiovascular risk factors, including hypertension, dyslipidaemia, chronic kidney disease, and obesity. Clustering of these cardiometabolic risk factors can increase the risk of heart failure through their impact on distinct and shared pathways.

Risk prediction and prevention of heart failure in diabetes

Diabetes management has until recently primarily focused on the prevention of atherosclerotic cardiovascular disease, with less attention dedicated to preventing heart failure [47]. Progress in reducing hospitalization for heart failure has lagged behind improvements observed in ischaemic heart disease [48]. Heart failure development occurs over a continuum from an at-risk stage identified by the presence of cardiovascular disease risk factors to subclinical abnormalities in cardiac structure and function, followed by eventual clinical heart failure. Prevention efforts have historically focused on targeting modifiable risk factors at earlier stages. Traditional risk factor management is critically important

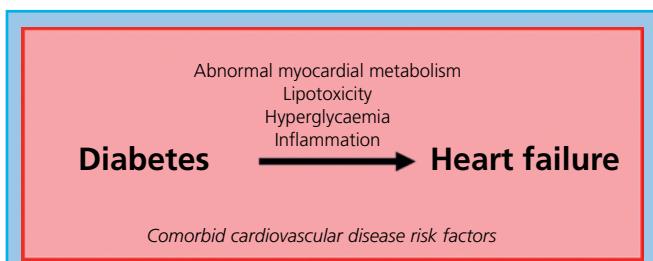

Figure 50.2 Proposed mechanisms underlying the pathophysiology of heart failure and diabetes.

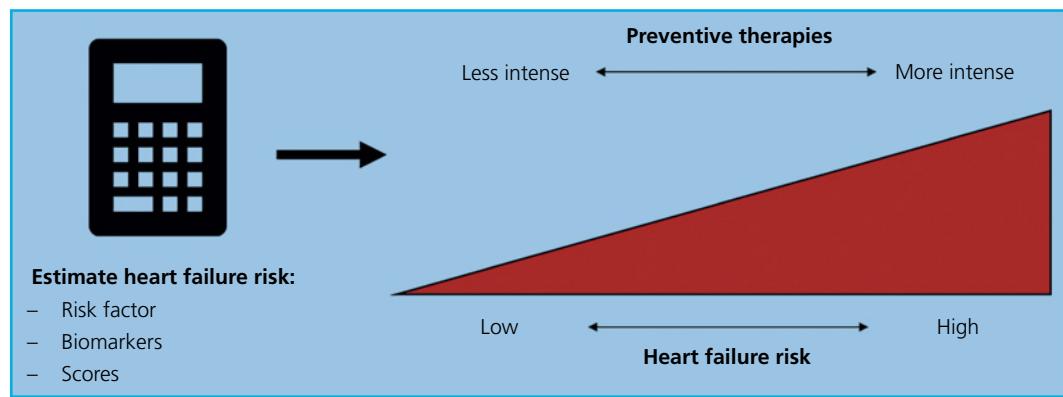

Figure 50.3 Preventive therapies can be targeted to people with diabetes and high risk for developing heart failure.

for cardiovascular disease prevention, but appears to be more beneficial for ischaemic heart disease than heart failure in the setting of diabetes [20]. Several tools have been developed to help guide the prescription of heart failure preventive therapies. Additionally, anti-diabetes therapies that effectively prevent heart failure are now available [49].

Heart failure risk assessment

A significant step in the primary prevention of heart failure is risk assessment. The estimated risk of heart failure can guide discussions and the selection of effective preventive therapies (Figure 50.3). People with diabetes and an elevated risk of heart failure are likely to derive the greatest absolute benefits from therapies.

Multiple risk scores are available to predict the risk of heart failure in the general population, with fewer specific to people with diabetes [50]. In an analysis from the Prospective Pioglitazone Clinical Trial in Macrovascular Events (PROactive) study, a risk score was developed to estimate incident heart failure risk among people with diabetes and established cardiovascular disease [51]. This heart failure risk score incorporated 12 variables, including demographics, medical history, medication use, and blood and urine laboratory measurements (Figure 50.4). This score had acceptable calibration and moderate discrimination (C-statistic 0.75) for predicting heart failure. The number of variables included in the risk score and the need for blood and urine studies may limit the usability of this tool, and external validation is needed. The WATCH-DM risk score was derived using machine learning to predict incident heart failure risk in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial [52]. The integer-based WATCH-DM risk score had fair calibration and moderate discrimination (C-statistic 0.72) in an internal validation cohort and has demonstrated similar model performance in a clinical trial cohort and community-based cohorts of people with diabetes [53]. Additionally, the TIMI Risk Score for Heart Failure in Diabetes (TRS-HF_{DM}) was developed to predict the risk of heart failure among people with diabetes [54]. The placebo arm of the Saxagliptin Assessment of Vascular Outcomes Recorded in patients with diabetes mellitus–Thrombolysis In Myocardial Infarction (SAVOR-TIMI 53) trial was the derivation cohort, and the placebo arm of the Dapagliflozin Effect on CardiovascuLAR Events (DECLARE-TIMI 58) trial was the validation cohort. The TRS-HF_{DM} risk score was calibrated and had good discrimination (C-index 0.81) for predicting heart failure. Unlike the WATCH-DM risk score and the heart failure risk score from PROactive, TRS-HF_{DM} helps inform the risk of heart failure among people with and without a prior history of heart failure.

Biomarker screening may be a useful strategy for risk assessment and prevention of heart failure in diabetes [55]. In the STOP-HF trial, adults at increased risk for developing heart failure based on clinical history were randomly assigned to undergo screening with brain natriuretic peptide (BNP) measurement or usual care [56]. Participants who had BNP levels of at least 50 ng/l in the BNP screening arm subsequently underwent echocardiogram assessment and referral to a cardiovascular disease specialist. The odds of incident heart failure or left ventricular dysfunction were 45% lower in the BNP screening group than in usual care. Additional data from the NT-proBNP Selected PreventiOn of cardiac eveNts in a populaTion of diabetic patients without A history of Cardiac disease (PONTIAC) trial suggests that individuals with diabetes and N-terminal pro-B-type natriuretic peptide (NT-proBNP) levels of at least 125 ng/l benefit from rapid uptitration of neurohormonal blocking therapies and referral to a cardiovascular disease specialist [57]. Intensified treatment in this population identified by NT-proBNP levels reduced the risk of cardiac events by 65%.

Heart failure risk scores incorporating biomarkers, including natriuretic peptides, have been developed. A biomarker score was developed in a pooled cohort study of community-dwelling adults that included high-sensitivity cardiac troponin T (hs-cTnT), NT-proBNP, high-sensitivity C-reactive protein, and left ventricular hypertrophy based on electrocardiogram [58]. In a population with diabetes, the biomarker risk score demonstrated adequate calibration and good discrimination (C-statistic 0.74) for predicting the five-year risk of developing heart failure. Finally, the TIMI Biomarker Score for Heart Failure in Diabetes was derived in the SAVOR-TIMI 53 trial. It incorporated a combination of blood-based biomarkers (hs-cTnT and NT-proBNP) and a prior history of heart failure to estimate the risk of hospitalization for heart failure among individuals with diabetes with and without prior history of heart failure [59]. This biomarker-based risk score demonstrated adequate calibration and good discrimination (C-index 0.87) for predicting heart failure risk.

Preventive therapies for heart failure

Healthy lifestyle

A healthy lifestyle focused on physical activity and weight loss in people with overweight or obesity is recommended to prevent heart failure [60]. Epidemiological studies have shown that higher BMI and lower physical activity and cardiorespiratory fitness are associated with a higher risk of heart failure [61–65]. The Look AHEAD (Action for Health in Diabetes) trial was a randomized controlled trial that evaluated the effect of an intensive lifestyle intervention focused on

PROactive HF risk score

Creatinine \geq 130 $\mu\text{mol/L}$	2

weight loss on cardiovascular outcomes among adults with diabetes and overweight or obesity [66]. In this trial, the intensive lifestyle intervention led to weight loss and fitness improvement at one year, but these benefits were not sustained over follow-up. During follow-up, the intensive lifestyle intervention did not reduce the risk of a composite cardiovascular disease endpoint of cardiovascular death, non-fatal myocardial infarction, non-fatal stroke, or hospitalization for angina. Additionally, the rate of heart failure was similar between participants randomized to the intensive lifestyle intervention and placebo groups [36]. A potential explanation for the null effect of the intensive lifestyle intervention on cardiovascular disease and heart failure outcomes is the lack of sustained improvements in weight and fitness. *Post hoc* analyses demonstrated that reduction in BMI was associated with a significantly lower risk of heart failure [36]. Similarly, reduction in other body composition measures such as waist circumference and fat mass were also associated with a

significantly lower risk of heart failure [35]. While the risk of cardiovascular disease was not reduced in this trial, the intensive lifestyle intervention improved several clinically relevant cardiovascular risk factors.

Blood pressure management

Hypertension is an important risk factor for heart failure for several reasons:

- Hypertension is common and affects almost half of all adults in the USA [67].
 - Heart failure risk is more than doubled in people with hypertension than in those with normal blood pressure [68].
 - Hypertension is a modifiable risk factor for cardiovascular disease. The beneficial effects of blood pressure lowering are greater for reducing heart failure risk compared with other cardiovascular diseases [69]. In the general population, for every 10mmHg reduction in

Table 50.1 Heart failure prevalence and outcomes in cardiovascular outcome trials of incretin-based therapies and sodium–glucose cotransporter 2 inhibitors.

Trial	Year	Drug	Number	History of heart failure (%)	Heart failure Hazard ratio (95% confidence interval)

CARMELINA [77]	2019	Linagliptin	6991	27	0.90 (0.74 to 1.08)
CAROLINA [78]	2019	Linagliptin	6042	4–5	1.21 (0.92 to 1.59)
Glucagon-like peptide 1 (GLP-1) receptor agonists					
ELIXA [79]	2015	Lixisenatide	6068	22	0.96 (0.75 to 1.23)
LEADER [80]	2016	Liraglutide	9340	18	0.87 (0.73 to 1.05)
SUSTAIN-6 [81]	2016	Semaglutide (SC)	3297	24	1.11 (0.77 to 1.61)
EXSCEL [82]	2017	Exenatide	14 752	16	0.94 (0.78 to 1.13)
HARMONY OUTCOMES [83, 156]	2018	Albiglutide	9463	20	0.71 (0.53 to 0.94)
REWIND [84]	2019	Dulaglutide	9901	9	0.93 (0.77 to 1.12)
PIONEER 6 [85]	2019	Semaglutide (oral)	3183	12	0.86 (0.48 to 1.55)
AMPLITUDE-O [86]	2021	Efpeglenatide	4076	18	0.61 (0.38 to 0.98)
Sodium glucose cotransporter 2 (SGLT-2) inhibitors					
EMPA-REG OUTCOME [72]	2015	Empagliflozin	7020	10	0.65 (0.50 to 0.85)
CANVAS [87]	2017	Canagliflozin	10 142	14	0.67 (0.52 to 0.87)
DECLARE-TIMI 58 [88]	2019	Dapagliflozin	17 160	10	0.73 (0.61 to 0.88)
CREDENCE [89]	2019	Canagliflozin	4401	15	0.61 (0.47 to 0.80)
VERTIS CV [90]	2021	Ertugliflozin	8246	24	0.70 (0.54 to 0.90)

systolic blood pressure, the risk of cardiovascular disease and heart failure is lower by 20% and 28%, respectively. However, diabetes appears to modify the association between systolic blood pressure and cardiovascular disease. The relative risk reduction in cardiovascular disease observed with blood pressure management was lower for people with diabetes (relative risk [RR] 0.88; 95% confidence interval [CI] 0.82 to 0.94) compared with those without diabetes (RR 0.75; 95% CI 0.70 to 0.80). Similarly, blood pressure management appears to have less of an effect on reducing heart failure risk in people with diabetes (RR 0.84; 95% CI 0.72 to 0.98) compared with those without diabetes (RR 0.75; 95% CI 0.65 to 0.87), although there was no significant interaction. In the ACCORD blood pressure trial, 4733 people with diabetes and an elevated risk for cardiovascular disease were randomly assigned to a systolic blood pressure target of <120 mmHg or <140 mmHg [70]. Intensive blood pressure management did not reduce the risk of a composite atherosclerotic cardiovascular disease endpoint or heart failure. In a meta-analysis of 24 444 people with diabetes, intensive blood pressure lowering was associated with a lower risk of all-cause death, myocardial infarction, and stroke, but not heart failure [71]. In 2022, the American Diabetes Association (ADA) recommended blood pressure targets based on the risk of future cardiovascular disease events [47]. A blood pressure target of <140/90 mmHg was recommended for individuals with diabetes and a 10-year estimated risk of atherosclerotic cardiovascular disease <15%. In contrast, a blood pressure target <130/90 mmHg was recommended for individuals with diabetes and either a history of cardiovascular disease or a 10-year estimated risk of atherosclerotic cardiovascular disease of at least 15%.

Sodium–glucose cotransporter 2 inhibitors

The Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients–Removing Excess Glucose

(EMPA-REG) OUTCOME trial evaluated the cardiovascular safety of empagliflozin, a sodium–glucose cotransporter 2 (SGLT-2) inhibitor, among 7020 people with diabetes and established cardiovascular disease [72]. People randomized to empagliflozin treatment received once-daily empagliflozin at a dose of 10 or 25 mg, and these doses were pooled in the primary analysis of the trial. After a median observed follow-up of three years, empagliflozin reduced the risk of a composite of cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke by 14%. The EMPA-REG OUTCOME trial was the first study to demonstrate a significant reduction in cardiovascular disease risk with an anti-diabetes medication in the modern era. The beneficial effects of empagliflozin in the composite atherosclerotic cardiovascular disease endpoint were significant, but perhaps more remarkable was the 35% reduction in heart failure hospitalization. The beneficial effects of the SGLT-2 inhibitor class of medications on the risk of heart failure hospitalization appear to be a class effect [49]. Canagliflozin, dapagliflozin, and ertugliflozin also demonstrated marked reductions in heart failure hospitalization among people with diabetes (Table 50.1) [87–90]. Due to the enrolment of few people with heart failure in these cardiovascular outcome trials, several SGLT-2 inhibitors are considered effective therapies to prevent heart failure. As discussed later, the cardiovascular effects of SGLT-2 inhibitors were studied further in prevalent heart failure. This class of medications has evolved from a glucose-lowering therapy to a therapeutic class that can be used to prevent and manage heart failure. The mechanism of benefit of SGLT-2 inhibitors is not well established, but is likely related to several complementary effects. A summary of the pleiotropic effects of SGLT-2 inhibitors that likely contribute to lowering heart failure risk is shown in Figure 50.5 [91].

Outcomes in people with comorbid diabetes and heart failure

The prevalence of comorbid diabetes is common among people with heart failure and is associated with an excess risk of adverse outcomes [92, 93]. Among people with heart failure, those with diabetes more commonly had New York Heart Association class III or IV symptoms and lower six-minute walk distance than those without diabetes [94]. Additionally, prevalent diabetes is associated with a 46% higher risk of unfavourable quality of life based on the Kansas City Cardiomyopathy Questionnaire [95]. After a diagnosis of heart failure, diabetes is one of the strongest predictors of hospitalization after accounting for other cardiovascular disease risk factors [96]. The risk of hospitalization and mortality in heart failure is also largely influenced by diabetes status. All-cause, cardiovascular, and heart failure hospitalizations and death were all higher among people who had heart failure with versus without diabetes [97]. After accounting for differences in cardiovascular risk factors, the risk of death is 28% higher among people with diabetes compared to those without diabetes [93]. The prevalence of comorbid diabetes and heart failure is similar across heart failure subtypes, but the prognosis differs [18]. In a *post hoc* analysis of the Candesartan in Heart failure—Assessment of Reduction in Mortality and morbidity (CHARM) trial, diabetes-associated risk of cardiovascular death or heart failure hospitalization was higher among people with HFrEF compared with HfPEF (hazard ratio [HR] 2.0; 95% CI 1.70 to 2.36; vs 1.60; 95% CI 1.44 to 1.77, respectively) [97]. In contrast,

diabetes was associated with similar excess risk of death in HFrEF and HfPEF (HR 1.55; 95% CI 1.38 to 1.74; vs 1.84; 95% CI 1.51 to 2.26, respectively).

Treatment considerations for heart failure and diabetes

Diabetes affects heart failure development through several underlying mechanisms, with direct and indirect effects on the myocardium, and may modify the response to heart failure therapies. Due to the increased risk of adverse outcomes with comorbid diabetes and heart failure and the broad impact of therapies, management considerations for each disease in the presence of the other will be highlighted. Large, randomized controlled trials of therapies for HFrEF and left ventricular systolic dysfunction enrolled a large proportion of participants with diabetes and provided evidence regarding therapeutic response across diabetes strata (Table 50.2).

Heart failure with reduced ejection fraction therapies among people with diabetes

Renin–angiotensin system inhibition

Inhibition of the renin–angiotensin system with angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and angiotensin receptor neprilysin inhibitor (ARNI) reduced the risk of cardiovascular disease in HFrEF across the

diabetes strata. In a meta-analysis, ACE inhibitors demonstrated 16% and 15% RR reduction in death among people with ($n = 2398$) and without diabetes ($n = 10\,188$), respectively [126]. Given the higher rate of mortality observed with diabetes, the absolute benefit of ACE inhibitors is expected to be large in this population with HFrEF. A similar pattern of benefits was observed for an ARB. In the CHARM programme, the beneficial effect of candesartan in heart failure was comparable among people irrespective of diabetes status [97]. The Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial evaluated the effects of ARNI with sacubitril-valsartan on morbidity and mortality among participants with HFrEF, of whom 35% had diabetes [105]. Diabetes status did not modify the benefit of sacubitril-valsartan for reducing cardiovascular disease. This trial enrolled a larger proportion of participants with diabetes compared with ACE inhibitor and ARB trials in HFrEF (Table 50.2). All three classes of agents appear to have glucose-lowering effects. Among people with HFrEF or left ventricular dysfunction, enalapril reduced the incidence of diabetes [127]. Similar findings were observed for candesartan in heart failure [128]. However, the effect of enalapril

and candesartan on glucose levels among people with comorbid diabetes and HFrEF is not well-established. In comorbid HFrEF and diabetes, sacubitril-valsartan reduced HbA_{1c} over three years, insulin use, and oral anti-diabetes medication use on follow-up [129]. Taken together, the renin–angiotensin system may affect both HFrEF and glucose homeostasis, and inhibition of this shared pathway may improve both comorbid conditions.

β -blockers

β -blockers reduce the risk of adverse outcomes in people with HFrEF with or without diabetes. A meta-analysis of three clinical trials of β -blockers (bisoprolol, carvedilol, and metoprolol succinate) included 1883 people with diabetes and 7042 people without diabetes and revealed a similar 23–35% reduction in death across diabetes strata [126]. However, there are several concerns regarding the adverse metabolic effects of β -blockers. Theoretically, β -blockers may decrease recognition of hypoglycaemia by slowing the heart rate and blunting tremors [130]. In the setting of hypoglycaemia, compensatory hepatic glucose production may be attenuated by blockade of the β_2 -receptor. β -blockers may also be associated with

impaired glucose tolerance or diabetes. Epidemiological evidence from the Atherosclerosis Risk in Communities (ARIC) study demonstrated a 28% higher risk of developing diabetes using β -blockers [131]. These findings are supported by separate studies showing that selective (atenolol, metoprolol) and non-selective β -blockers (propranolol) reduce glucose uptake [132, 133]. In contrast, blockade of the α -receptor can promote insulin sensitivity and enhance glucose uptake [134]. Carvedilol, an α - and β -adrenergic blocker, reduces HbA_{1c} and the incidence of diabetes in people with HFrEF [135, 136]. These favourable metabolic effects of carvedilol were not observed with metoprolol or bisoprolol and may be related to the vasodilatory properties of this medication [137].

Mineralocorticoid receptor antagonists

Mineralocorticoid receptor antagonists reduce morbidity and mortality in HFrEF [109–111]. Randomized clinical trials of eplerenone demonstrated consistent benefits among people with and without diabetes [110, 111]. In the Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF) trial, eplerenone did not increase the rate of new-onset diabetes compared with placebo [138]. In contrast, spironolactone increases HbA_{1c} and appears to have worse metabolic effects than eplerenone [139, 140]. Taken together, eplerenone may have a more favourable metabolic profile compared with spironolactone in HFrEF.

Sodium–glucose cotransporter 2 inhibitors

As discussed earlier, SGLT-2 inhibitors were originally developed to lower glucose, but were serendipitously found to reduce the risk of cardiovascular disease. One of the most consistent findings of the SGLT-2 inhibitor class was their effect on reducing the risk of heart failure hospitalization [72, 87, 88, 90]. The majority of people enrolled in SGLT-2 inhibitor cardiovascular outcome trials were free of heart failure, suggesting that SGLT-2 inhibitors prevented the development of heart failure (Table 50.1). The DECLARE-TIMI 58 trial was the largest diabetes cardiovascular outcome trial, which enrolled 17160 participants with type 2 diabetes and evaluated the safety of dapagliflozin [88]. In a secondary analysis, approximately 12% of participants had a history of heart failure at baseline, and this subgroup benefited the most from dapagliflozin, thus suggesting that SGLT-2 inhibitors may be beneficial among people with prevalent heart failure [141]. As such, SGLT-2 inhibitors were subsequently evaluated in clinical trials of people with a history of heart failure.

Dapagliflozin and Prevention of Adverse Outcomes in Heart Failure (DAPA-HF) was the first phase 3 clinical trial to evaluate the effects of an SGLT-2 inhibitor among people with HFrEF with and without diabetes [112]. Among 4744 people with HFrEF, dapagliflozin reduced the composite endpoint of cardiovascular death or worsening heart failure by 26%. These beneficial effects of dapagliflozin were similar for people with and without diabetes [142]. Compared with people randomized to placebo, those in the dapagliflozin group had lower rates of hospitalization for heart failure (9.7% vs 13.4%) and death from cardiovascular causes (9.6% vs 11.5%). A similar pattern of benefit was observed with empagliflozin among people with HFrEF in the EMPagliflozin outcomE tRial in patients with chroNic heaRt failure with Reduced ejection fraction (EMPEROR-Reduced) trial [113]. Compared with placebo, empagliflozin reduced the primary composite endpoint of hospitalization for heart failure or cardiovascular death by 25%, with similar benefits across diabetes strata [143]. The proportion of people who died from cardiovascular causes was not different across the two treatment arms [144]. The DAPA-HF and

EMPEROR-Reduced trials enrolled people with clinically stable HFrEF in an outpatient setting. In contrast, the Effect of Sotagliflozin on Cardiovascular Events in Participants with Type 2 Diabetes Post Worsening Heart Failure (SOLOIST-WHF) trial enrolled people with diabetes and heart failure across the spectrum of left ventricular ejection fraction who were recently hospitalized for heart failure and evaluated the effects of sotagliflozin, an SGLT-1 and SGLT-2 inhibitor, on cardiovascular outcomes [114]. In the study, 1222 people were randomized to receive either sotagliflozin or placebo prior to or within three days of discharge. Due to funding issues, the SOLOIST-WHF trial was terminated prior to enrolling the planned number of participants. The primary outcome was modified to increase the power of the study, and study outcomes were based on investigator-reported events rather than standard adjudication. In the context of these major limitations, sotagliflozin reduced the risk of a total composite number of cardiovascular deaths and heart failure hospitalizations and urgent visits by 33%.

Implantable cardioverter-defibrillators

Implantable cardioverter-defibrillators (ICDs) are used in HFrEF to reduce mortality by preventing sudden cardiac death. The Multi-center Autonomic Defibrillator Implantation Trial II (MADIT-II) enrolled people with myocardial infarction and reduced left ventricular systolic function and found that ICDs reduced mortality risk by 31% [115]. The beneficial effect of ICDs on mortality was similar across diabetes strata [116]. The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) was designed to evaluate whether ICDs would prevent death among people with HFrEF [117]. ICDs reduced the risk of death in SCD-HeFT, with no difference in results according to ischaemic aetiology. In the subgroup analysis by diabetes status, the beneficial effects of ICD therapy varied according to diabetes status. ICDs reduced the risk of death among people without diabetes but not those with diabetes [118]. Potential explanations for the lack of benefit of ICDs in people with versus without diabetes may be related to less effective ICD therapy or higher risk of death from causes other than sudden cardiac death in this population. In a separate study, inappropriate ICD therapy was found to be less common among participants with diabetes [145]. A pooled analysis of several studies suggested that ICD therapy may be less beneficial in people with a high burden of comorbidities [146]. Taken together, the risk–benefit profile of each person with diabetes should be considered when considering ICD therapy in this high-risk group.

Cardiac resynchronization therapy

Cardiac resynchronization therapy (CRT) reduces intraventricular conduction delays among people with HFrEF and cardiac desynchrony. In the Comparison of Medical Therapy, Pacing and Defibrillation in Heart Failure (COMPANION) trial, 1520 people with HFrEF (New York Heart Association class III or IV) and a QRS interval ≥ 120 ms were randomly assigned to either optimal medical therapy or optimal medical therapy plus CRT with and without an ICD [119]. CRT reduced the risk of death or hospitalization for any cause, with consistent benefits among people with and without diabetes [120]. The effect of CRT on cardiovascular events was not modified by diabetes status. Similar findings were observed in the CArdiac REsynchronization in Heart Failure (CARE-HF) trial with moderate or severe HFrEF [121, 122]. The Multicenter Automatic Defibrillator Implantation Trial–Cardiac Resynchronization Therapy (MADIT-CRT) and Resynchronization–defibrillation for Ambulatory heart Failure Trial (RAFT) investigated the effects of CRT among

people with less severe HFrEF and demonstrated improvements in cardiovascular outcomes that were similar among people with and without diabetes [123–125].

Heart failure with preserved ejection fraction therapies among people with diabetes

Efforts to improve cardiovascular outcomes in HFpEF with pharmacological therapies have historically been met with challenges, due in part to the heterogeneity of the clinical syndrome. Inhibition of the renin–angiotensin system, β -blockers, mineralocorticoid receptor antagonists, and other HFrEF therapies have not yielded robust benefits in clinical trials of HFpEF. Preliminary evidence from the SOLOIST-WHF trial suggested that inhibition of SGLT-1 and SGLT-2 with sotagliflozin reduced cardiovascular death and heart failure hospitalizations and urgent visits, with beneficial effects in heart failure across the spectrum of left ventricular ejection fraction extending to the preserved range [114]. However, the SOLOIST-WHF trial should be interpreted in the context of the major limitations noted earlier in this chapter. The EMPagliflozin outcome tRial in patients with chroNic heaRt failure with Preserved ejection fraction (EMPEROR-Preserved) trial enrolled 5998 people with HFpEE, of which approximately one-half had diabetes, to receive the SGLT-2 inhibitor empagliflozin or placebo [147]. Empagliflozin reduced cardiovascular death or heart failure hospitalization by 21% compared with placebo. The effect of empagliflozin on cardiovascular disease events in HFpEF was consistent across diabetes strata, with a 21% and 22% relative risk reduction in the primary endpoint among participants with and without diabetes, respectively.

Anti-diabetes medications among people with or at high risk for developing heart failure

Thiazolidinediones

The relationship between certain anti-diabetes medications and heart failure risk is well-established. Thiazolidinediones cause peripheral oedema and can provoke heart failure, leading to recommendations against using this class of medications in people with heart failure [148]. In the PROactive study, 5238 people with diabetes and established cardiovascular disease were randomised to pioglitazone or placebo [149]. After ~3 years of follow-up, pioglitazone reduced the risk of a composite atherosclerotic cardiovascular disease endpoint non-significantly, but increased the risk of heart failure (11% vs 8%). The concerns for heart failure risk with thiazolidinediones were further bolstered by an analysis of clinical trial data from five studies of muraglitazar that demonstrated an increased risk of cardiovascular disease, including heart failure [150]. After concerns were raised regarding the cardiovascular safety of another thiazolidinedione, rosiglitazone [151], an unplanned interim analysis of a cardiovascular outcome trial evaluating rosiglitazone was performed and revealed increased heart failure risk [152]. The cardiovascular safety concerns for anti-diabetes medications such as thiazolidinediones led the US Food and Drug Administration (FDA) to issue guidance in 2008 recommending new anti-diabetes medications to demonstrate cardiovascular safety in cardiovascular outcome trials [6].

Dipeptidyl peptidase 4 inhibitors

Incretin-based therapies, including dipeptidyl peptidase 4 (DPP-4) inhibitors and glucagon-like peptide 1 (GLP-1) receptor agonists, have been evaluated in several diabetes cardiovascular outcome trials. The SAVOR-TIMI 53 trial [75] was one of the first diabetes

cardiovascular outcome trials published after the FDA modified its approval process for anti-diabetes medications. In this trial, 16492 people with diabetes and established or at high risk for developing cardiovascular disease were randomly assigned to receive the DPP inhibitor saxagliptin or placebo. Saxagliptin did not significantly increase the risk of the composite atherosclerotic cardiovascular disease endpoint of cardiovascular death, non-fatal myocardial infarction, or non-fatal ischaemic stroke. However, the risk of heart failure hospitalization was higher among people who received saxagliptin compared with placebo. Excess risk of hospitalization for heart failure was apparent as early as six months after randomization and persisted during follow-up [153]. A similar pattern of cardiovascular effects was observed for another DPP-4 inhibitor, alogliptin.

In the Examination of Cardiovascular Outcomes with Alogliptin versus Standard of Care (EXAMINE) trial, 5380 people with diabetes who had a recent acute coronary syndrome were randomized to treatment with alogliptin or placebo [73]. There were no major differences in atherosclerotic cardiovascular disease between the groups. Due to the elevated heart failure risk observed with saxagliptin, a separate analysis of the EXAMINE trial was performed to evaluate whether alogliptin increased the risk of heart failure [74]. A summary of the DPP-4 inhibitor trials, including heart failure prevalence and risk of heart failure, is shown in Table 50.1. More than one-quarter of participants enrolled in EXAMINE had heart failure at baseline. The absolute rate of heart failure hospitalization was higher, although not statistically significant, among people randomized to treatment with alogliptin versus placebo. Among people with no history of heart failure, alogliptin increased the risk of hospitalization for heart failure by 76%. However, the excess heart failure risk observed with saxagliptin and alogliptin is not a class effect. In the Trial Evaluating Cardiovascular Outcomes with Sitagliptin (TECOS) trial, among 14 671 people with diabetes and established cardiovascular disease, sitagliptin did not affect the risk of heart failure hospitalization [76]. Similarly, in two cardiovascular outcome trials with linagliptin, the DPP-4 inhibitor did not meaningfully modify heart failure risk among people with diabetes compared with placebo or glimepiride [77, 78].

The DPP-4 inhibitor cardiovascular outcome trials described here included a small proportion of participants enrolled with prevalent heart failure, limiting the safety assessment of this class of medication in this population (Table 50.1). The Vildagliptin in Ventricular Dysfunction Diabetes (VIVIDD) trial enrolled 254 people with HFrEF and diabetes and evaluated the safety of the DPP-4 inhibitor vildagliptin on left ventricular function [154]. Based on the trial's primary objective, vildagliptin appeared safe for its effects on left ventricular ejection fraction. A similar increase in left ventricular ejection fraction was observed in people who received vildagliptin and placebo. However, people who received vildagliptin had an increase in left ventricular end-diastolic volume, which is correlated with elevated mortality risk [155]. These findings paired with the trend towards higher death in the vildagliptin versus placebo group suggest further study is warranted regarding the safety of this agent in HFrEF.

Glucagon-like peptide 1 receptor agonists

Several GLP-1 receptor agonists have demonstrated consistent benefits in lowering the risk of atherosclerotic cardiovascular disease [156]. However, the effects of this drug class on heart failure outcomes have been less consistent (Table 50.1). Most GLP-1 receptor agonists demonstrated neutral effects on heart failure in

cardiovascular outcome trials, except for albiglutide and efglenatide. In the Harmony Outcomes trial, 9463 participants with diabetes were randomly assigned to receive albiglutide or placebo [83]. Participants randomized to receive albiglutide had a 29% lower risk of heart failure hospitalization compared with placebo [156]. The Effect of Efpeglenatide on Cardiovascular Outcomes (AMPLITUDE-O) trial, which enrolled 4076 people with diabetes, similarly demonstrated a 39% reduction in the risk of heart failure hospitalization with efpglenatide [86]. A meta-analysis pooled data from eight GLP-1 receptor agonist cardiovascular outcome trials and found an 11% relative risk reduction in heart failure hospitalization with this class of medications [156].

The mechanisms underlying the beneficial effects of GLP-1 receptor agonists on heart failure are not well-established [157, 158]. A potential explanation may be related to the effect of GLP-1 receptor agonists in preventing myocardial infarction, a major risk factor for heart failure. Compared with other agents in the class, albiglutide and efpglenatide demonstrated the most considerable reductions in risk of myocardial infarction in their respective cardiovascular outcome trials.

Most people enrolled in the Harmony Outcomes trial did not have a prior history of heart failure (80%), suggesting that albiglutide was effective in preventing heart failure, but its effects on prevalent heart failure were less clear [83]. The cardiovascular effects of albiglutide were evaluated in a trial of 82 people with HFrEF and no history of diabetes [159]. Albiglutide mainly had neutral effects in HFrEF, with no meaningful differences compared with placebo on left ventricular ejection fraction and myocardial glucose uptake. A similar neutral effect on left ventricular ejection fraction was observed among people with HFrEF with and without diabetes who were randomly assigned to receive liraglutide or placebo in the Effect of Liraglutide on Left Ventricular Function in Chronic Heart Failure Patients with and without Type 2 Diabetes Mellitus (LIVE) trial [160]. However, there were some concerns regarding the safety of liraglutide in HFrEF. People who received liraglutide had an increase in heart rate and the rate of serious adverse cardiac events compared with placebo. These safety concerns of GLP-1 receptor agonists in HFrEF were further supported by evidence from the Functional Impact of GLP-1 for Heart Failure Treatment (FIGHT) trial, which evaluated the effects of liraglutide among 300 high-risk people with HFrEF with and without diabetes [161]. The rate of rehospitalization for heart failure was higher, although not statistically significant, among people randomized to receive liraglutide versus placebo. Despite the safety concerns for GLP-1 receptor agonist use in HFrEF, there may be a role for this class of agents in HFpEF. The pathophysiology of heart failure subtypes is distinct, and the non-cardiac effects of GLP-1 receptor agonists, specifically weight loss, may be beneficial in HFpEF and require further study [157].

Sodium glucose cotransporter 2 inhibitors

Several large cardiovascular outcome trials examining the effects of SGLT-2 inhibitors have been published in the last five years. SGLT-2 inhibitors are now recommended for the prevention and management of heart failure [60]. Among people with diabetes who are at increased risk for developing heart failure, SGLT-2 inhibitors are recommended to prevent heart failure. Additionally, SGLT-2 inhibitors are recommended in the management of both heart failure subtypes.

Metformin

Metformin has historically been recommended as the first-line agent for managing hyperglycaemia in diabetes [162, 163]. In the

heart failure setting, there were concerns early on regarding lactic acidosis associated with metformin, limiting its use. However, the initial contraindication to metformin use in heart failure was removed as more data emerged. It should be noted that there are limited randomized controlled trial data available examining metformin use in people with heart failure.

Sulfonylureas

Sulfonylureas are commonly used, but there are no placebo-controlled trials evaluating the cardiovascular safety of this class. Glimepiride, a sulfonylurea, was evaluated in the randomized, active-controlled Cardiovascular Outcome Study of Linagliptin vs Glimepiride in Type 2 Diabetes (CAROLINA) trial [78]. In this trial, 6991 people with diabetes were randomly assigned to receive glimepiride or linagliptin. The rate of heart failure hospitalization was not significantly different among people who received linagliptin (3.7%) and glimepiride (3.1%).

Insulin

The effect of different types of insulin on cardiovascular outcomes has been evaluated in two trials. The Outcome Reduction with Initial Glargine Intervention (ORIGIN) trial randomly assigned 12 537 people with pre-diabetes or diabetes plus cardiovascular risk factors to receive insulin glargine or standard of care [164]. People randomized to receive glargine targeted a fasting plasma glucose of 95 mg/dl (5.3 mmol/l) or less. After six years of follow-up, there was no significant difference in the risk of heart failure hospitalization between the two groups. Heart failure hospitalization occurred in 4.9% of people in the glargine group and 5.5% of people in the standard care group. A separate cardiovascular outcome trial was performed to evaluate the cardiovascular safety of insulin degludec, an ultra-long-acting basal insulin, compared with insulin glargine [165]. In the Trial Comparing Cardiovascular Safety of Insulin Degludec vs Insulin Glargine in Patients with Type 2 Diabetes at High Risk of Cardiovascular Events (DEVOTE), among 6509 people with diabetes and high risk for cardiovascular disease, there was no difference in heart failure risk among people randomized to the insulin degludec or glargine groups [166].

Overall, the response to most heart failure therapies is not modified by diabetes status and management of both HFrEF and HFpEF is similar for people with and without diabetes. In contrast, several factors should be considered in the use of anti-diabetes medications in people who are at elevated risk for developing heart failure or who have heart failure.

Conclusion

The burden of diabetes is growing in the community, highlighting the need for greater focus on preventive efforts to reduce the risk of downstream cardiovascular complications such as heart failure and for optimal management of people with coexisting diabetes and heart failure. To this end, substantial therapeutic advances have been made in the past decade with the use of SGLT-2 inhibitors for prevention and management of heart failure. The future challenges pertain to the development of efficient implementation strategies to identify and treat the people with diabetes who will most benefit from effective but expensive therapies in the real world.

Cerebrovascular Disease and Diabetes

Colum F. Amory¹, Jesse Weinberger², and Travis S. Smith¹

¹ Albany Medical College, Albany, NY, USA

² Mount Sinai School of Medicine, New York, NY, USA

Key points

- Diabetes is a strong and independent risk factor for ischaemic cerebrovascular disease with a relative risk of ~2.
- Ischaemic stroke in people with diabetes has worse outcomes, including a higher rate of mortality, than in people without diabetes.
- Although transient ischaemic attacks (TIAs) appear to occur less frequently in individuals with diabetes, those who experience a TIA are more likely to go on to have a completed stroke in the immediate period following.
- Individuals with diabetes are predisposed to vascular events, including stroke, for several reasons, such as premature

atherosclerosis, reduced response to nitric oxide, and a general state of hypercoagulability.

- Prevention of stroke in people with diabetes is best accomplished through aggressive management of coexisting hypertension and hyperlipidaemia, in addition to health behaviour modifications.
- Reduction of glycated haemoglobin as a proxy for good glycaemic management is likely associated with a reduction in macrovascular events.
- Aggressive management of hyperglycaemia in the acute stroke period may improve outcomes.

Epidemiology of stroke in general

Cerebrovascular disease is a leading cause of morbidity and mortality. It is a highly prevalent disease, with ~795 000 strokes occurring each year in the USA. Of these, 610 000 are first-time events and 185 000 are recurrent [1]. Stroke prevalence is 2.6% in people over 20 years of age. While the incidence and mortality rates of stroke have declined over the past several decades, it remains the fifth leading cause of death in the USA, following heart disease, all forms of cancer, trauma, and chronic lower respiratory disease [2]. Thus, a woman is nearly twice as likely to die from a stroke as she is from breast cancer, and 10% more likely than to die from lung cancer [3]. Furthermore, it is the number one reason listed for discharge diagnosis for people discharged from hospitals to chronic care facilities. In total, the cost of stroke to the healthcare system in the USA was \$36.5 billion in 2010 [1].

Statistics in other countries are similar to those seen in the USA. The Oxford Vascular Study, which compiled stroke statistics for every person in the county of Oxfordshire in the UK, demonstrated an overall incidence of 1.62 strokes per 1000 per year [4]. The World Health Organization (WHO) Multinational MONItoring of trends and determinants in CArdiovascular disease (MONICA) study looked at 21 populations in 11 countries (10 in Europe plus China) and found an incidence of 125–361 per 100 000 men, and 61–194 per 100 000 women [5].

Diabetes as a risk factor for stroke

There is strong evidence that diabetes mellitus, whether type 1 diabetes or type 2 diabetes, is a significant risk factor for ischaemic cerebrovascular disease (Table 51.1). Observational studies have demonstrated associations between the two diseases. A model created from data from the Framingham Heart Study showed that diabetes confers an increased relative risk (RR) of 1.4 in men and 1.72 in women [6]. The Honolulu Heart Study showed that diabetes increases the risk of thromboembolic stroke two- to threefold over individuals without the disease in Japanese men living in Hawaii [7]. A 2019 meta-analysis found the prevalence of diabetes in ischaemic stroke to be as high as 33% [8].

The effect of diabetes is stronger in ethnic minority populations in the USA. The Greater Cincinnati and Northern Kentucky Stroke Study found that as a sole risk factor, diabetes increased the odds ratio (OR) for having an ischaemic stroke by 2.1 in people of white European ancestry; however, in African Americans, that OR was increased by 2.7. These results held true across all age cohorts [9].

Similarly, the Northern Manhattan Study found that diabetes was a stronger risk factor for ischaemic stroke among African Americans and Caribbean Hispanics than among white Europeans. In these ethnicities, diabetes increased stroke risk by 1.8 and 2.1, respectively, partly due to increased prevalence of the disease. The fraction of strokes that could be directly attributable to diabetes as

Table 51.1 Risk factors for stroke.

Hypertension
Diabetes
Tobacco use
Hyperlipidaemia
Atrial fibrillation
Carotid artery disease

a risk factor was 14% among African Americans and 10% among Caribbean Hispanics [10].

The Copenhagen City Heart Study found a difference in the effect of diabetes among men and women. Thus, while diabetes increased the RR of first stroke, incident stroke, and hospital admission for stroke among men by 1.5–2, among women the same RRs were increased by 2.0–6.5 [11].

In addition to its effects as a sole risk factor, diabetes also exacerbates the effects of other risk factors. Thus, in people with isolated systolic hypertension, diabetes confers additional risk of ischaemic stroke or transient ischemic attack (TIA).

Stroke in people with diabetes

In epidemiological studies, ischaemic stroke occurs at a younger age in individuals who have diabetes. They are also more likely to be African American. Among other risk factors, people with

diabetes who have ischaemic stroke are more likely to have hypertension and hyperlipidaemia, and to have experienced a myocardial infarction in the past [9].

Diabetes is a negative predictor for functional outcome following strokes, and most studies have demonstrated longer hospitalizations after stroke in people with diabetes, increased readmission rates, and increased stroke recurrence [8]. Furthermore, diabetes increases the risk of death from stroke. In a prospective study in a Finnish cohort, men had an increased RR of 6 for mortality from ischaemic stroke, whereas women had an RR of 8.2. These RRs were higher than those for systolic blood pressure, smoking, or total serum cholesterol. In this cohort, the fractions of stroke deaths directly attributable to diabetes were 16% in men and 33% in women [12].

In terms of stroke subtype, diabetes is most commonly associated with lacunar infarcts; that is, a small, deep infarct in the region of a single penetrating arterial branch. Conversely, the highest prevalence of diabetes is found in people with demonstrated microvascular disease. Similarly, lacunar disease is more likely to be associated with diabetes than haemorrhages in the same location [13–16] (Figure 51.1).

Diabetes is also associated with both extracranial and intracranial stenosis. In a study of 510 people referred for asymptomatic carotid bruits, only 200 had extracranial stenosis by Doppler examination. There were 66 with asymptomatic intracranial stenosis, of whom 37 had concurrent extracranial stenosis. Of those with intracranial stenosis, 19 had diabetes [17] (Figure 51.2). Interestingly, a recent analysis of the Secondary Prevention of Small Subcortical Strokes (SPS3) study demonstrated that people

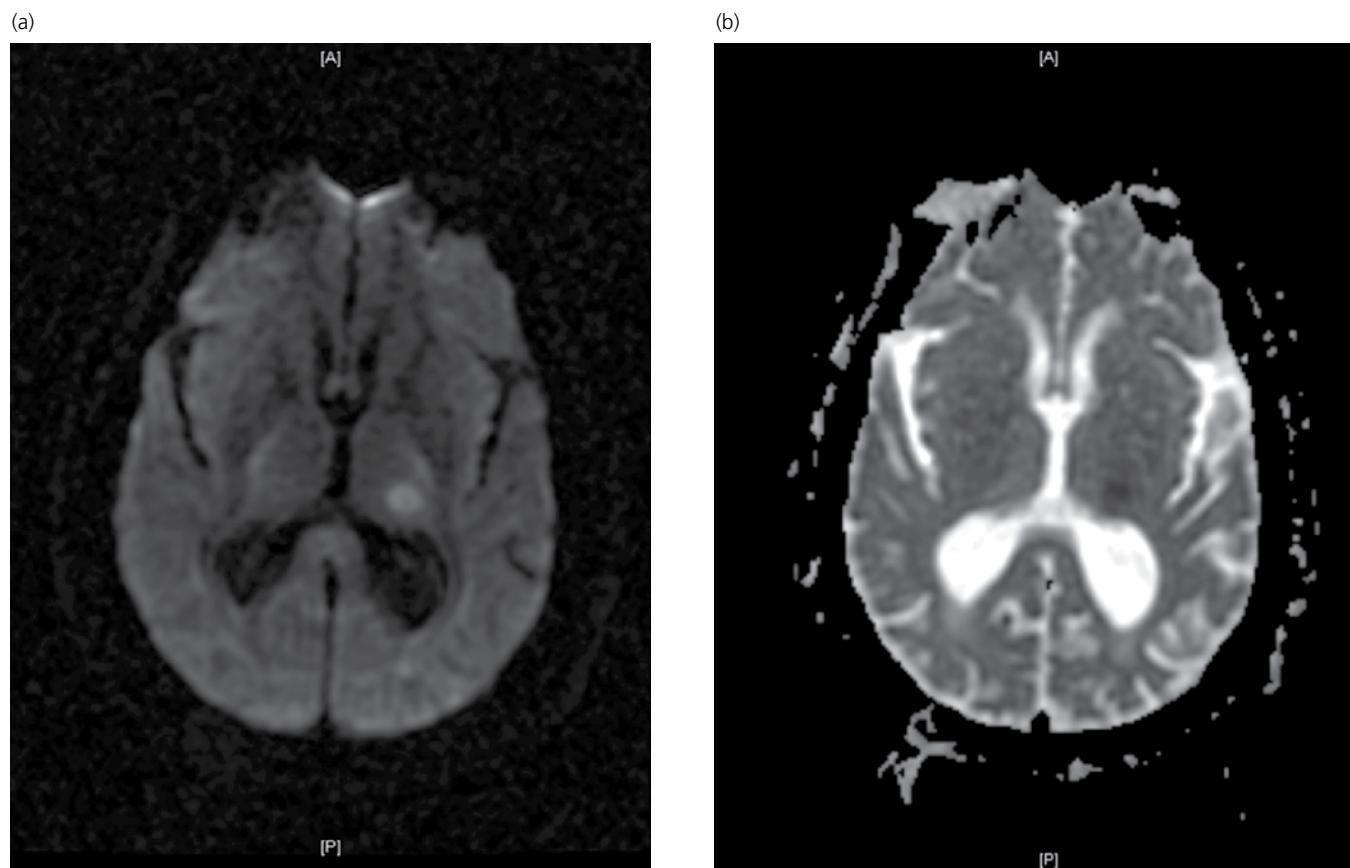

Figure 51.1 Lacunar infarct in the left posterior thalamus. (a) Diffusion-weighted imaging, showing hyperintensity in the area of restricted diffusion, corresponding to acute ischaemia. (b) Apparent diffusion coefficient image corresponding to the slice seen in (a), demonstrating hypointensity in the same distribution, confirming the presence of acute ischaemia.

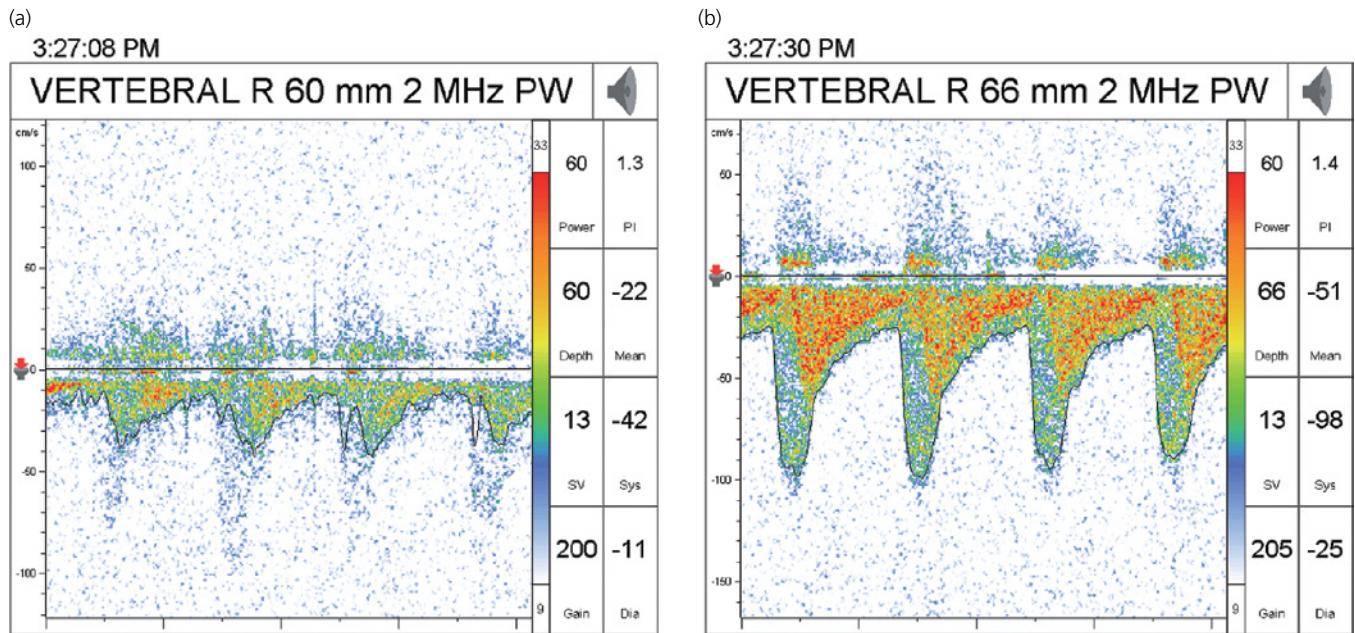

Figure 51.2 Intracranial vertebral artery stenosis as seen by transcranial Doppler ultrasound: (a) normal flow pre-stenosis; (b) increased velocity of flow post-stenosis.

with diabetes and lacunar strokes had higher rates of intracranial stenosis, although whether this causally related to the infarct is not clear [18].

TIA is less common in people with diabetes than in those without. This may indicate that people with diabetes are more likely to present with completed infarct rather than reversible ischaemia [19]. However, individuals with diabetes who do present with TIA are more likely to go on to a full-blown ischaemic stroke in the following two days, as predicted by the ABCD2 score, representing the predictive factors of age >60 yr, blood pressure >140/90 mmHg, clinical features of motor or speech involvement, duration >60 min, and diabetes [20].

Diabetes is a risk factor for coronary artery disease, and therefore for myocardial infarction and subsequent development of atrial fibrillation. In one large retrospective study of the relation between diabetes and atrial fibrillation or atrial flutter, diabetes was found after logistic regression to be a strong independent predictor for atrial arrhythmias in a review of over 850 000 charts over a 10-year period. The OR found for diabetes was 2.13, 95% confidence interval (CI) 2.10 to 2.16 [21]. In turn, atrial fibrillation has been repeatedly demonstrated to be a strong risk factor for cardioembolic stroke, with an estimated 75 000 strokes per year attributable to the arrhythmia [22].

Furthermore, diabetes increases the risk of cardiac embolization. The CHADS2 score is a validated method of stratifying risk of cardioembolic stroke in people with atrial fibrillation. It assigns one point each for the presence of congestive heart failure, hypertension, age >75 yr, and diabetes, and two points for previous stroke or transient ischaemic attack. Each point increase was associated with a 1.5-fold increased risk of stroke. Diabetes alone, then, would increase the risk of stroke in a person with atrial fibrillation from 1.9 to 2.8 [23]. Although the CHADS2 score is not perfect, and attempts have been made to improve its precision [24], it has the benefit of being very easy to use, thus guiding the non-stroke practitioner towards using anticoagulation in the appropriate section of the population.

From large observational studies, there does not appear to be an association between diabetes and haemorrhagic strokes. However, in the Haemorrhagic Stroke Project, a case–control study of young people with intracerebral haemorrhage, diabetes conferred an adjusted OR of 2.4. The risk factor with the most impact was, as predicted, hypertension, which outweighed the contribution from diabetes by more than twofold [25].

Pre-diabetes and other risk factors

Whereas it is well established that diabetes is a strong risk factor for ischaemic stroke, forms of pre-diabetes are not so clearly indicated as risk factors. Selvin et al. studied individuals with and without diabetes in the Atherosclerosis Risk In Communities (ARIC) trial and compared glycated haemoglobin (HbA_{1c}) levels drawn at a specified visit, not necessarily related to the time of the incident stroke [26]. With increasing tertiles of glycation across the normal distribution within each group, the risk of stroke increased in both cohorts, although it was only in those with diabetes that the difference achieved statistical significance.

In contrast, Myint et al. abstracted data from the European Prospective Investigation into Cancer (EPIC) on HbA_{1c} levels in persons without known diabetes and correlated these data with stroke risk [27]. In this population, it was only after levels were higher than 7.0% (53 mmol/mol) that an increased risk of stroke was demonstrated, compared with those with $\text{HbA}_{1c} < 5.0\%$ (31 mmol/mol). Given that these individuals most likely actually had undiagnosed diabetes, this finding may not implicate chronic hyperglycaemia alone as the primary risk factor for stroke.

Insulin resistance, another element of type 2 diabetes, likewise has demonstrated conflicting evidence for association with stroke. The ARIC study investigated hyperinsulinaemia in people without diabetes and found a mild increase in risk of stroke of 1.19 with each increase of 50 pmol/l of fasting insulin. After adjustment for

other risk factors such as age, systolic blood pressure, and smoking, the increase in risk was not as well defined [28].

Obesity, a proxy for insulin resistance and pre-diabetes, has also been linked to stroke through several epidemiological studies. For example, the Copenhagen City Heart Study found that body mass index (BMI) was independently associated with increased risk of stroke [29]. Similarly, the Nurses' Health Study found, as expected, an increasing risk of stroke with increasing BMI, with an RR of stroke of 2.37 (95% CI 1.60 to 3.50) seen in people with $\text{BMI} > 32 \text{ kg/m}^2$ [30]. However, the ARIC study did not demonstrate any relationship between BMI and stroke, or between waist/hip ratio, a better measurement of abdominal obesity, and stroke [28]. In addition, when adjustment for cardiovascular risks is performed, the relative risk of BMI for stroke is once again attenuated.

Although these individual forms of pre-diabetes have not conclusively been shown to predispose people to stroke, the constellation of diseases together called the metabolic syndrome has. The combination of hypertension, hyperlipidaemia, insulin resistance, and abdominal obesity creates an environment that is highly susceptible to vascular damage and ischaemic sequelae.

In a Finnish cohort, the metabolic syndrome in the absence of diabetes or cardiovascular disease was associated with stroke with an RR of ~2, after adjustment for multiple other risk factors [31]. Similarly, a cohort from the ARIC study who likewise were free of diabetes, coronary heart disease, or stroke had an increased RR of 1.5–2 for ischaemic stroke. In addition, on separating out each risk factor, there appeared to be a synergistic effect from the combination over the RRs inherent in each component [32].

Pathophysiology of ischaemic stroke in diabetes

Diabetes predisposes individuals to vascular thrombo-occlusive events in several ways. There is accelerated atherosclerosis in both large and medium-sized vessels. There is a disordered endothelial response, and the blood is hypercoagulable [33].

Carotid intima-media thickness (IMT) is a useful proxy for early atherosclerosis, as it is easily measured by Doppler examination. Furthermore, IMT is associated with primary stroke, with an increased RR per standard deviation (0.163 mm) of 1.57 in individuals who had not had a previous stroke [34]. It also predicts recurrent stroke, with each 0.1 mm increase in IMT associated with an increased risk of 18% [35]. Diabetes is associated with increased IMT. The Insulin Resistance Atherosclerosis Study demonstrated an increase in common carotid IMT in people with long-standing diabetes, but not in those with newly diagnosed diabetes. Nor was there an association with internal carotid artery IMT [36].

Conversely, people with diabetes with stroke have been found to have greater IMT. In a study of 438 Japanese people with type 2 diabetes, common carotid IMT was significantly higher in those who had stroke, even after adjustment for age, BMI, and smoking status [37]. Similarly, in a Czech cohort, IMT was increased in people with stroke and diabetes [38]. A recent study on glycaemic indices revealed significant associations between IMT and time in goal glycaemic range, suggesting that better overall glycaemic management reduces macrovascular disease [39].

Atherosclerosis also affects the ability of endothelium to release nitric oxide (NO), a potent vasodilator. In diabetes, blood vessels

have either reduced NO production or altered NO metabolism. In addition to its vasodilating effects, NO protects against platelet aggregation and enables the blood vessel to withstand ischaemic conditions. With decreased NO activity, the vessel will tend more towards vasoconstriction, with predictably poor response to ischaemia.

People who have suffered a stroke have decreased NO in circulating blood, along with increased peroxynitrite (ONOO^-), a reactive oxygen species. These results were particularly evident in larger strokes. Since the measurements were performed for acute stroke, these levels are likely to represent the outcome of ischaemia rather than the cause. However, the correlation supports a role for decreased NO in the effects of stroke [40].

The cerebral vasculature has a diminished response to inhibition of NO synthase (NOS). In a small study of men with diabetes treated with a synthetic NOS inhibitor, N^G -monomethyl-L-arginine, the blood flow through the internal carotid artery was significantly lower than in men without diabetes treated likewise [41].

As further indirect evidence of the role of NO in stroke, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) have multiple beneficial effects beyond their most common one, that of lowering plasma cholesterol. Among these effects are increasing the expression of endothelial NOS and also decreasing the activity of Rho-kinase, a proconstrictor enzyme [42]. Statins lower the risk of recurrent stroke in several large studies [43–45]. Whether the beneficial effect of statins in stroke is due to their cholesterol-lowering effect, their ability to stabilize atherosclerotic plaques, their effects on vascular function, or more likely a combination of all of these is difficult to ascertain.

In addition to these predisposing factors, the blood of someone with diabetes is hypercoagulable. Studies have demonstrated increased thrombin generation [46], increased prothrombin fragments, and increased thrombin-antithrombin III complexes [47]. Furthermore, the elevated prothrombotic levels were significantly associated with macroangiopathic complications.

Thrombus formation is further promoted by platelet hyperreactivity in the blood of individuals with diabetes. In people with metabolic syndrome, platelets have increased activity both through closure time as measured by the platelet function analyser (PFA-100), by increased fibrinogen binding after exposure to adenosine diphosphate, implying activation of the glycoprotein (GP)IIa/IIIb receptors, and by expression of activated ligands on the platelet surface [48]. In diabetes, platelets were hyper-reactive as measured by light transmittance aggregometry and expression of surface ligands [49].

Hence, taken together, the person with diabetes has a vascular environment that is highly susceptible to thrombo-occlusive complications. With early atherosclerosis and disordered endothelial response, the person with diabetes is predisposed to thrombophilia. The blood, in its hypercoagulable state combined with platelets that are highly active in themselves, is far more likely to form clots.

Lacunar strokes are caused by damage to smaller parenchymal vessels. The most common cause is microatheroma, as demonstrated in the pathological case series published by Fisher [50–52], the neurologist responsible for naming the lacunar syndromes. Lipohyalinosis and fibrinoid necrosis also cause microangiopathies, and both are most commonly found in the setting of chronic hypertension or severe acute blood pressure elevations, as seen in hypertensive encephalopathy [53, 54].

Primary prevention of stroke in people with diabetes

Primary prevention of stroke is of paramount importance, as the disability from stroke and healthcare costs associated with the acute and chronic care of stroke are so extensive. The approach to prevention in the person with diabetes is of necessity multifactorial.

Medical therapy aimed at achieving normoglycaemia is the foundation. The Diabetes Control and Complications Trial (DCCT) investigated intensive insulin regimens including subcutaneous insulin injections and external insulin pumps in people with type 1 diabetes. The goal for treatment was HbA_{1c} levels of <6.0% (42 mmol/mol). The comparison group had no such goals apart from prevention of hyperglycaemia or hypoglycaemia [55]. The intensive treatment group achieved a reduction of 57% in the combined endpoints of non-fatal myocardial infarction or stroke, cardiac death, or revascularization procedure. The majority of this improvement was associated with the decrease in HbA_{1c} [55].

The UK Prospective Diabetes Study (UKPDS) did not show any reduction in macrovascular complications of type 2 diabetes despite a 0.9% (10 mmol/mol) reduction in HbA_{1c} in an intensive treatment group. Microvascular complications such as retinopathy and neuropathy were significantly reduced [56]. A 10-year follow-up study of the same cohort after attempts to maintain treatment differences had desisted showed that the original treatment cohort had a persistent decrease in microvascular complications and also in myocardial infarctions and deaths from any cause [57]. Hence glycaemic management, at least in type 2 diabetes, has not been linked to a reduction in risk for stroke.

Among oral anti-diabetes agents, metformin was the first to be shown to decrease diabetes-related endpoints including stroke by 32% and diabetes-related mortality including from stroke by 42% compared with conventional therapy in UKPDS. Furthermore, it was more effective in reducing these outcomes compared with other intensive therapies such as sulfonylureas (e.g. chlorpropamide or glibenclamide) or insulin. However, it should be noted that HbA_{1c} was similar among the groups, so the benefits obtained were not explicable on the basis of improved glycaemic levels [58].

Rosiglitazone, a thiazolidinedione, on the other hand, has been linked with increased risk of myocardial infarction and death from cardiovascular causes, although stroke was not assessed separately in the meta-analysis reporting these findings [59]. However, in the RECORD trial, treatment with rosiglitazone was associated with a trend towards a decreased risk of stroke during the follow-up period, although this finding was somewhat offset by an increased risk of heart failure. In addition, the control group was less likely to be treated with statins, which may confound the decreased risk of stroke [60]. Pioglitazone, another medication in the same class, was not associated with worse cardiovascular outcomes including stroke, and in fact reduced a secondary outcome of all-cause mortality, non-fatal myocardial infarction, and non-fatal stroke by 16% [61].

Further trials on the effects of glucagon-like peptide 1 (GLP-1) receptor agonists and sodium-glucose cotransporter 2 (SGLT-2) inhibitors have added little to our understanding of their impact on risk of stroke. For example, the Researching cardiovascular Events with a Weekly INcretin in Diabetes (REWIND) trial found a small but significant reduction in the risk of non-fatal stroke for people treated with the GLP-1 receptor antagonist dulaglutide, but no difference in fatal strokes [62]. The EMPAgliiflozin cardiovascular outcome event trial in type 2 diabetes mellitus patients—Removing

Excess Glucose (EMPA-REG) found a non-significant increased risk in both fatal and non-fatal strokes in participants treated with the SGLT-2 inhibitor empagliflozin [63]. At this time, in the absence of strong consistent evidence, it is recommended to utilize metformin as a first-line agent, and then to choose a GLP-1 receptor agonist as the next agent where the prevention of further vascular events is the priority, or an SGLT-2 inhibitor when prevention of worsening heart failure is the priority [64].

Given how susceptible people with diabetes are to the effects of other vascular risk factors such as hypertension and hyperlipidaemia, the therapeutic regimen must also address these states. In treating hypertension in people with diabetes, the classes of medications with effects on the renin–angiotensin system appear to have the greatest benefit (Chapter 47).

The Heart Outcomes Prevention Evaluation (HOPE) trial examined people either with vascular disease (including coronary artery disease or stroke) or diabetes plus one other cardiovascular risk factor, such as hypertension, tobacco use, or elevated low-density lipoprotein (LDL) cholesterol levels. In this high-risk population, ramipril, an angiotensin-converting enzyme (ACE) inhibitor, decreased the risk of death from cardiovascular causes with an RR of 0.74, and reduced the risk of stroke with an RR of 0.68. As the mean reduction in blood pressure was only 3/2 mmHg, the benefits were not attributable to the blood pressure-lowering effect of the medication. The effect was similar whether or not the participants had had a stroke prior to enrolment [65].

The LCZ696 in Advanced Heart Failure (LIFE) trial examined people with diabetes, hypertension, and left ventricular hypertrophy. Participants were treated with either losartan, an angiotensin-2 receptor antagonist, or atenolol. Although, again, both medications achieved the same reduction in blood pressure, the primary endpoint of cardiovascular mortality, myocardial infarction, or non-fatal stroke was reduced with an RR of 0.76. Notably in this trial only 40% of participants achieved a systolic blood pressure of <140 mmHg, implying that further benefits would likely accrue with more intensive management [66].

A trial of intensive multifactorial medical management in individuals with diabetes with microalbuminuria showed a reduction in all-cause mortality, cardiovascular mortality, and cardiovascular events. The regimen was designed to achieve the following goals: HbA_{1c} <6.5% (48 mmol/mol), fasting total serum cholesterol <175 mg/dl (4.5 mmol/l), systolic blood pressure <130 mmHg, and diastolic blood pressure <80 mmHg. Stroke was not a prespecified endpoint in this study; however, there were 6 strokes in 6 participants in the intensive medical group, compared with 30 strokes in 18 participants in the control group [67].

Antiplatelet treatment for the primary prevention of major adverse cardiovascular events has undergone a reversal in recent years, due to the publication of large trials that have failed to show a good risk-to-benefit ratio [68]. The Antithrombotic Trialists' Collaboration meta-analysis did not demonstrate a significant improvement in the primary prevention of ischaemic stroke in people with diabetes. Overall, nearly 5000 people were treated with aspirin, with only a 7% reduction in serious vascular events. The 95% CI was wide enough to include a possible 25% risk reduction, a value that is consistent with the prevention of secondary stroke in this population [69]. However, A Study of Cardiovascular Events iN Diabetes (ASCEND) found only a non-significant trend towards risk reduction of 12% [70]. Currently, low-dose aspirin of at least 70 mg/d is recommended for primary prevention of cardiovascular events only for those with diabetes at high risk of such events.

Most of the early trials of antithrombotic medications were performed only on men. In the Women's Health Study, a study performed among female health professionals with no history of coronary or cerebrovascular disease, low-dose aspirin (100 mg every other day) was associated with a 17% risk reduction in stroke, a result of a 24% risk reduction in ischaemic stroke, and a non-significant increase in haemorrhagic stroke. These findings were especially pronounced in women older than 65 years of age at the time of enrolment, and also in the subgroup with diabetes [71].

Treatment of acute stroke in persons with diabetes

Treatment of acute stroke is limited by the vulnerability of the neuron to ischaemic insult. With decreasing cerebral blood flow, the parenchyma becomes less likely to recover from even short-duration ischaemia. With cerebral blood flow <20 ml/100 g of tissue, neurological dysfunction begins to appear. However, it is not until the cerebral blood flow falls below 10 ml/100 g of tissue that irreversible ischaemia occurs, in a matter of minutes [72].

Thrombolysis is effective in the treatment of acute stroke provided that the medication is given within the first three hours after symptom onset, as defined by the last time the individual was seen at their neurological functional baseline (Table 51.2). The National Institute of Neurological Disorders and Stroke (NINDS) trial of intravenous tissue plasminogen activator (t-PA) demonstrated a 30–50% increased likelihood of minimal or no disability three months after treatment. The thrombolysis was associated with a 6.4% chance of symptomatic intracranial haemorrhage, but the mortality data at three months were not statistically different between the treatment and the placebo groups [73]. Based on this trial, treatment with intravenous t-PA became standard of care in this early time period. The European Cooperative Acute Stroke Study III (ECASS-III) trial [74] also suggested that it is not only safe but also clinically effective to a lesser extent in a select group to give intravenous t-PA in the window between 3 and 4.5 hours after the onset of symptoms. However, individuals with diabetes who had had a previous stroke by history or on imaging were excluded from the trial.

Thrombolysis in the person with diabetes with acute stroke is not as successful as in the general population. In a series of 27 individuals treated with intravenous t-PA, none of those with diabetes achieved recanalization of the occluded artery as measured by

transcranial Doppler ultrasound [75]. The series was not large enough to demonstrate a significant difference. In another study examining which factors might predict major neurological improvement in people treated with intravenous t-PA, there was a trend towards people with diabetes being less likely to achieve that improvement [76]. It has been proposed that the poor collateral circulation seen in those with diabetes accounts for the reduced benefit in t-PA in this population [77].

Beyond intravenous thrombolysis, intra-arterial thrombolysis has been examined up to six hours after the onset of stroke symptoms. The Prolyse in Acute Cerebral Thromboembolism II (PROACT II) trial found that participants treated with intra-arterial urokinase had a 58% RR reduction to achieve minimal or no functional disability at 90 days after treatment. Mortality rates were comparable, and recanalization rates were greatly improved with the medication [78]. Current guidelines support the use of intra-arterial thrombolysis in the period between three and six hours after the onset of symptoms. However, the medication has not been approved by the US Food and Drug Administration (FDA) for this indication [79].

In a case series of 100 people treated with intra-arterial thrombolysis with urokinase, diabetes was associated with poor functional outcome at three months. It was not associated with symptomatic intracranial haemorrhage [80]. However, since diabetes is independently associated with worse outcomes following acute ischaemic stroke, it is unclear whether these data have any meaning for clinical practice.

Other interventional techniques include clot retrieval. Three devices have been tested: the Mechanical Embolus Removal in Cerebral Ischemia (MERCI) device (UCLA, Los Angeles, CA, USA), a corkscrew-type device; the Penumbra System® (Penumbra, Alameda, CA, USA), a direct clot aspirator; and the Solitaire™ stent retrieval system (Covidien, Mansfield, MA, USA). The last device is the one most commonly used clinically today: compared with the MERCI device, it had improved chances of restoring partial or complete restoration of blood flow with an OR of 4.87 [81]. In support of the use of interventional therapy, the Multicenter Randomized Clinical trial of Endovascular treatment for Acute ischemic stroke in the Netherlands (MR CLEAN) trial enrolled 500 people and randomized them to endovascular intervention plus usual care (which could include intravenous t-PA) versus usual care alone. The majority of interventional treatments used stent retrieval. The interventional group had an absolute risk reduction of achieving a good functional outcome of 13.5%, with a number needed to treat of 7.4 [82]. The more recent Highly Effective Reperfusion using Multiple Endovascular Devices (HERMES) meta-analysis reviews several similar studies across multiple populations worldwide. The results align with those of MR CLEAN and provide overwhelming evidence for the use of mechanical thrombectomy in the setting of acute ischaemic stroke [83].

Follow-up studies have sought to extend the window in which people may undergo mechanical thrombectomy. The DWI or CTP Assessment with clinical mismatch in the triage of Wake-up and late presenting strokes undergoing Neurointervention with Trevo (DAWN) and Endovascular Therapy Following Imaging Evaluation for Ischemic Stroke (DEFUSE-3) trials utilized computed tomography (CT) and magnetic resonance (MR) perfusion technology to extend the thrombectomy window up to 24 hours from symptom onset. Both studies demonstrated significantly improved outcomes at 90 days without increase in adverse events like intraparenchymal haemorrhage [84, 85]. These landmark studies all follow the

Table 51.2 Management of acute ischaemic stroke.

0–3 h Intravenous tissue-plasminogen activator (t-PA)
0–6 h Intra-arterial t-PA
0–24 h Mechanical clot retrieval (stent retriever device) in appropriately selected individuals
Permissive hypertension for the first 3–5 d
Aspiration precautions
Deep vein thrombosis (DVT) prophylaxis

Intravenous t-PA is the only acute intervention approved by the US Food and Drug Administration. Both intra-arterial t-PA and mechanical clot retrieval remain experimental, although widely used. Intravenous t-PA should remain the standard of care when it is not contraindicated, with the other interventions to be used as auxiliary therapy.

Interventional Management of Stroke (IMS-III) trial, which demonstrated no increased risk nor benefit to endovascular therapy after treatment with intravenous t-PA [86], though analysis of this study shows that many participants did not have an appropriate target thrombus [87].

Hyperglycaemia at the time of stroke treatment is associated with worsened outcomes. In a series of 73 people treated with intravenous t-PA, age, diabetes, admission glucose >140 mg/dl (7.8 mmol/l), and early reocclusion on transcranial Doppler ultrasound were significantly associated with worsened functional outcome as defined by a score of >3 on the modified Rankin scale. However, after logistic regression, only the hyperglycaemia remained as an independent predictor of poor outcome. In particular, it was associated with larger infarct size, lower degree of neurological improvement, and worse clinical outcome if recanalization was achieved [88].

Similarly, baseline hyperglycaemia is associated with a greater likelihood of going on to symptomatic intracranial haemorrhage after intravenous thrombolysis. There appears to be a dose-response relationship between plasma glucose levels and likelihood of haemorrhage. This was especially true when levels were above 11.1 mmol/l (200 mg/dl), where 25% suffered symptomatic intracranial haemorrhage. In a repeat analysis substituting the presence of diabetes for glucose levels, diabetes was associated with an OR of 3.61 for all haemorrhages, and 7.46 for symptomatic haemorrhage [89].

Furthermore, both those individuals who acutely worsened and those who showed lack of improvement at 24 hours were more likely to have elevated blood glucose at baseline. Hyperacute worsening in people treated with either intravenous or intraarterial thrombolysis, or both, was unsurprisingly associated with intracerebral haemorrhage and lack of recanalization. However, it was also associated with higher serum glucose. With every increase of 50 mg/dl (2.8 mmol/l) of glucose, the OR for worsened outcome was 1.50 and the OR for mortality was 1.38. Even in those individuals who achieved recanalization, higher blood glucose predicted worse outcomes [90]. Similarly, serum glucose >144 mg/dl (8.0 mmol/l) and also cortical involvement and time to treatment were independent predictors of lack of improvement at 24 hours after treatment with intravenous thrombolysis. The OR for hyperglycaemia was 2.89. Furthermore, lack of improvement at 24 hours predicted poor functional outcome at three months [91].

Although these data are understandably disheartening, they should by no means be taken to imply that people with diabetes and acute stroke should not receive thrombolysis, or that these individuals do not benefit from the treatment. Furthermore, it is not clear whether the hyperglycaemia seen in people with acute stroke and diabetes is secondary to the ischaemic insult as a stress response, or instead part of the chronic diabetic state and thus purely a complicating factor.

Interestingly, one study examined how persistent hyperglycaemia differed from transient hyperglycaemia in functional outcomes in addition to mortality. When hyperglycaemia was present at baseline and when measured 24 hours after admission, it was inversely associated with neurological improvement in the first 7 days, 30-day functional outcome, and 90-day negligible dependence. At the same time, persistent hyperglycaemia was positively associated with increased mortality at 90 days and parenchymal haemorrhage. When hyperglycaemia was absent at baseline but present at 24 hours after admission, it was likewise inversely associated with 90-day negligible dependence and positively associated with death and parenchymal haemorrhage. In this study, baseline hyperglycaemia

alone (without persistence at 24 hours) was not associated with poor outcomes. These data suggest that it may not be the stress response hyperglycaemia that causes damage in the acute stroke setting [92].

However, intensive treatment of hyperglycaemia may be associated with improved outcomes, as has been demonstrated for myocardial infarction [93]. A small pilot study found that hyperglycaemia could be treated with insulin infusions safely, but the numbers were too small to compare functional outcomes at one month [94]. In another study to maintain glucose levels between 5.0 and 7.2 mmol/l (90–130 mg/dl) in people with acute ischaemic stroke, the use of insulin drips started no later than 12 hours after the onset of symptoms was associated with a trend towards better functional outcomes and minimal or no neurological symptoms, as measured by the National Institutes of Health (NIH) stroke scale. There were hypoglycaemic episodes in the group treated with continuous infusion, but the majority of these were asymptomatic [95]. Clearly, further study is required on this subject.

Hyperglycaemia as defined by serum glucose >400 mg/dl (22.2 mmol/l) was a contraindication for inclusion in the NINDS trial for some of the reasons discussed, and also because extreme hyperglycaemia can cause focal neurological deficits that mimic stroke [73]. Current guidelines recommend starting aggressive glycaemic management if serum glucose is >200 mg/dl (11.1 mmol/l), while acknowledging that levels above 140–185 mg/dl (7.8–10.3 mmol/l) may still be harmful [79]. Although it may be reasonable to attempt to bring down the glucose level and see if any focal symptoms improve or resolve, and then treat with thrombolysis if no improvement is seen, this approach has yet to be tested.

In terms of oral anti-diabetes agents in the acute stroke setting, one study looked at the role of sulfonylureas taken pre-stroke and during the acute hospitalization. Sulfonylureas have an effect on NC_{Ca}-ATP channels, which are regulated by the SUR1 receptor, like pancreatic β cells, and are open only during ischaemic episodes, causing cell death. Theoretically, then, treatment with sulfonylureas should be neuroprotective during ischaemia. Although the numbers were small, and people with more severe strokes (NIH stroke scale >9) were excluded, those on the medication were more likely to have a decrease of 4 points on the NIH stroke scale or a score of 0, and were more likely to achieve an excellent functional recovery at discharge. The effect was particularly noticeable in non-lacunar strokes [96].

Further care for the person with acute stroke is best handled in a certified stroke unit, with multidisciplinary care from a team consisting of vascular neurologists, stroke-trained registered nurses, physical therapists, occupational therapists, and speech and swallow specialists. This care results in a reduction in mortality of ~25% [97].

Blood pressure control in acute ischaemic stroke is a subject of ongoing debate. Current thinking still supports the concept of permissive hypertension in the peri-stroke period. Most vascular neurologists would allow the blood pressure to remain untreated until the systolic blood pressure rises above 220 mmHg or the diastolic blood pressure above 120 mmHg. The period when permissive hypertension should be allowed is also controversial. Typically, the blood pressure is left untreated for the first 3–5 days after stroke [79].

The majority of medical complications after stroke relate to the disability associated with neurological deficits. However, deep venous thrombosis and aspiration pneumonitis are two preventable complications. Prevention of deep venous thrombosis is accomplished through subcutaneous anticoagulation with either heparin or low molecular weight heparin with or without external

compressive devices [79]. Initiation of treatment is typically immediately on admission, regardless of the size of infarct. One unblinded study studied heparin versus enoxaparin and found a reduction in thrombosis with the low molecular weight heparin [98].

Prevention of aspiration is more complicated. Protection of the airway is often compromised in the acute period after stroke. Frequent suctioning and positioning help to prevent aspiration. Swallow evaluations should be undertaken before oral nutrition is started in anyone in whom dysphagia is suspected. Placement of nasogastric tubes (NGTs) is often required for nutrition, and frequently patients will require a percutaneous endoscopic gastrostomy (PEG) tube for long-term provision of nutrition. Hydration is necessary, either intravenously before enteral access is established, or via NGT or PEG tubes to prevent dehydration and electrolyte abnormalities. Antibiotics should be started where infection is suspected, and fever should prompt an aggressive search for a source. Hyperthermia itself causes neurological deterioration, so antipyretics should be administered [79].

Secondary prevention of stroke in diabetes

The management of the people with diabetes after stroke is similar to that for primary prevention as already outlined. The eighth report of the Joint National Committee on Prevention and Treatment of Hypertension recommends that people with diabetes should be treated to a blood pressure target of <140/90 mmHg, and that it may take multiple antihypertensive medications to achieve this goal [99]. As suggested by the studies described earlier, ACE inhibitors and angiotensin receptor blockers provide greater protection against cardiovascular events including stroke.

Similarly, the American Heart Association and the American College of Cardiology have published guidelines on the management of cholesterol in individuals with diabetes [100]. All people who have clinical atherosclerotic cardiovascular disease, including stroke or TIA, should be offered treatment with a statin medication, at high intensity if there are no known safety concerns. In the situation where such an event has not occurred, people with diabetes and an LDL cholesterol >70 mg/dl (1.8 mmol/l) should also be treated with a statin. The guidelines suggest a goal of lowering the LDL cholesterol by 50% when high-intensity statin treatment is used. Guidelines from the Endocrine Society likewise endorse aggressive lowering of LDL cholesterol without specific goal thresholds for treatment [101].

Antiplatelet therapy should be started in all people who have had a non-cardioembolic ischaemic stroke (Table 51.3). Although the Antithrombotic Trialists' Collaboration meta-analysis did not show

benefit in people with diabetes, *post hoc* analysis of data from the Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) study found that such individuals treated with clopidogrel had a decreased rate of stroke, myocardial infarction, or death of 15.6% compared with a 17.7% risk in those treated with aspirin [102]. Similarly, in a *post hoc* subgroup analysis of a study of cilostazol, people with diabetes had a decreased rate of recurrent stroke on the medication compared with placebo, with a relative risk reduction of 41.7%. This finding was especially evident in those with lacunar stroke [103]. These findings need to be verified with further trials. The use of a combination of dipyridamole and aspirin was not demonstrated to be non-inferior to clopidogrel in the prevention of recurrent stroke in the Prevention Regimen For Effectively avoiding Second Strokes (PRoFESS) trial. The prevalence of diabetes in this study was 28% in each group, and subgroup analysis within diabetes likewise did not demonstrate any difference between the two treatments [104].

In individuals who have had ischaemic stroke secondary to extracranial carotid stenosis, carotid endarterectomy remains the preferred treatment of choice for carotid artery stenosis >70% (Figure 51.3). For degrees of stenosis between 50% and 70%, the benefits of surgery are much smaller, and decisions to treat will depend on the complication rate at local institutions [31]. However, the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) suggests that carotid artery stenting is equivalent to surgical revascularization with respect to rates of periprocedural stroke, myocardial infarction, or death, or rate of recurrent stroke. However, periprocedural stroke was more likely in the stenting group, whereas myocardial infarction was more likely in the endarterectomy group. People younger than 70 years fared better when stented, whereas those over 70 years had better outcomes when they received endarterectomy. This dichotomization likely represents

Figure 51.3 Computed tomography angiography with iodinated contrast of the neck. There is mild stenosis seen at the origin of the right internal carotid artery. There is critical stenosis (*string sign*) at the origin of the left internal carotid artery, corresponding to severe atherosclerotic plaque.

Table 51.3 Prevention of ischaemic stroke in the person with diabetes.

Tight glycaemic management
Antihypertensives with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers
Anti-cholesterol treatment, especially with 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins)
Health behaviours modifications (tobacco cessation, weight loss, etc.)
Antiplatelet therapy (either aspirin, clopidogrel, or dipyridamole)
Anticoagulation in people with atrial fibrillation

the risk of undergoing an endovascular procedure with an increasing atherosclerotic burden [105].

People with diabetes with atrial fibrillation, paroxysmal or otherwise, should be anticoagulated with warfarin to a goal of an International Normalized Ratio (INR) of 2.0–3.0. The risk reduction associated with treatment with anticoagulation is 68%, with an absolute risk reduction in the annual stroke rate from 4.5% to 1.4% [106]. This reduction in risk is so strong that one study estimated that a person would have to fall 295 times in one year for the risk of subdural haematoma secondary to trauma to outweigh the benefits gained from anticoagulation [107]. There is no reason to assume that this is any different for people with diabetes.

Several novel oral anticoagulants have been developed for the prevention of stroke in people with atrial fibrillation. Dabigatran [108], a direct thrombin inhibitor, and rivaroxaban [109] and apixaban [110], both direct factor Xa inhibitors, are at least equivalent to warfarin in reducing the risk of recurrent ischaemic stroke, with fewer haemorrhagic complications. These medications have a significant advantage over warfarin, in that they do not require monitoring of levels, nor do they interact significantly with other medications or require dietary adjustment. There is a reversal agent available (andexanet alfa) for treatment of those

with bleeding complications while on direct factor Xa inhibitors, with demonstrated effectiveness in normalizing factor Xa levels [111]. Our current first-choice agent for the prevention of ischemic stroke in the setting of atrial fibrillation is apixaban.

Conclusions

Diabetes is a strong risk factor for ischaemic stroke, and stroke in diabetes is both more severe in presentation and outcome and more recalcitrant to acute treatment. Although many aetiologies of stroke are made more common by diabetes, the most common type of stroke found in people with diabetes is lacunar microvascular infarction. Prevention of stroke in the person with diabetes is best served through aggressive management of concurrent hypertension and hyperlipidaemia. Careful glycaemic management also likely reduces the risk of stroke, but the risk reduction is not nearly as robust. Antiplatelet therapy also plays an important role: a single antithrombotic agent is sufficient for the prevention of ischaemic stroke. Hyperglycaemia in the acute phase after ischaemic stroke is associated with poor outcomes, and aggressive management likely improves functional recovery.

Peripheral Vascular Disease

Henrik H. Sillesen

Department of Vascular Surgery, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Key points

- Peripheral arterial disease is very common, affecting up to 30% of all people with diabetes.
- Amputations are much more common in people with diabetes and occur 5–8 times more often than in those without diabetes.
- Atherosclerosis is common in people with diabetes, and measurement of ankle blood pressure may identify individuals with symptomatic peripheral arterial disease, but also people at an early asymptomatic stage.
- People with diabetes have atherosclerotic lesions located more peripherally than those without diabetes and therefore are more commonly inoperable for technical reasons.
- People with diabetes have more complications in surgery, both locally (infections) and systemically (e.g. cardiac, pulmonary), than those without diabetes.
- Treatment of atherosclerosis in people with diabetes is basically the same as in those without diabetes.

Peripheral vascular disease includes diseases to arteries and veins outside the thoracic region. Because of space limitations, this chapter mainly covers the three most common arterial diseases:

- Peripheral arterial disease (insufficient blood supply to the lower limb).
- Carotid artery disease.
- Aortic aneurysms.

Other, rarer manifestations of atherosclerotic disease (e.g. renovascular hypertension, abdominal angina, and ischaemia of the upper extremities) are mentioned briefly. Special considerations in individuals with diabetes are dealt with in relevant sections, for example infection in an ischaemic foot in a person with diabetes is described in the section that includes critical limb ischaemia.

Atherosclerosis is the main cause of peripheral arterial disease, and the overall pathogenesis is covered in Chapter 46. It is important to appreciate that the pathogenetic mechanisms of clinical atherosclerosis are dual: chronic obstructive and thrombotic. Although the chronic obstructive mechanism is the main cause of lower-limb ischaemia, including in people with diabetes, it is often preceded by a thrombotic event: a person with mild *claudication* (pain when using the leg) suddenly experiences a significant shortening of walking distance or sudden onset of rest pain. Alternatively, the seemingly healthy person suddenly develops claudication. A myocardial infarction or stroke in a person with chronic obstructive arterial disease and claudication is also a thrombotic event.

In general, individuals with diabetes more often develop symptoms of atherosclerotic complications, they do so at a younger age, they are more difficult to treat, and they have more complications with treatment (especially with invasive treatment).

Peripheral arterial disease

Peripheral arterial disease is a chronic condition that, like atherosclerosis in other vascular beds, develops over decades. The World Health Organization (WHO) definition includes exercise-related pain and/or ankle brachial index (ABI) <0.9. On average, symptoms from the lower limbs develop 5–10 years later than from the coronary circulation. Acute ischaemia may develop because of:

- Thrombosis in a vessel with pre-existing atherosclerotic plaques and/or stenosis.
- Embolism (e.g. from mural thrombus in the heart or from an arterial lesion upstream).
- Trauma.

Peripheral arterial disease is traditionally divided into four stages (Fontaine):

1. Asymptomatic (ABI <0.9).
2. Functional pain (claudication).
3. Rest pain.
4. Non-healing ulcers or gangrene.

Diabetes is a major contributor to peripheral arterial disease.

Incidence

In population-based studies in Western Europe, the incidence of symptomatic peripheral arterial disease is 3–4% among 60–65-year-old individuals, increasing to 15–20% in people aged 85–90 years [1–3]. Similar findings have been reported in the USA. The incidence of asymptomatic cases where the ABI is <0.9 is much higher, ~20% of

all people above 65 years of age, ranging from 10% in those aged 60–65 years to almost 50% in those aged 85–90 years [1–3]. Critical limb ischaemia, defined as ABI <0.4 or rest pain and/or non-healing ulcers, occurs in 1% of people aged 65 years or older.

Prevalence of peripheral arterial disease in people with diabetes

The prevalence of peripheral arterial disease in people with diabetes depends on the usual atherosclerosis risk factors and duration of diabetes. There have been only a few demographic studies of the general population. Using ABI <0.9 as the selection criterion, Lange et al. [4] found a prevalence of 26.3% in people with diabetes compared with 15.3% in people without diabetes on screening 6880 Germans above 65 years of age, of whom 1743 (25%) had diabetes. Similar findings have been reported by others: 20–30% of those with diabetes have peripheral arterial disease [5, 6]. Claudication is twice as common in people with diabetes as those without diabetes.

Pathophysiology

The pathophysiology of peripheral arterial disease is described in detail in Chapter 46; however, in brief, the pathophysiology in people with diabetes is similar to that in people without diabetes. The abnormal metabolic state that accompanies diabetes directly contributes to the development of atherosclerosis. Proatherogenic changes include increases in vascular inflammation and alterations in multiple cell types. Both mechanisms of atherosclerotic complications are of importance in peripheral arterial disease (gradual narrowing resulting in stenosis and acute thrombosis in existing atherosclerotic lesions). The long-term accumulation of lipids in the vessel wall is important and sudden local thrombosis can occur at any time, although in most cases this happens after symptoms (claudication) have developed.

To reach the stage of critical limb-threatening ischaemia, advanced atherosclerosis has developed. Often, multiple segments of the arterial tree from the aorta to the foot are affected (stenotic and/or occluded). In people with diabetes, the atherosclerotic lesions are more peripherally located than in those without diabetes. Whereas the iliac and femoral arteries are most commonly stenotic and/or occluded in individuals without diabetes, in those with diabetes it is most often the crural or pedal arteries that are severely affected by atherosclerosis. In some cases of ischaemic ulcers of the toe in a person with diabetes, foot pulses may be present due to very distal occlusive disease. This poses a challenge for revascularization, because the results are generally better with more proximal reconstruction and worse with distal disease and poor run-off (vessels to receive the blood supply as a result of the revascularization procedure).

Perfusion has to be very poor to develop ischaemic non-healing ulcers. The most reliable method for assessment of peripheral perfusion in those with diabetes is measurement of toe pressure. A toe pressure below 20–25 mmHg signals a poor chance of healing of a peripherally located ulcer. The special considerations related to the potentially dramatic course of infection in a diabetic foot are covered in Chapter 53.

Asymptomatic stage

The asymptomatic stage of peripheral arterial disease is especially interesting because it is associated with an approximately threefold increased mortality compared with matched controls [7, 8]. This excess mortality is caused by accompanying cardiovascular disease. Asymptomatic peripheral arterial disease can be identified by a

very simple test, measurement of ankle blood pressure. This test takes only a few minutes and is expressed as the ABI, where the ankle pressure is divided by the highest of the two arm blood pressures. In this manner, variations in blood pressure between measurements do not influence the test result. Not only is an ABI <0.9 associated with increased mortality from cardiovascular causes, but also the level of ABI reduction is predictive: the lower the ABI, the worse the prognosis [7]. Identifying an asymptomatic person with an ABI <0.9 is not a case for evaluation with respect to revascularization of the lower limbs, but a case for serious preventive cardiovascular medicine.

Claudication

Claudication is experienced by the individual as pain in lower-limb muscles appearing after walking, most often in the calf, the thigh, and more rarely the buttocks. The walking distance eliciting the pain is very variable, beginning after 10–15 m in severe cases, whereas others may report pain only when walking fast uphill for >500 m. It is important for both clinician and individual with claudication to understand that, although it may be incapacitating for a few and troublesome for many, claudication signals severe vascular disease systemically, and that cardiovascular morbidity and mortality are high (elevated three- to fourfold compared with matched controls).

Rest pain

Rest pain typically begins at night when the individual is in the horizontal position. The positive effect of gravity on lower-limb perfusion is then abolished. The person typically complains about pain in the toes or feet during the night, and most have experienced that standing or sitting up relieves the pain. Many people will sleep sitting in a chair.

In individuals with diabetes, symptomatology may differ because of coincidental peripheral neuropathy. Just as myocardial ischaemia can be masked, symptoms from the lower extremity may be lacking even though peripheral ischaemia exists. This is especially important when a person with diabetes presents with a small ulcer or wound on the lower limb, even if they think that there is a good explanation for developing the ulcer, such as a relevant trauma. The lack of symptoms to signal peripheral ischaemia, combined with the risk of escalating infection in a diabetic foot, has prompted many diabetes healthcare professionals to recommend routine assessment of peripheral circulation at regular intervals in all people with diabetes.

Non-healing ulcers

Non-healing ulcers often begin after minor trauma (e.g. hitting a toe against a chair or wearing shoes that are too small). In some cases, the ulcers develop without any trauma and these will often progress to gangrene if not treated. Ischaemic ulcers develop on the toes or foot, typically at points where shoes are in firm contact. Hence they are usually easy to discriminate from venous ulcers, which are located at the level of the ankles or lower calf.

Rest pain, non-healing ulcers, and/or gangrene are often referred to as critical ischaemia (Chapter 53).

Diagnosis

Most often the history and objective findings will ensure the diagnosis, but measurement of ankle blood pressure will quantify the ischaemia and can be used to monitor changes in the disease (Figure 52.1). In some people with diabetes, the media of smaller arteries become calcified, making them incompressible. Thus, very

Figure 52.1 Measurement of ankle pressure using the Doppler technique.

Figure 52.2 Measurement of toe pressure using the strain gauge technique.

high ankle pressures resulting in elevated ABI (>1.3) signal media sclerosis and should be recognised as a falsely elevated measurement. In fact, $\text{ABI} > 1.3$ is associated with a marked increased mortality because media sclerosis is found in people with diabetes and those with renal failure.

Because small arteries are rarely affected by media sclerosis, measurement of toe pressure is an alternative for the assessment of peripheral arterial disease. The strain gauge technique is most commonly used (Figure 52.2), although alternative methods for

measurement of toe pressure have been developed recently. Toe pressure is also useful for the prediction of healing of ulcers and amputation wounds.

Prognosis

The risk of amputation is only 1–2% at five years. Around 25% of people with claudication will experience a worsening of their symptoms from the lower legs; however, 75% will be unchanged or improve without revascularization [9]. In contrast, the *systemic* risk is huge; mortality at five years will be 15–25% and even more people will have non-fatal myocardial infarction or stroke.

The risk for a person with diabetes and peripheral arterial disease is much higher than that of a person with peripheral arterial disease only. An individual with diabetes has an eight times greater risk of amputation at the level of the transmetatarsal bones or above than someone without diabetes [10]. In addition to the already severely increased mortality of peripheral arterial disease, people who additionally have diabetes have a further doubling of risk of death [10–12].

Treatment

Treatment of people with symptoms from the lower limb therefore involves two aspects:

- Treatment of symptoms from the lower limb.
- Prevention of cardiovascular complications.

The former includes health behaviour modification, medical therapy, and interventional therapy by either percutaneous transluminal angioplasty (PTA) or open surgery, whereas the latter includes lifestyle modification and preventive medical therapy.

It is beyond the scope of this chapter to detail all aspects of behaviour modification and preventive medical therapy; however, it is extremely important for the reader to understand that individuals with peripheral arterial disease derive at least as much benefit from health behaviour modification and aggressive preventive medical therapy than any other group of people. Most lifestyle changes will benefit the peripheral arterial disease, especially smoking cessation, regular exercise, weight loss, and dietary changes.

Medical prevention follows the same guidelines as for other clinical atherosclerotic manifestations such as ischaemic heart disease and can be summarized as follows: aggressive statin treatment almost irrespective of cholesterol levels, antiplatelet therapy, and blood pressure control. Recently dual-pathway inhibition by low-dose rivaroxaban and aspirin has been shown to reduce major adverse cardiovascular and limb events both in stable peripheral arterial disease and after revascularization [13].

This chapter only discusses details of health behaviour modification and medical therapy relevant to treatment of peripheral arterial disease symptoms, including revascularization by PTA and surgery.

Treatment of symptoms from the lower limb

Most people should be managed without invasive intervention with PTA and/or surgery. Because the risk of cardiovascular complications (cardiac and cerebral) is much higher than the risk of amputation, the main focus should be on preventive measures to halt the atherosclerotic process. The conservative approach with respect to revascularization is especially important for people with diabetes because of the increased risk of surgical complications and poorer results of revascularization. An important exception is critical limb ischaemia, when early revascularization before widespread infection can be limb saving.

Exercise therapy is effective for improving walking distance, and regular exercise for three months can be expected to increase walking distance by 200–250% [14]. Because exercise also reduces cardiovascular morbidity and mortality, it cannot be stressed enough that this is extremely important. Because the effect on walking distance is so good, and because it is important for survival, exercise therapy should always be tried before considering interventional treatment. There are only a few exceptions where interventional treatment may be considered early on:

- Individuals with a very short walking distance, who are not able to carry out important daily responsibilities such as their work.
- Those at risk of amputation (rest pain and non-healing ulcers).

It is challenging to explain to individuals that the symptoms they are experiencing from the lower limb are signalling high cardiovascular risk rather than lower-limb risk. First, there is (or has been) a general perception that atherosclerosis in the limb is less dangerous than in other locations. The author hopes that the introductory remarks in this chapter have changed this potential misperception. Medical therapy for claudication includes as a minimum a platelet inhibitor and statins. In addition to preventing cardiovascular complications, statins have been shown in placebo-controlled trials to improve walking distance by 30–50%.

Interventional treatment

Interventional treatment (endovascular or open surgery) for peripheral arterial disease is indicated when:

- Exercise and other lifestyle modifications have failed to improve symptoms to an acceptable state.
- Claudication is incapacitating.
- Critical limb ischaemia is present (rest pain, non-healing ulcers, and/or gangrene).

Again, for the person with diabetes, the indication for revascularization should be considered very carefully in those with only claudication. The choice between PTA and open surgical management depends on the location and extent of disease. In general, endovascular treatment can be expected to perform well in cases of

shorter lesions, whereas open surgery is preferred for extensive occlusive disease. Obviously, whenever comparable results can be obtained, PTA is preferred because it is less invasive and associated with fewer complications than open arterial reconstructions. In people with severe comorbidity that might complicate the outcome of open surgery, PTA would be preferred, even though theoretically surgery would be the treatment of choice if only patency of the revascularization procedure was considered.

The arterial lesions that cause obstruction of blood supply to the lower limb are most often located in the distal abdominal aorta just proximal to the aorta–iliac bifurcation, in the iliac arteries, and in the common and superficial femoral arteries. The arteries in the calf, the anterior and posterior tibial and the peroneal arteries, are often involved in people with diabetes with critical ischaemia. In general, when individuals with diabetes present with symptoms, they have a more distal involvement with open arteries down to the level of the popliteal artery, and then occlusive disease of the calf vessels and sometimes also the arteries in the foot. The results of revascularization for people with diabetes with toe or foot ulcers are worse than those for the general population, partly because reconstructions yield better results with respect to patency when the lesions are more centrally located.

Percutaneous transluminal angioplasty

In principle, PTA can be performed anywhere between the heart and the feet. In general, the more centrally located the lesions being treated are, the better the results (especially with PTA). Also, the shorter the stenosis or occlusion, the better the results, and stenting improves patency in most cases. Endovascular-treated common iliac arteries, as an example, remain patent in 60–80% of cases after five years, and thereafter they may be redilatated. Primary stenting has become the preferred treatment in most cases. Because serious complications are rare, the tendency to offer PTA for iliac artery obstruction is greater than for occlusive disease that is more peripherally located.

PTA of the superficial femoral artery (Figure 52.3) may relieve symptoms, but the results depend on the extent of disease. With

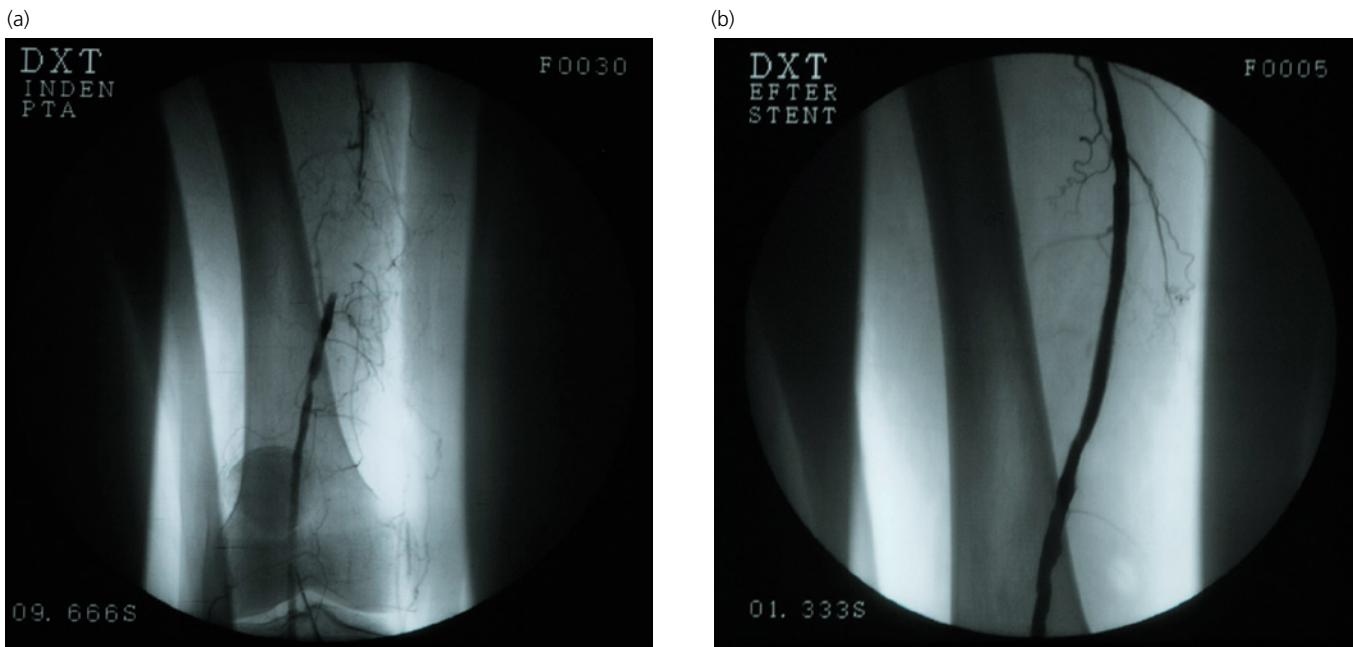

Figure 52.3 Short occlusion of the superficial femoral artery treated with (a) percutaneous transluminal angioplasty and (b) stenting.

Table 52.1 Pooled patency of vascular reconstructions.

Reconstruction	Patency (%)			
	1 yr	3 yr	5 yr	10 yr
Endovascular				
Iliac artery	86	82	71	
Fem-pop stenosis PTA	77	61	55	
Fem-pop occlusion PTA	65	48	42	
Fem-pop stenosis PTA + stent	75	66		
Fem-pop occlusion PTA + stent	73	64		
Open surgery

increasing length of a lesion there is an increasing risk of early reocclusion. Stenting appears to improve patency, at least for longer lesions (Table 52.1) [15]. When the indication for PTA is claudication, patency is better than if the indication is critical ischaemia. This difference relates to the more extensive nature of the disease in critical limb ischaemia (poor run-off vessels). The three-year patency is 48%, which may be improved to 64% if stenting is added. In critical limb ischaemia, the results at three years show a patency of 30% without stenting and 63% with stenting (Table 52.1) [15]. PTA of crural vessels is also feasible; however, the long-term results are not good. Data on limb salvage with PTA of crural vessels alone are still scarce, despite these procedures having been developed extensively in the last five years. Dual-antiplatelet therapy may be used after endovascular therapy, although guidelines recommend either dual or monotherapy [16]. Recently dual-pathway inhibition by low-dose rivaroxaban and aspirin has been shown to reduce major adverse cardiovascular and limb events in individuals with peripheral arterial disease undergoing revascularization [13].

Open surgical revascularization

Open surgical revascularization and PTA are both used similarly for treatment of critical limb ischaemia, but for longer lesions (>20–25 cm) many clinicians prefer bypass surgery using autologous vein grafting [16]. For claudication, open surgical treatment is rarely performed, whereas for extensive disease of the distal aorta and iliac arteries, the aorto-bifemoral bypass may still be performed because it is the procedure with the best long-term outcome. However, PTA is by far the dominant therapy and endarterectomy of the femoral artery, as described in what follows, may also be an option for treatment of claudication. Only one trial, the Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial, has compared open surgery with endovascular treatment of critical limb ischaemia [17]. The primary efficacy outcome measure was amputation-free survival, but because approximately two-thirds of the endpoints were deaths, only one-third of the endpoints really determined which procedure was best. Within six months

postoperatively there was no difference in the primary endpoint, but thereafter bypass individuals seemed to do better [17]. The Best endovascular vs. Best surgical therapy in individuals with Critical Limb Ischaemia (BEST-CLI) trial has randomized and treated almost 2000 individuals with either PTA or bypass surgery; results are anxiously awaited.

In general, two surgical techniques are used: endarterectomy and bypass. Endarterectomy is performed by separating the intima from the media, and in this manner the atherosclerotic lesion can be removed. Endarterectomy can be used in cases with severe occlusive lesions of limited anatomical extension in the external iliac or in the common femoral artery. The advantage of this technique is that it can often be performed without the use of artificial graft material and patency is excellent. Bypass is preferred when the obstructive and/or occlusive lesions are extensive (e.g. total superficial femoral artery occlusion or multiple serial lesions warranting a femoral–crural bypass; Figure 52.4). Bypass surgery can be performed with artificial materials or with autologous veins. For bypass of aortic or iliac artery origin, artificial grafts are almost always used. This is because there is no easily removable vein with similar dimensions that can be used in these locations. Dacron or polytetrafluoroethylene (PTFE) grafts perform very well in the aorto–iliac–femoral region. For peripheral bypasses, typically originating from the common femoral artery, autologous vein grafts are preferred for two reasons: they last longer (much better patency;

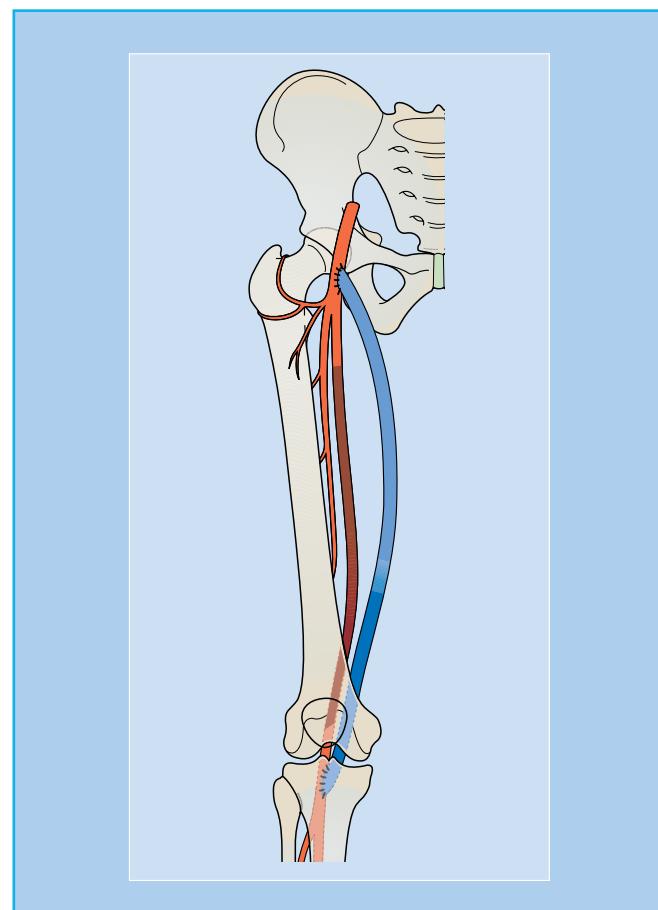

Figure 52.4 Long superficial femoral artery occlusion treated with femoro-popliteal bypass.

Table 52.1) and they carry less risk of infection. For longer bypasses, such as from the common femoral to the popliteal artery below the knee, a saphenous bypass is performed, leaving the vein *in situ*. This means that the vein is left in its original anatomical location; however, the proximal and distal ends are anastomosed to the arterial system. The venous valves are cut with a knife mounted on a catheter and side branches are occluded. In this manner, the vein retains its nervous innervations and native vascularization.

Complications of endovascular treatment

Complications relate mainly to the site of puncture and the risk of peripheral embolization. *Systemic* cardiovascular complications are rare. Haematoma in the groin access point is common; however, it only rarely requires any action to be taken. Development of an iatrogenic pseudo-aneurysm is seen in 0.5–1% of cases and can easily be treated with ultrasound-guided compression or ultrasound-guided thrombin injection.

Complications of open surgical treatment

Complications can be divided into local and systemic categories. The former relate to the actual incisions and dissections, including wound healing and infections. Whereas complications from accidental damage to other organs and/or structures are very rare, wound-healing problems and infections are unfortunately fairly common. In particular, surgery on the lower limb involving the groin and peripheral incisions have wound complications in 10–20% of cases (e.g. haematoma, lymph oozing, or necrosis of the wound) [18]. Infections are seen in 3–5% of cases, approximately one-third involving the vascular reconstruction. Infection of the vascular reconstruction is more frequent when using artificial graft material [18].

Systemic complications to open surgical revascularization relate to the surgical trauma and to the stress response. In vascular reconstructions involving the aorta and other central arteries, the cardio-pulmonary complication rate is considerable. Implantation of an aorto-bifemoral bypass graft is associated with a 30-day mortality of 2–5% and a rate of *general* complications of 10–15% (e.g. pulmonary, cardiac, renal, prolonged stay in the intensive care unit, and stroke) [18]. Systemic complications to peripheral revascularizations occur less frequently; nevertheless, they are considerable. When the indication is claudication, the morbidity with respect to general complications is low, 2–4%; however, in cases of critical ischaemia and peripheral bypass surgery, the morbidity increases to 10%, with a 30-day mortality of 3–5%. This difference in morbidity reflects the more advanced generalized atherosclerotic disease in individuals with critical ischaemia. In people with diabetes, complications are more common, especially with open surgery. A doubling of risk should be expected.

Results of endovascular and open surgical reconstructions

Results of reconstructions are summarized in Table 52.1. In general, when treating more centrally located arterial obstruction, the long-term results are better. In addition, treating people with claudication results in better long-term outcomes than operating on those with limb-threatening ischaemia. This difference relates to the generally poorer condition of the peripheral circulation in cases of critical ischaemia, with better run-off vessels in the person with claudication.

Vein grafts perform better in peripheral reconstructions. It may seem unrewarding to treat people with critical limb ischaemia with a peripheral bypass using an artificial graft when there is only a 50%

chance of its being patent at one year; however, if the alternative is amputation and/or very poor quality of life (i.e. severe rest pain), one year with a functioning graft may very well be worthwhile for both the individual and the surgeon. Limb salvage as a result of revascularization is almost always better than patency of the reconstruction, because in many cases, once the ischaemic limbs with tissue loss have healed, the *need* for amputation becomes less. This is because wound healing increases the needed blood supply, but once wounds are healed, resting blood flow needs are less. People with diabetes typically have poorer outcome of vascular reconstructions, with patency rates that are inferior to those in individuals without diabetes. People with diabetes have more complications to treatment; not only infections but also systemic complications are more common.

Acute lower-limb ischaemia

Acute lower-limb ischaemia is most often caused by thrombosis in existing atherosclerosis (i.e. a person with previous symptoms of chronic peripheral arterial disease). Another common cause is thrombosis of a popliteal aneurysm. Embolism remains a further common cause, although not as often as in the past because of better anticoagulant therapy for people with atrial fibrillation. Around 80% of emboli are of cardiac origin; however, aneurysms of the aorta or peripheral aneurysms as well as atherosclerosis in a proximal artery may give rise to peripheral emboli.

Other causes include trauma and iatrogenic lesions (e.g. from arteriography with puncture of the femoral artery). Aortic dissection may cause lower-limb ischaemia and also acute deep venous thrombosis (*phlegmasia cerulea dolens*). The incidence of acute limb ischaemia in Western Europe is 300–400 per million per year.

Pathophysiology

Thrombosis is caused by plaque rupture and subsequent thrombosis. Distal to the acute occlusion, arterial flow is slow and, when combined with a hypercoagulable condition, it may lead to further thrombosis. The degree of ischaemia depends on the location and degree of collateral development. Therefore, thrombosis is often better tolerated than embolism because people with existing atherosclerosis most often have developed collaterals.

Embolii will typically occlude an artery at a bifurcation: in the lower limbs, at the aortic bifurcation (saddle embolus), iliac artery, and femoral artery bifurcation. Around 60% of cardiac emboli will end in the lower limbs, 15% in the arms, and the rest in the brain and other organs. Microemboli, typically from aneurysms, affect small peripheral arteries, and are therefore the cause of *blue toe syndrome*.

Symptoms

Acute ischaemia is characterized by pallor, pain, pulselessness, paraesthesia, and paresis (the 5 Ps). Symptoms may begin dramatically and in some cases the late signs of ischaemia, paraesthesia, and paresis occur within a few hours. More often, symptoms begin with pain and paraesthesia and later sensory and muscular paresis. Acute ischaemia is traditionally divided into three classes: viable, threatened, and irreversible (Table 52.2).

Diagnosis

Diagnosis is often easy with typical clinical signs. ABI will be low, if measurable at all. Individuals with a history of intermittent claudication in the affected limb will probably have suffered thrombosis in the stenotic/affected arterial region. Imaging with either duplex

Table 52.2 Separation of threatened from viable extremities.

Category	Description/prognosis	Findings		Doppler signals	
		Sensory loss	Muscle weakness	Arterial	Venous
Viable/threatened	Not immediately threatened	None	None	Audible	Audible
a. Marginal	Salvageable if promptly treated	Minimal (toes) or none	None	(Often) inaudible	Audible
b. Immediate	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	(Usually) inaudible	Audible
Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, aesthetic	Profound, paralysis (rigour)	Inaudible	Inaudible

ultrasound, magnetic resonance angiography (MRA), computed tomography angiography (CTA), or digital subtraction angiography (DSA) is possible, but may delay treatment. In cases of thrombosis, it is most often desirable to perform arteriography with subsequent thrombolysis in order to visualize the underlying pathology causing the thrombosis.

Prognosis

If revascularization is possible before irreversible ischaemia has occurred, the limb can be salvaged and normal function regained. Comorbidity is high in cases of acute ischaemia; when acute revascularization is needed, outcomes after hospitalization are poor, with ~15% disabled or dead [19]. This is due to release of toxic substances from ischaemic tissue combined with existing severe cardiovascular atherosclerotic disease.

Treatment

Thrombosis in existing atherosclerotic lesions may be treated by endovascular or open surgery. The former is preferred if revascularization is not imminent. By catheter-directed intra-arterial thrombolysis, the underlying atherosclerotic lesions will be exposed and may in some cases be treated by PTA and/or stenting. In other cases, bypass surgery may be needed. Inoperable cases may be converted into operable cases by thrombolysis, because distal thrombosis most often makes surgery (and PTA) useless when there are no run-off vessels. Another advantage of thrombolysis is that emergency surgery is converted into a less urgent intervention. Emboli can be treated by embolectomy by inserting a balloon catheter, in either the femoral or popliteal artery, and retracting the emboli after inflating the balloon (Figure 52.5). Some cases of embolism may also be treated by thrombolysis.

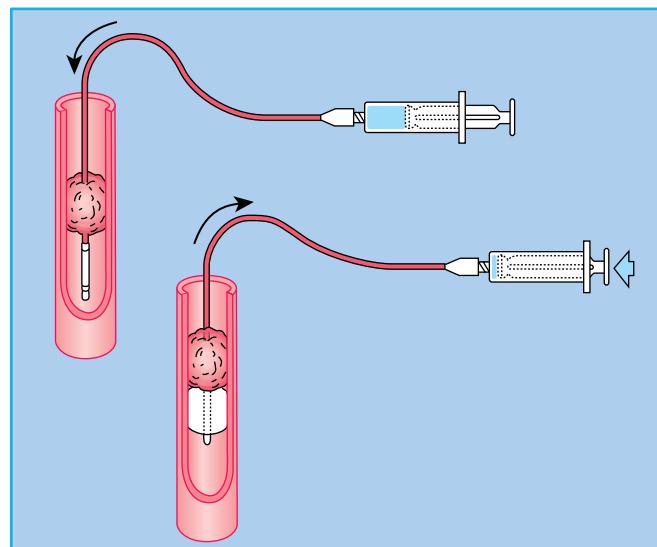

Prevention

Arterial emboli have a high recurrence rate and the underlying cause should be treated, if possible, with corrective treatment for atrial fibrillation and resection or exclusion of aneurysms. If the source of embolism cannot be eliminated, anticoagulation must be considered.

Atherosclerosis of renal and mesenteric arteries

Renal artery obstruction

Renal artery obstruction can cause severe hypertension and renal failure, but interventional treatment may improve both conditions. Today, open surgical management is only rarely performed, because endovascular management is much less invasive and is feasible in

**Figure 52.5** Embolectomy performed with a balloon catheter.

the majority of cases. Open surgery, thromboendarterectomy or bypass, is performed when renal artery disease is combined with other pathology such as aortic occlusion or abdominal aortic aneurysms.

However, the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) study showed that renal artery revascularization (stenting) of atherosclerotic lesions in order to treat renovascular hypertension is in general not better than optimal medical therapy [20]. This was surprising and has reduced the use of this intervention, and so it is now mainly indicated for renal artery stenosis due to fibro-muscular dysplasia. There may be rare cases where revascularization is performed to improve renal function; however, this is done against an empirical background.

Mesenteric artery occlusive disease

Mesenteric artery occlusive disease may cause abdominal angina. Just like atherosclerotic lesions in other locations, many cases are asymptomatic and probably do not need intervention with regard to the obstructive disease, but lifestyle changes and medical preventive treatment are indicated. Individuals with classic symptoms, post-prandial pain occurring 10–20 minutes after a meal in addition to weight loss, often benefit from revascularization. However, many individuals have less obvious symptoms, and the mere occurrence of a lesion on one of the three main vessels supplying blood to

the gastrointestinal tract (coeliac trunk and superior and inferior mesenteric arteries) does not warrant interventional treatment. In general, a single lesion in one of the three arteries is seldom thought to cause ischaemia. Diagnosis is possible by ultrasound of the suprarenal vessels in most cases, otherwise CTA, MRA, or DSA may be needed. Interventional treatment is mainly balloon angioplasty and stenting. Long occlusions of the superior mesenteric artery and/or occlusive mesenteric disease combined with other pathology of the aorta may be treated by open surgery (e.g. aortomesenteric bypass or transposition).

Ischaemia of the arm

Atherosclerosis and ischaemia of the arm are much less common than in the lower limb. The most common location for development of atherosclerosis in the arteries supplying the upper extremity is in the brachiocephalic trunk and subclavian arteries central for the origin of the vertebral arteries. Rarely, occlusive lesions are located more peripherally in the subclavian or axillary arteries. Takayasu vasculitis may also cause upper extremity ischaemia.

Typical symptoms of chronic arm ischaemia

Symptoms include claudication. In typical cases, pain is encountered when performing tasks with the arms elevated, such as hanging laundry, or other physical use of the arm. Critical ischaemia with rest pain or gangrene is rare, but may occur. Diagnosis is easy, with lack of pulses at palpation. Measurement of bilateral blood pressure may show a difference and ultrasound may locate and quantitate the stenotic lesion. If blood pressure cannot be measured by auscultation, a Doppler device may be used as for measurement of ankle blood pressure. Additionally, or in case of severe ischaemia, finger pressure measurement by the strain gauge technique may be used. Upper-arm angiography by CTA, MRA, or DSA may be supplemental.

The prognosis is often good, because development of critical ischaemia and the necessity for amputation are rare. Individuals with finger gangrene should be investigated for vasculitis.

Treatment of upper-extremity atherosclerosis is similar to that of atherosclerosis in other vascular distributions: risk factor reduction by lifestyle changes and preventive medications for all, and revascularization in some. In fact, only rarely is interventional treatment indicated, but in cases of incapacitating functional pain and/or critical ischaemia, revascularization should be considered. Endovascular treatment dominates because of its less invasive nature for lesions near the origin of the brachiocephalic trunk and subclavian arteries. For lesions that cannot be treated by endovascular techniques, such as long lesions or lesions that cannot be crossed by a guide wire, bypass surgery is indicated (carotid-subclavian bypass). Peripheral bypass of the upper extremity (e.g. at the level of the brachial artery) is rare and patency is poor.

Acute arm ischaemia

Acute arm ischaemia is most often caused by embolization, but alternatively can be caused by thrombosis in an existing stenosis, such as of the subclavian artery. Whereas the former may be treated easily by embolectomy via a small incision in the cubital fossa, the latter may be more complex to treat, perhaps requiring intra-arterial thrombolysis before vascular reconstruction. Embolism is most often of cardiac origin, from either atrial fibrillation, mural thrombus in the heart, or valve disease. Vascular causes include a subclavian aneurysm or stenosis. Microemboli may occur peripherally and present as gangrene of one or more fingers. Extravascular

causes include a cervical rib. Obviously, eradication of the embolic source is crucial, if possible. Treatment of peripheral ischaemia may include thrombolysis, but in most cases collaterals develop and amputation does not become necessary.

Aortic aneurysmal disease (abdominal aortic aneurysm)

This section focuses on abdominal aortic aneurysms, because thoracic aortic aneurysms are not considered part of peripheral vascular disease. The main difference between individuals with and without diabetes with respect to treatment of aneurysms is that those with diabetes are more prone to complications after surgery; however, because of the nature of preventive surgery for aneurysms, this only rarely causes changes in management once the risk of surgery has been weighed against non-surgical treatment.

Aneurysm of the aorta is a common condition in older people, especially in the infrarenal aorta. An artery by definition becomes aneurysmal when the diameter locally increases by more than 50% compared with the *normal* diameter proximal or distal to this site. In cases of infrarenal aorta, an aneurysm is present when the diameter exceeds 30 mm.

The prevalence of abdominal aortic aneurysm is ~5% in men over 70 years of age; however, only a minority of them will have a size that mandates surgery (diameter >5–6 cm). In individuals with other atherosclerotic manifestations, such as peripheral arterial disease or carotid disease, the incidence of abdominal aortic aneurysms is 2–3 times greater. There is a 2:1 ratio of aortic aneurysms occurring in men to women. Finally, the tendency to develop abdominal aortic aneurysms is partly inherited, as the risk for a man with a father or brother with aortic aneurysm is ~20%. People with diabetes seem to have a slightly lower incidence of abdominal aortic aneurysm, ~80% of those without diabetes [21].

Pathophysiology

Arteries enlarge with age, and the diameter of the infrarenal aorta is normally <20 mm in a 70-year-old man. If the wall weakens locally, an aneurysm develops. A true aneurysm develops when all three layers in the arterial wall are involved and dilate, as in the case of the typical infrarenal aortic aneurysm. False aneurysms or pseudoaneurysms develop after iatrogenic trauma, such as PTA or other transfemoral procedures, and at arterial anastomotic sites. Finally, dissection occurs when a rupture of the intima allows blood to enter between the layers of the artery wall.

Aortic aneurysms may rupture, almost certainly leading to death. It is estimated that 80–90% of all individuals with ruptured aneurysms die before they get to hospital. Ruptured aneurysms cause an estimated 2–3% of all deaths among men, whereas the proportion for women is 1%.

In most abdominal aortic aneurysms, there is an atherosclerotic degeneration of the vessel wall that dilates; however, it is unclear why atherosclerosis in some people results in occlusive disease and in others in aneurysm development. Accelerated breakdown of elastin has a role in aneurysm development. The simultaneous presence of both occlusive and aneurysmal disease is common in many individuals. Inflammatory aneurysms are present in 5–10% of aortic aneurysms where the aortic wall is thickened as part of peri-aneurysmal or retroperitoneal fibrosis.

Symptoms from abdominal aortic aneurysms

Symptoms are rare and most are asymptomatic. Diagnosis is often made coincidentally, such as when a person complains of slight

upper gastric pain and has an ultrasound of the gallbladder, which discloses the aortic aneurysm. Also, typically the individual may complain of back pain and have a lumbar X-ray. Whether the pain is really related to the abdominal aortic aneurysm, to gallstones, or to the back is often difficult to ascertain.

Some individuals will sense a pulsation in the abdomen, while large aneurysms may cause discomfort or compress surrounding organs, mainly the gastrointestinal tract. The main risk is rupture, which, when intraperitoneal, most often leads to immediate death. If rupture is into the retroperitoneal space, a haematoma may be contained and the person may survive for hours. Rupture and development of a haematoma lead to pain in the abdomen and/or back. Chronic rupture is rare, because almost all cases will be fatal within hours. Aneurysms may cause peripheral embolization, resulting in a cyanotic or gangrenous toe as the first symptom.

Diagnosis

Diagnosis is easy, as ultrasound is very accurate in making the diagnosis and estimating the diameter of the aneurysm (Figure 52.6). In the few cases where ultrasound is inconclusive, a primary computed tomography (CT) scan may be necessary. Otherwise, CT or magnetic resonance (MR) scanning is only performed when the size of the aneurysm dictates that intervention should be considered (aortic diameter of >5 cm). Arteriography is rarely performed for abdominal aortic aneurysm; however, in cases of both abdominal aortic aneurysm and symptoms of peripheral arterial disease, an arteriogram may be warranted for planning of the revascularization procedure (CTA). Anyone with acute abdominal pain in pre-shock should always be suspected of ruptured abdominal aortic aneurysm.

Prognosis

The risk of rupture is related to the size of the aneurysm. When the diameter exceeds 6 cm, the annual risk of rupture is 10–20%, whereas the risk of rupture in the case of an aortic aneurysm with a diameter of 3–4 cm is <1%. Aneurysms tend to expand; small aneurysms dilate by 1–2 mm/yr, whereas larger aneurysms may expand 2–3 times faster. Smoking and hypertension seem to increase the rate of growth. Rupture is associated with 90% mortality, but the survival for those who reach hospital and have immediate surgery is ~50–60%. Concomitant coronary disease is responsible for a

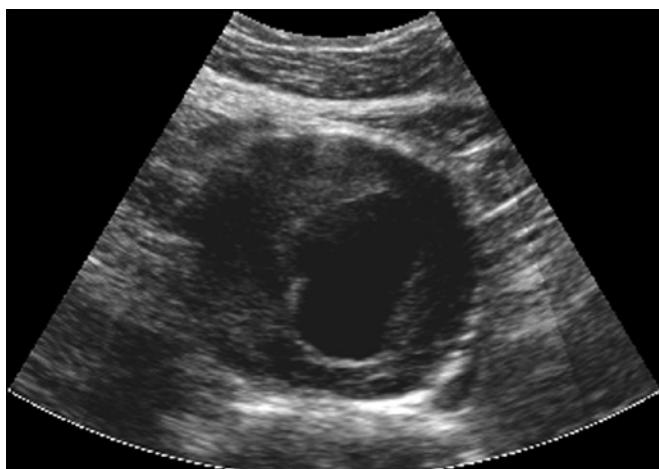

Figure 52.6 Ultrasound image of an abdominal aortic aneurysm. Note the presence of a large thrombus inside the aneurysm sac.

50–100% increased mortality of individuals with aneurysms even when aneurysm mortality is disregarded.

Treatment

Treatment of abdominal aortic aneurysms involves, in addition to surgery for some, the same preventive treatment as is given to other people with atherosclerotic manifestations: lifestyle changes and medical therapy with platelet inhibitors, statins, and blood pressure control.

Treatment of a ruptured aortic aneurysm is always interventional (open surgical or endovascular), unless the overall condition is considered too poor to attempt rescue. In some cases, a fatal aortic aneurysm may be a dignified death, for example in an older person with end-stage renal or heart failure. Symptomatic non-ruptured aneurysms should be treated acutely or subacutely because of the risk of imminent rupture.

Treatment of a large asymptomatic abdominal aortic aneurysm reduces mortality [22], and those with an asymptomatic aneurysm should be offered elective interventional treatment if the risk of rupture exceeds the risk of the procedure, and if the person is fit for the procedure and expected to have good-quality years remaining. Because any procedure for treatment of aortic aneurysm either carries a considerable perioperative risk or involves a very long post-operative period with potential reinterventions, the decision to offer interventional treatment is not always easy, and a decision should be taken in consultation with the individual and their family.

The choice between treatment modalities is made keeping the following facts in mind.

Open surgical treatment with resection of the aneurysm and replacement of the diseased part of aorta with an artificial graft has been performed for ~50 years (Figure 52.7). It is a well-proven procedure with known risks and long-term results, including an overall 3–5% perioperative mortality, but limited aneurysm morbidity after the procedure. Complications of open surgical repair relate to the considerable surgical trauma of this major procedure. Around 10–20% of individuals will develop general complications such as cardiac, pulmonary, and renal complications, in addition to requiring a prolonged stay in the intensive care unit and stroke.

Endovascular aneurysm repair (EVAR) involves inserting a collapsed prosthesis via the femoral artery, placing it below the renal arteries, and deploying and fixing it (stenting) under X-ray guidance. The technique mostly used today involves inserting a bifurcated graft from one femoral artery and then placing the other limb via the contralateral femoral artery (Figure 52.8). EVAR has lower perioperative morbidity: 1.5% compared with 4.5% for open surgery [23–26]. There are few complications to EVAR in the perioperative period, but a considerable number of individuals will need repeat interventions, which in most cases can be performed by endovascular techniques. These include placement of another proximal stent because of endo-leak (blood re-entering the excluded aneurysm sac, which is thereby again at risk of rupture) and embolization of inferior mesenteric or internal iliac arteries. Because the long-term results of EVAR are not well known (>10 years), continuous surveillance with annual CT or ultrasound scans is necessary. Until a few years ago, the number of repeat interventions because of either migration or failure of the implanted device, both leading to endo-leak were considerable; however, more recent data show improvement to 10–15% at three years [25].

As an example of choice of treatment modality, a 65-year-old man with a 6 cm aneurysm and no other known comorbidity should be offered treatment, preferentially open surgery, because

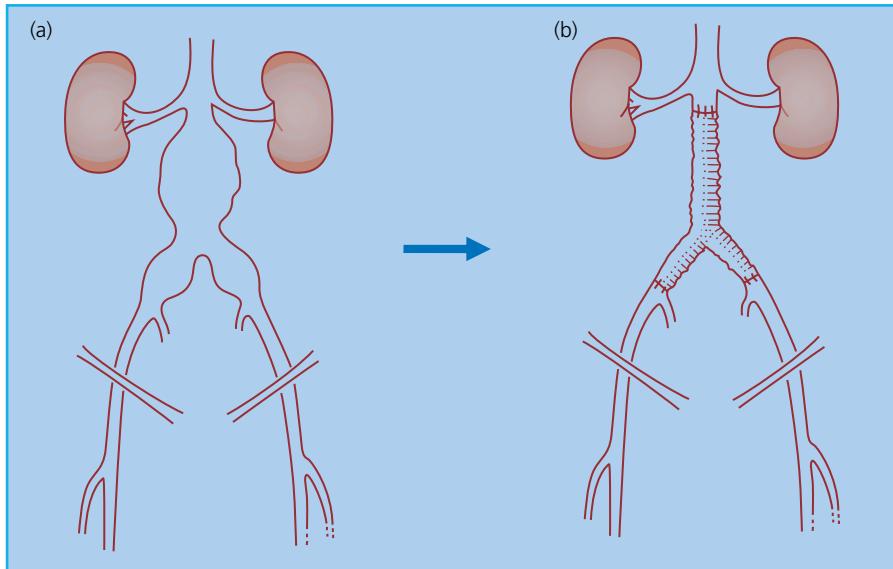

Figure 52.7 (a, b) Abdominal aortic aneurysm treated by resection and implantation of an aorto-bi-iliac bypass graft.

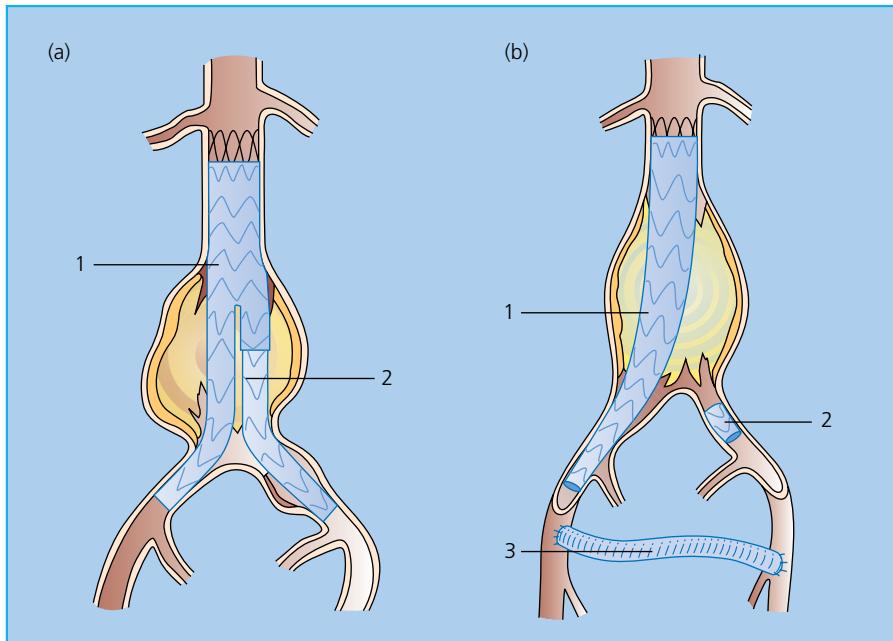

Figure 52.8 Abdominal aortic aneurysm treated by endovascular repair. (a) First the bifurcated graft (1) is inserted via the right femoral artery and fixed by stenting at the proximal and distal end of the graft. The left limb (2) is inserted via the left femoral artery and connected to the main graft. (b) Insertion of an aorto-uni-iliac endograft (1) combined with a femoro-femoral bypass graft (3) is used when one of the iliac arteries (2) cannot be passed.

his perioperative risk will be low (2–3%), whereas the annual risk of rupture is ~10%. At the other end of the spectrum is the 80-year-old man with previous coronary artery bypass graft surgery and a similar-sized aneurysm of 6 cm. His risk with open surgery includes >10% 30-day mortality in addition to a considerable risk of other complications. Endovascular treatment could be a good alternative for this man if he is expected to live at least 3–5 years.

EVAR has been considered to be a treatment alternative for individuals unfit for open surgery. The EVAR-2 trial tested this hypothesis and participants found to be unfit for open repair were randomized to either conservative management or EVAR. Survival was not improved by EVAR and it was poor in both groups: ~50% of participants in both groups were dead at three years and only one-quarter of deaths were aneurysm related [26]. Hence being found unfit for surgery in this study indicated a poor prognosis in general that EVAR did not affect.

The most recent European guidelines recommend EVAR for most cases now, but it is always a matter of discussion between clinician and person with the aneurysm, so that the advantages and disadvantages of both techniques are clear to the individual. In cases of ruptured abdominal aortic aneurysm EVAR is recommended if possible [27].

Screening

The value of population-based screening for abdominal aortic aneurysms is now well documented. A meta-analysis of four randomized controlled trials found aneurysm-related mortality to be reduced by 43% in those offered screening [28]. Today, it is recommended in many countries that men >65 years and previous smokers undergo ultrasound screening. Family members who are direct descendants and siblings of those with aortic aneurysms should also undergo screening.

Peripheral aneurysms

Aneurysms may develop at other locations, the popliteal and femoral arteries being the second and third most common locations. More than 50% of individuals with peripheral aneurysms also have an aortic aneurysm. Symptoms are different in the sense that rupture is less common; however, symptoms derived from compression (popliteal vein thrombosis, pain, and other symptoms of nerve compression), peripheral embolization, or thrombosis of the aneurysm most often bring the individual to medical attention.

Treatment is the same as for aortic aneurysms: general prevention against atherosclerotic disease and intervention in symptomatic cases. Popliteal aneurysms are generally treated surgically by exclusion and bypass or by resection and replacement by a short graft. Femoral aneurysms are treated by resection and placement of a graft. Endovascular management is possible; however, graft thrombosis and failure of stent graft material have so far made indications unclear. Large asymptomatic peripheral aneurysms should probably be treated by either open or endovascular surgery, although no documentation is currently available that such treatment is beneficial.

Aneurysms of visceral or renal arteries may occur but are rare. Treatment is interventional when they are large. Endovascular management is under development, but its indications are not yet settled.

Carotid artery disease

This section focuses on stroke and carotid disease, while Chapter 51 addresses cerebrovascular disease in general, including pathophysiology and symptoms. The relationship to atherosclerosis for many people with stroke is well documented, although stroke, unlike other ischaemic conditions, has other common pathogenetic mechanisms.

It is very important to discriminate between symptomatic disease and asymptomatic cases. People with recent cerebrovascular symptoms and an ipsilateral stenosis are comparable to those with a recent acute coronary event: the risk for a new thromboembolic event is very high and diagnostic work-up and treatment should be started immediately. The pathogenetic mechanism is similar to that of an acute coronary event with plaque rupture and subsequent thrombosis; however, in the case of the carotid, embolization into a cerebral artery is much more common than thrombotic occlusion of the carotid artery itself. Perhaps the larger diameter of the carotid artery explains this difference.

The prevalence of carotid stenosis is high. Among people with acute cerebrovascular symptoms, an ipsilateral stenosis of >50% diameter reduction is found in 15–20% of cases. In people with other clinical atherosclerotic manifestations, a carotid stenosis is found in 20–30%.

Prognosis

The risk of stroke is increased in the presence of carotid stenosis. For asymptomatic people with a carotid stenosis exceeding 60% diameter reduction, the annual risk of ipsilateral stroke is ~1% with optimal medical prevention (anti-atherosclerotic treatment). When carotid stenosis is related to recent ipsilateral cerebral ischaemic symptoms (symptomatic stenosis), the risk is much higher, especially just after the first event. The 30-day risk of stroke in people with previous cerebrovascular symptoms is as high as 10% when an ipsilateral carotid stenosis is present. Thereafter, the risk gradually declines and after one year it is ~2–3% annually, almost similar to

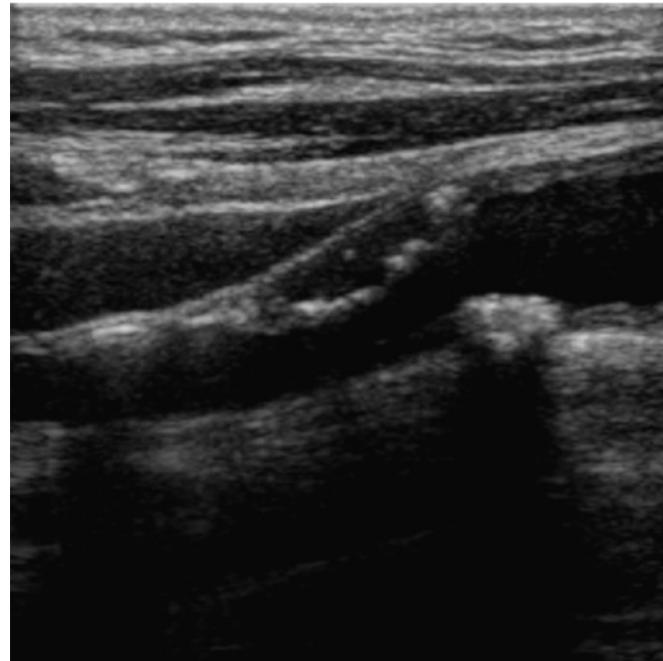

Figure 52.9 B-mode ultrasound image of carotid stenosis. The top part is echolucent, indicating a high content of lipid/necrotic core; the bottom part is echogenic, indicating a fibrous plaque.

asymptomatic carotid stenosis. The three-year risk of ipsilateral stroke is 15–30% in symptomatic individuals with a stenosis >70% diameter reduction.

Diagnosis

Diagnosis of carotid disease should be carried out by duplex ultrasound scanning (Figure 52.9). The accuracy of the method is well documented for both identification and quantification of degree of stenosis. Many surgeons will perform carotid endarterectomy based only on ultrasound examination.

Treatment

Treatment of people with carotid stenosis is like that of any other condition related to atherosclerosis: treatment of the atherosclerotic disease itself and treatment of local manifestations. Risk factor reduction, including changes in health behaviours, is exactly the same as for individuals with other clinical manifestations of atherosclerosis, although there may be regional variation in the choice of antiplatelet agents. Aggressive lipid lowering reduces both the risk of recurrent stroke and the risk of coronary events, especially in this group of individuals [29–31].

It is important to realize that any invasive treatment for carotid stenosis is performed to prevent future *local* events (stroke). Hence the risk of the intervention itself should be weighed against the absolute risk of an event. Furthermore, the most common complication of surgery and stenting is ipsilateral stroke, the event that the procedure is supposed to prevent. Most importantly, the overall risk to the individual (including that of other conditions) should be weighed against the absolute risk reduction derived from the procedure.

Symptomatic carotid stenosis

Symptomatic individuals with carotid stenosis benefit from endarterectomy when the stenosis is >50–70% diameter reduction and neurological symptoms are within six months of surgery [32, 33].

The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and European Carotid Surgery Trialist's Collaborative Group (ECST) trial [32, 33] randomized simultaneously, but independently, symptomatic individuals with carotid stenosis to best medical treatment or best medical treatment plus endarterectomy. Both trials showed significant benefit (50% relative risk reduction) in those with stenosis >70% diameter reduction, whereas in the group with 50–69% stenosis there was only a marginal effect, and in participants with stenoses <50% there was no benefit.

Subsequent reanalysis of the pooled data from these two trials, however, showed that the time interval between onset of neurological symptoms and surgery was the most important predictive factor of benefit for the individual [34]. In general, the earlier an operation is executed, the greater is the benefit. The overall absolute risk reduction of ~15% conveyed by endarterectomy could be doubled when individuals received surgery within two weeks of symptoms (number needed to treat to prevent one stroke = 3). With the knowledge gained during the last 10–15 years concerning vulnerable plaques and plaque rupture, this finding does not come as a great surprise; however, when these trials were designed, this pathogenetic mechanism of acute ischaemia was unknown.

Male sex, older age, and greater severity of stenosis all increase the risk of future stroke in people with stenosis without any increased risk of the surgical procedure, hence the overall benefit is greater [34]. In addition, imaging parameters seen on ultrasound, MR, and CT scans further increase the risk of future stroke and should be considered [35].

Asymptomatic carotid stenosis

Asymptomatic carotid stenosis is more controversial, although two major trials have shown a small but statistically significant benefit of surgery. First, the Asymptomatic Carotid Atherosclerosis Study (ACAS) trial showed a 50% relative risk reduction of ipsilateral stroke, but the absolute risk reduction was marginal, only 1% per year [36]. Later, the Asymptomatic Carotid Surgery Trial (ACST) reproduced these findings [37]. Taking into consideration that the average annual mortality during the trials was 3–4%, in addition to other ischaemic events that were unaffected by the procedure, it may be questioned whether the cost-benefit is reasonable both for the individual and for society. The medical treatment offered during these trials was much poorer than that recommended today; hence the outcomes of these trials may not be reflective of the risk in these individuals today. If or when better criteria for selection of individuals at higher risk become available, selective surgery for high-risk cases of asymptomatic carotid stenosis may yield greater or even much greater benefit.

Technical considerations

Technically, carotid endarterectomy may be performed in two ways: classic endarterectomy (Figure 52.10) or eversion endarterectomy. In the latter, the internal carotid artery is divided from the bifurcation, and endarterectomy is performed by evertting the vessel wall, thereby removing the carotid lesion. After the stenosis has been removed, the bifurcation is reconstructed by reanastomosing the internal carotid to the bifurcation.

Carotid endarterectomy may be performed under general or local anaesthesia. Classically, general anaesthesia has been preferred; however, this has carried the challenge of monitoring cerebral circulation during clamping of the carotid artery. Various methods have been used, including electroencephalography, stump pressure, distal internal carotid artery pressure, evoked potentials,

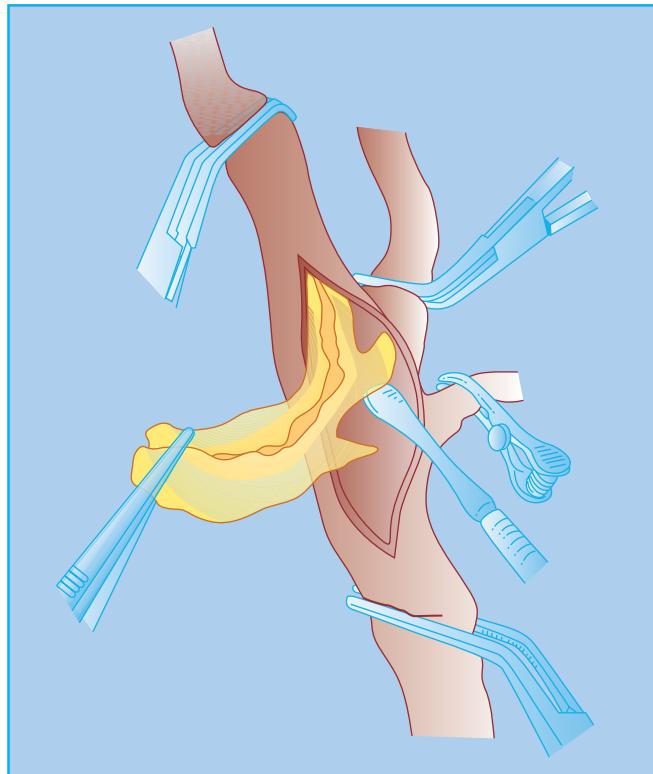

Figure 52.10 Carotid endarterectomy where the intima–media complex is dissected free of the adventitia and removed.

near-infrared spectroscopy, transcranial Doppler ultrasound, and more. None of these methods has proven ideal, and so some surgeons use a shunt on a selective basis, whenever their method for monitoring indicates risk of cerebral ischaemia during clamping, whereas others use a shunt routinely. By contrast, performing endarterectomy under local anaesthesia gives the surgeon the opportunity to communicate with the patient during clamping. Having the person awake and responsive during surgery may represent the best monitoring of cerebral function during clamping. Also, local anaesthesia may carry less cardiac and pulmonary risk. Smaller trials and a meta-analysis indicated superiority of local anaesthesia [38]; however, the later General Anaesthesia versus Local Anaesthesia for carotid surgery (GALA) trial reported its results after randomizing 3529 participants to either universal or local anaesthesia for carotid endarterectomy, and there was no difference in the risk of perioperative stroke or death [39].

Carotid stenting

Carotid stenting has yet to be proven to prevent ipsilateral ischaemic events in randomized clinical trials. Seven randomized controlled trials comparing stenting with endarterectomy have been published; however, so far they have focused only on comparison of perioperative complications. The two most recent trials, Endarterectomy Versus Angioplasty in patients with Symptomatic Severe carotid Stenosis (EVA-3S) and Stent-Protected Angioplasty versus Carotid Endarterectomy (SPACE), failed to show an advantage of the less invasive carotid stenting method with respect to perioperative events [40, 41]. In fact, the EVA-3S trial was stopped early because of excess complications in the stenting group [40]. A Cochrane meta-analysis including all seven randomized controlled trials

favoured surgery with respect to the primary outcome of perioperative death and ipsilateral stroke [42]. Most recently, the Carotid Revascularization Endarterectomy vs. Stenting Trial (CREST) showed equivalence of stenting and endarterectomy, but in a trial with a combined endpoint of death, stroke, and myocardial infarction, as detected by the increase in enzymes in individuals without any other symptoms. Accordingly, focusing on the risk of death and stroke, stenting was associated with more complications [43]. Nevertheless, it is important to acknowledge that technology develops rapidly and some of the trials may have used devices and/or technologies that are already outdated. Similarly, there may be differences in trial design, and criticism has been made specifically regarding the training of the investigators in some studies. Interestingly, stenting appears to be associated with higher complication rates when performed early after onset of neurological symptoms and in older people – the two strongest indications. Finally, one should keep in mind that stenting should be evaluated in long-term studies, and compared not only with endarterectomy, but also with medical therapy, which has improved dramatically in the last 10–20 years. However, the most recent Cochrane analysis still recommends endarterectomy over stenting for symptomatic carotid disease [44] in accordance with most recent guidelines [35].

It may be questioned whether the evidence for carotid endarterectomy is outdated. Three of the four major trials proving

endarterectomy to be of value for symptomatic and asymptomatic surgery were performed when the only fairly constant preventive medication given was aspirin. The last randomized trial was 8–10 years ago, and only 30% of the participants were taking statins. It was stated in the design of these trials that hypertension and hypercholesterolaemia were treated when present; however, in that era the treatment goals for both hypertension and hypercholesterolaemia were much laxer than they are now. Also, new drugs have been introduced and their benefit documented since these trials initially randomized individuals (e.g. statins, newer antiplatelet agents, dual-antiplatelet therapy, and newer antihypertensive drugs). It may be speculated that if these drugs were used systematically, the risk in people with carotid stenosis would be much less, not least in those with vulnerable plaques. Therefore, new trials are needed to test how today's medical therapy compares with intervention and if the best medical therapy remains inferior to surgery or stenting. New trials are *not* unethical – it is unethical not to undertake new trials.

Carotid revascularization prior to coronary artery bypass surgery has been practised in some institutions whereas others have not found it useful. The potential advantage is avoiding cerebral ischaemia during the relative hypotension *on pump*; however, the complications of carotid revascularization have outweighed the gains, as evaluated by recent reviews.

² Miller School of Medicine, University of Miami, Miami, FL, USA

Key points

- Diabetes-related foot problems remain the commonest cause of hospital admissions among people with diabetes in high-income countries.
- There are estimated to be 60 000 active diabetes-related foot ulcers in UK at any one time.
- Up to 50% of older individuals with type 2 diabetes have risk factors for foot problems.
- The risk of death five years after an individual with diabetes has acquired a foot ulcer is 2.5 times higher than the risk for a person with diabetes who does not have a foot ulcer.
- Up to 85% of lower-limb amputations are preceded by foot ulcers.
- Mortality after diabetes-related amputation exceeds 70% at five years for all individuals with diabetes.
- All people with diabetes should be screened for risk of foot problems on an annual basis. Those with risk factors require regular podiatry, self-management education, and instruction in foot self-care.
- Most foot ulcers should heal if pressure is removed from the ulcer site, the arterial circulation is sufficient, and infection is managed and treated aggressively.
- Any individual with a warm, unilaterally swollen foot without ulceration should be presumed to have an acute Charcot neuroarthropathy until proved otherwise.

Diabetes-related foot disease is a global challenge. This chapter discusses all aspects of foot disease in people with diabetes, focusing particularly on diagnosis and management in the prevention of lower-limb amputation. The chapter is underpinned by high-quality evidence and recently updated recommendations developed by the International Working Group on the Diabetic Foot.

The most feared manifestation of diabetes-related foot disease is amputation and at any one time 2–4% of people with diabetes are likely to have an active foot ulcer, equating to 62 000 people in England, 1.2 million across Europe, and 8.4 million globally [1, 2]. People with diabetes in England are 23 times more likely to have a leg, foot, or toe amputation [3]. Five-year mortality is 45%, 18%, and 55% for neuropathic, neuroischaemic, and ischaemic ulcers, respectively, on multivariate regression analysis, with only increasing age predicting shorter survival time [4]. Around 8 in every 10 000 will undergo a major amputation and ~18 out of 10 000 will undergo a minor amputation. The Vascular Society of Great Britain and Ireland defines a major amputation as above the level of the ankle joint and a minor amputation below [5]. There were 2515 major amputations and 6640 minor amputations carried out in England between 2015 and 2018. All types of diabetes-related foot ulcers are associated with high morbidity and mortality. The increased mortality appears to be independent of factors increasing ulcer risk, such as neuropathy and peripheral arterial disease, in individuals with established foot ulcers [2].

Foot ulcers do not occur spontaneously, but arise from a combination of factors that can be modified to reduce the risk of ulceration. The International Diabetes Federation focused on the diabetic

foot throughout 2005 with a worldwide campaign to *put feet first*, highlighting that diabetes is the leading cause of non-traumatic lower-extremity amputation throughout the world [6].

Epidemiology and economic aspects of diabetes-related foot disease

The Global Burden of Disease Study in 2016 was the first study to provide an estimate of the number of individuals living with diabetes-related lower-extremity complications [7]. The study reported that 131 million people (1.8% of the global population) had a diabetes-related lower-extremity complication at the time of the study [8]. The 2015 prevalence data from the International Diabetes Federation estimated that, annually, foot ulcers develop in between 9 and 26 million people with diabetes worldwide [6]. Diabetes increases the risk of lower-extremity amputation by 10–20 times and is associated with half of all lower-limb amputations globally.

Health economics of diabetes-related foot disease

In the USA, the direct costs of treating diabetes-related foot complications exceed the treatment costs for many common cancers; \$176 billion is spent annually on direct costs for diabetes care, with one-third of that expenditure related to lower-extremity complications [9]. *The Lancet* launched an issue focusing on the burden of diabetes-related foot disease, which was the first time any major non-specialist journal had specifically focused directly on the issue. However, major challenges still exist if we are to reduce amputations globally [10].

Aetiopathogenesis of diabetes-related foot lesions

Diabetic neuropathy

Diabetic peripheral neuropathy affects up to 50% of people with diabetes and is a leading cause of lower-limb amputation and incapacitating neuropathic pain [11]. Diabetic peripheral neuropathy can be either painful or painless, which makes the diagnosis challenging (Chapter 45) [11]. The loss of protective sensation renders individuals vulnerable to trauma without awareness in the latter stages of diabetic peripheral neuropathy and is also associated with unsteadiness, resulting in an increased risk of falls [11]. Symptoms, if present, include neuropathic pain, which can be difficult for individuals to describe but may include burning or electric shock-type pain, stabbing or shooting sensations, all of which are worse at night, or negative symptoms such as numbness, tingling, or the feet *feel dead* [11].

Sensory loss

Diabetic peripheral neuropathy results in loss of sensory protection in the foot for 75–90% of all cases [12]. The power of clinical observation is highly relevant to people with diabetes-related foot ulcer, and anyone with a plantar ulcer who is able to walk without limping should be considered to have diabetic peripheral neuropathy [13]. Lack of pain serves to reduce individual awareness of the foot, subsequently increasing the risk of delayed healing of injuries and ulcerations, infection, and in turn amputation (Figure 53.1) [13]. Risk management is based on developing the visual perception of the foot, in the absence of perception of sensation, which can be realized through daily foot examinations to identify sites of injury and potential ulceration.

Figure 53.1 A typical non infected neuropathic plantar ulcer located under the 2nd metatarsal head, the 2nd digit is dorsally dislocated resulting in metatarsal head depression a *plunger effect*.

Peripheral sympathetic autonomic neuropathy

Peripheral sympathetic neuropathy presents with dry skin that is prone to cracking (fissures) and often accompanied by fissures around the heel [13]. These characteristics are caused by autonomic dysfunction, which reduces sweating and production of natural moisturizing factors in the skin [14]. In the absence of large-vessel obstructive peripheral vascular disease, arteriovenous (distended dorsal veins) shunting leads to a warm foot. The *high-risk* neuropathic foot typically presents with high arches, clawing of the toes, prominent metatarsal heads, and small muscle wasting (Figure 53.2) [13]. Callus is often present on the plantar aspect of the foot, which is generally under the first metatarsal head where foot pressures are highest [13].

Screening

Over 50% of individuals with type 2 diabetes show signs of diabetic peripheral neuropathy, which can be identified through a comprehensive assessment. Guidance can be located via the American Diabetes Association document 'The comprehensive diabetic foot assessment', which provides clarity on the structure and content of a robust assessment. The International Working Group on the Diabetic Foot has also issued recent guidelines [15]. A disciplined screening assessment is the key to a comprehensive foot exam, including history and clinical examination (Box 53.1).

Bedside screening tools for neuropathy

Current guidelines advocate the use of simple tests such as the 10 g monofilament, but unfortunately not all 10 g monofilaments generate 10 g of linear pressure. Furthermore, they become fatigued and wear out. The literature is unclear about the definitive sites determining ulcer risk; however, there are sites that are common, such as the plantar surface of the metatarsal heads and apices (pulp) of the great toe [16].

The VibraTip™ 128 Hz (McCallan Medical, Derby, UK) is a device comparable with the 10 g monofilament and therefore could be considered a useful tool for screening for peripheral sensory neuropathy. Both the VibraTip and the Ipswich Touch Test are reliable and sensitive tests for identifying the high-risk foot [13].

Figure 53.2 The high-risk neuropathic diabetic foot demonstrating high arch, prominent metatarsal heads, clawing of toes, and callus under first metatarsal head.

Box 53.1 Salient features of a structured foot examination**History**

- Ulcer past or present
- Minor or major amputation
- Past or present neuropathic symptoms
- Bypass surgery or angioplasty, intermittent claudication
- Other diabetes complications:
 - Visual impairment
 - End-stage renal failure (on dialysis or post-transplant)
- Social factors, living alone, smoking

Clinical examination

- Skin temperature, insensate, unilateral warm foot with intact skin
- Evidence of a Charcot foot
- Anhidrosis (reduced sweating), fissure (cracks)
- Soft tissue loss (ulceration)
- Bacterial/fungal infections
- Alteration in shape, prominent metatarsal heads
- Footwear suitability

Peripheral arterial disease

Although peripheral arterial disease is described in detail in Chapter 52, brief mention of its role in the genesis of foot ulcers is necessary here. Peripheral arterial disease tends to occur at a younger age in people with diabetes and is more likely to involve distal vessels. Peripheral arterial disease is a major contributory factor in the pathogenesis of foot ulceration and subsequent major amputations. Peripheral arterial disease in isolation rarely causes ulceration; it is the combination of risk factors with minor trauma that ultimately leads to ulceration (Figure 53.3). Thus, minor injury and subsequent infection increase the demand for blood supply beyond the circulatory capacity and ischaemic ulceration and the risk of amputation ensue. In recent years, neuroischaemic ulcers in which the combination of neuropathy and peripheral arterial disease exists in the same individual, together with some form of trauma, are becoming increasingly common in diabetes foot clinics.

The main risk factors for peripheral arterial disease in diabetes are hyperlipidaemia, hypertension, history of cardiovascular disease, and cerebrovascular disease. A smoking history and being male are also significant influences [17]. Clinical manifestation of peripheral arterial disease is commonly through symptoms of intermittent claudication, but it can progress to tissue necrosis and gangrene in the latter stages (Figure 53.4) [17].

The term *chronic limb-threatening ischaemia* has been recommended by the Global Vascular Guidelines to encompass the broad spectrum of arterial disease presentations and the relative risk of amputation [18]. *Critical limb ischaemia* is reserved for the most severe form and defined as the presence of peripheral arterial disease in combination with rest pain, gangrene, or lower-limb ulceration >2 weeks' duration [19].

Bedside screening tools for peripheral arterial disease

Screening for vascular disease can be difficult in individuals with diabetes, as many are asymptomatic or report atypical symptoms. During the screening process it is important to establish whether there is any ischaemic rest pain at night, intermittent claudication, and history of vascular procedures such as bypass or angioplasty [19].

Palpation of the posterior tibial and dorsalis pedis pulses to determine their relative presence or absence can be influenced by practitioner skill and/or room temperature and should therefore be interpreted with caution. A Doppler ultrasound probe can assess flow signal waveforms, but vessel wall calcification can give a falsely elevated reading on an ankle brachial pressure index [19].

Individuals being considered for imaging modalities requiring the use of contrast must be identified as safe for contrast use in the context of renal disease [13].

Long-term risk factors for foot ulceration

Previous foot ulceration and/or amputation are the most important risk factors for developing a foot ulcer. In some series, the annual recurrence rate is up to 50% and, although there are a plethora of influencing factors, psychosocial and behavioural components are increasingly recognized. Studies of behaviour and attitudes of

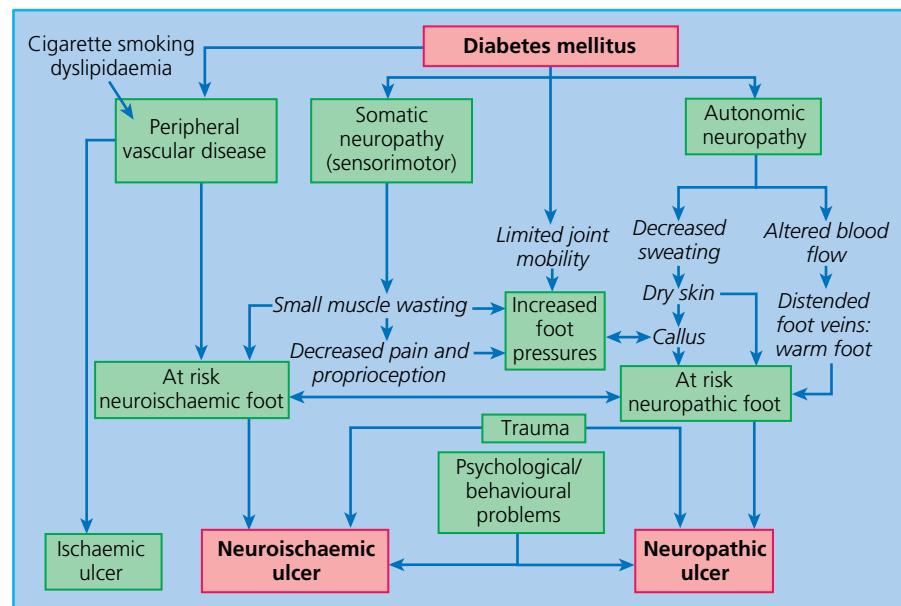

Figure 53.3 Pathways to foot ulceration in diabetes.

Figure 53.4 Infected diabetes-related foot lesion, necrotic 2nd digit, surrounding erythema and purulent discharge suggesting infection.

people with diabetes-related foot ulcerations have identified that individual perception of risk does not necessarily concur with clinician assessment and that behaviour is driven by the individual's own perception [20].

Renal disease, even at the preliminary stage of microalbuminuria, is a strong predictor of foot ulceration. Individuals most at risk include those with end-stage renal disease receiving dialysis or renal transplant/combined pancreas–renal transplants. The latter group are often described as being *non-diabetic* postoperatively and their newly increased energy levels are often accompanied by an increase in activity levels. However, the sensorimotor and autonomic peripheral nerves remain in their *diabetic* state; that is, neuropathic [13].

The risk of ulceration and amputation can increase two- to four-fold with age, and the relationship between duration and prevalence is equal for type 1 diabetes and type 2 diabetes. Men have a 1.6-fold increased risk of ulceration and amputation compared to women. Foot ulcers are more common in white Europeans than in people from other ethnic backgrounds [13].

Pathway to ulceration

Psychosocial factors together with abnormalities in pressures and loads under the foot are contributory factors to foot ulceration [21]. Peripheral and autonomic neuropathies represent the commonest long-term complications of diabetes and as such are the key components in the pathogenesis of diabetic foot ulceration [22].

Plantar callus

Callus accumulates under weight-bearing surfaces where skin is dry due to autonomic neuropathy. Exposure to repetitive stresses from focal high-pressure areas in the foot increases callus formation [22]. It acts as a foreign body and may cause ulceration.

Elevated foot pressures

A plethora of studies have confirmed the role of abnormal plantar pressures in the formation of diabetes-related foot ulcers. Studies have employed a variety of techniques, such as pedobarography and

other expensive imaging modalities to obtain data, but in clinical practice they are not required (Figure 53.5) [23].

Foot deformities

Foot deformities contribute to ulceration through increased pressures and may include motor neuropathy, cheiroarthropathy, increased small muscle wasting (intrinsic minus), prominent metatarsal heads, and clawing of the toes, which are said to result in the high-risk neuropathic foot (Figure 53.2) [13].

Prevention of diabetes-related foot ulcers

Research of diabetes-related foot ulceration has primarily focused on interventions to promote healing [24] and this is mirrored in clinical practice. Prevention of foot ulceration is poorly studied and within health systems underfunded. A paradigm shift from stratified healthcare towards personalized medicine for diabetes-related foot disease is required [24]. Focusing on prevention of foot ulceration should be at the forefront of foot care to achieve better outcomes for individuals with diabetes and reduce the immense burden on global healthcare systems. Modifiable risk factors should focus on all aspects of evidence-based offloading devices, barefoot and in-shoe pressure factors, as well as tissue stress patterns [25]. Such strategies can be delivered in an integrated, objective, quantitative, and evidence-based approach [25].

The International Working Group on the Diabetic Foot has identified five important elements in the prevention of foot ulcers:

- Identifying the at-risk foot.
- Regularly inspecting and examining the at-risk foot.
- Educating the person with diabetes, their family, and healthcare professionals.
- Ensuring routine wearing of appropriate footwear.
- Treating risk factors for ulceration [25].

Foot care education is crucial in the prevention of ulceration, although there is little evidence available to support this in terms of randomized controlled trials [25]. Nevertheless, clinicians have a responsibility to comprehensively evaluate and educate individuals with diabetes, empowering them to engage in self-care and active

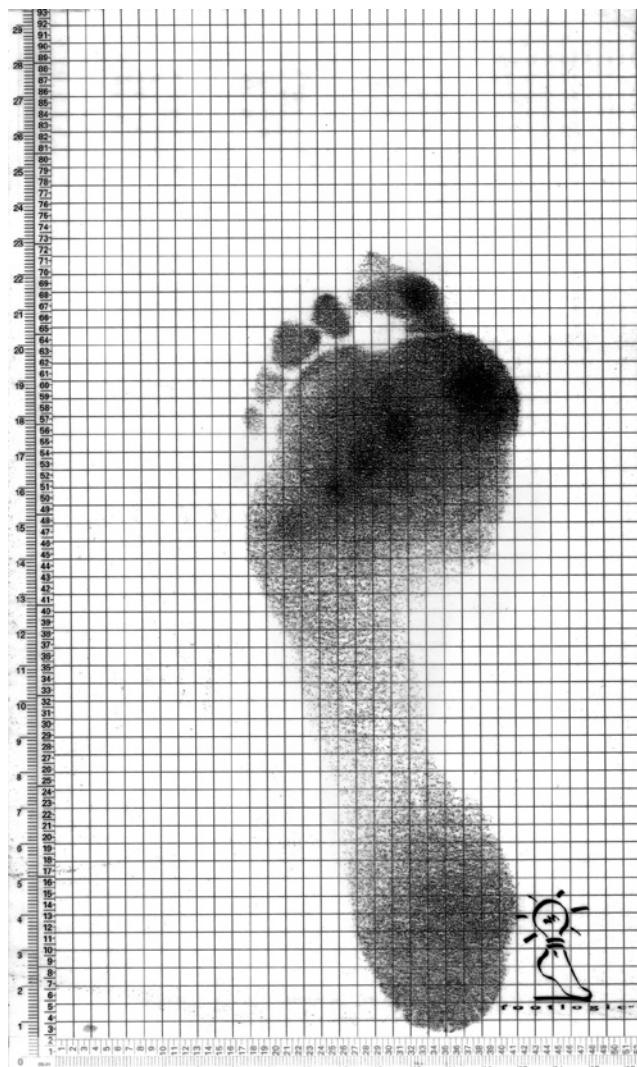

Figure 53.5 A black-and-white pressure distribution of one footprint using PressureStat: the darkest areas represent highest pressures, in this case under metatarsal heads 1 and 3 and the hallux.

prevention of foot ulceration [14]. A structured diabetes education programme is an essential component of preventive care [14]. Engagement with family members and carers may also be necessary to improve and reinforce self-care in people with foot ulcers [26].

Footwear

Appropriate footwear is vital in the reduction of foot ulcer occurrence and recurrence (Figure 53.6) [25]. Randomized controlled trials support the use of specialist hosiery with the potential to reduce foot pressures and provide protection for the high-risk neuropathic foot [25]. Mobilizing the bare foot is an absolute contraindication even while standing or sitting and should be reinforced at all times [25].

Skin temperature

Monitoring of skin temperature combined with preventive action when a temperature threshold is breached has been reported as effective in preventing diabetes-related foot ulcers [27]. However, the reliability of home thermometers in detecting temperature

Figure 53.6 Inappropriate footwear high heel wedge increasing forefoot plantar pressures.

changes is questionable. It is also difficult to determine whether the positive effect originated with the temperature or visualization of the foot while obtaining the temperature [27].

Foot ulcer classification

SINBAD (Site, Ischaemia, Neuropathy, Bacterial infection, And Depth) is the most commonly used evidence-based international classification system for diabetes-related foot ulceration and is advocated by the International Working Group on the Diabetic Foot [28]. SINBAD is recognized by health professionals as a *common language* used in communicating information about diabetes-related foot ulcers [28].

In 2014 the Society for Vascular Surgery published the Wound Ischaemia and Infection (WIFI) classification system for the clinical staging of chronic limb-threatening ischaemia, to review amputation risk and need for revascularization (Figure 53.7) [29]. The WIFI classification is especially useful in predicting the possibility of amputation for one year and has benefits to assist with the management of individuals who have presented with a foot ulcer [30].

Wound healing in the diabetic foot

The management and healing of diabetes-related foot ulcer are a global challenge [13]. Adverse outcomes are common, including delay and failure to heal, infection, sepsis, amputation, and the high risk of recurrence [13]. Biological elements such as loss of protective sensation, abnormal biomechanics, peripheral arterial disease, and persistent infection create a difficult environment for a diabetes-related foot ulcer to heal successfully [13].

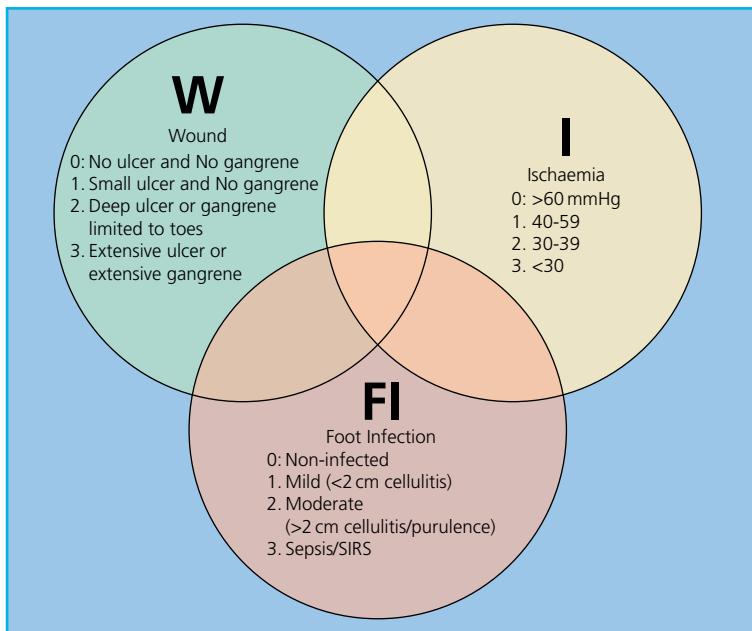

Figure 53.7 The Wound Ischaemia and Infection (WIFI) classification system for the clinical staging of chronic limb threatening ischaemia. The three circles represent Wound, Ischaemia and Foot Infection.

Impaired wound healing occurs due to low cellular proliferation rates, irregular keratinocyte differentiation, and slow angiogenesis [31]. People with end-stage renal disease and moderate to severe comorbidities relating to diabetes are at higher risk of non-healing ulcers and lower-limb amputation [32].

A vital component of wound management is removal of slough, necrotic tissue, and surrounding callus utilizing sharp debridement, subject to contraindications such as increased pain or severe ischaemia [33]. Products available for wound protection can be divided into broad categories of those with debriding properties, antiseptic-based dressings, those that are moisture providing, and those that influence the healing process [33].

Offloading

Decades of extensive evidence have cemented offloading as a highly effective intervention for healing diabetes-related foot ulcers. A total contact cast was considered the gold standard treatment for plantar foot ulcers; however, prefabricated, removable, knee-high walkers can be modified to non-removable and are as effective as the total contact cast [34]. There are several different offloading devices that are defined as an *ankle-high offloading device*, such as an ankle-high walker, forefoot offloading shoe, cast shoe, healing sandal, postoperative healing shoe, and custom-made temporary shoe [34]. Further research is required for the use of ankle-high offloading due to the alteration in mechanical stress [34]. Mechanical stress levels leading to different healing outcomes, such as plantar pressure, shear stress, and weight-bearing activity, need to be a focus for future research and randomized controlled trials. There are limited data relating to offloading in the healing of plantar ulcers in complicated infection or ischaemia, heel ulcers, and non-plantar ulcers [34].

Although effective offloading is vital in the successful healing of diabetes-related foot ulcer, total contact casting is contraindicated for ischaemic ulcers and osteomyelitis due to the risk of additional complications associated with poor arterial inflow. Total contact casts by their nature prevent wound monitoring, thereby preventing the early detection of iatrogenic pressure wounds [34]. The removal of pressure, eradication of infection, appropriate wound

management, and restoration of perfusion are key factors necessary for successful wound closure [13].

Dressings

Dressings are used to keep the surface of diabetes-related foot ulcers protected from trauma and infection and to ensure the wound surface has the correct level of moisture required for the stage of healing [35]. Appropriate dressings enhance healing of diabetes-related foot ulcers. There is a wide variety of dressings available, necessitating careful consideration of the wound's current stage in the healing process and its specific characteristics prior to selection [35] (Table 53.1).

Management of infection

Appropriate wound debridement and offloading together with antibiotics are vital in the management of infected foot ulcers. There is no evidence to suggest that clinically non-infected neuropathic ulcers warrant treatment with oral antibiotics; however, some evidence suggests a benefit from antibiotics in treating neuroischaemic ulcers. Caution and clinical vigilance should prevail when treating infected diabetes-related foot ulcers with antibiotics [36]. A recent large-scale randomized clinical trial, the Oral Vs IntraVenous Antibiotics study (OVIVA), demonstrated that people randomized to oral versus intravenous antibiotics showed no superiority with either delivery modality [36].

The severity of infection of diabetes-related foot ulcers is related to location, depth (fascia, muscles, tendons, joints or bone), presence of necrosis, and/or gangrene [13]. If foot infections are not managed promptly, serious complications can result in lower-extremity amputations [13]. On presentation 60% of diabetes-related foot ulcers are already infected [13]. Pathogens such as Gram-positive *Staphylococcus aureus*, *pseudomonas*, and *Enterobacteriaceae* species easily enter the wound and to a lesser extent *streptococcus* Gram-negative species can thrive [13]. Anaerobic infection must also be considered in neuroischaemic ulcers [13].

Delayed healing can occur due to the complex microbiome and polymicrobial organization on the surface of the wound.

Table 53.1 Dressings that can be used to treat diabetes-related foot ulcers.

Dressing	Description	Contraindications
Hydrocolloid	Facilitates rehydration and autolytic debridement Dry, sloughy, necrotic wounds Promotes granulation.	Infected wounds Twice-weekly change
Hydrogels	Donates liquid to dry wounds and absorbs exudates Dry, sloughy wounds Autolytic debridement	Hydrogel sheets avoided in infected wounds
Silver	Antimicrobial Colonization	Sensitivity to silver
Vapour-permeable	Provides a moist healing environment Mild exudates	Heavily exuding wound
Foam dressing	Primary or secondary cover Light and heavy exudates	Remove if strike-through occurs
Odour-absorbent	Absorbs odour Malodorous	Silver (sensitivity)
Larval therapy	Debridement, promotes granulation Heavily sloughy necrotic wounds	Increase in pain
Alginate	Haemostat Heavy exudates	Blockage Loose fibres
Skin substitutes	Living skin Obstinate wounds	Colonized Infected wound
Iodine	Antibacterial Exudating wounds	Iodine (sensitivity) Renal/thyroid conditions
Honey	Antimicrobial Sloughy necrotic wounds Autolytic debridement	Medical grade only

Multidrug-resistant Gram-negative strains of bacteria such as highly resistant *pseudomonas*, extended-spectrum β -lactamase, and carbapenemase-producing Gram-negative bacilli are commonly found in cultures of diabetes-related foot ulcers [37].

Inflammatory response to pathogens can be reduced or absent in individuals with neuropathy and ischaemia, with ~50% of presenting foot ulcers being asymptomatic for infection [13]. Pain, warmth, erythema, raised C-reactive protein, tenderness, prolonged healing, and wound malodour are indicators of infection. Poor granulation tissue and increased purulent discharge often occur with chronic hyperglycaemia [13].

To implement a specific and effective antibiotic regimen, tissue samples or deep wound swabs should be taken for culture and sensitivity, as superficial cultures are very often contaminated by colonizing bacteria [13]. It is most effective to swab foot ulcers following curettage and aggressive debridement if appropriate [13].

Empirical antibiotic therapy against *Staphylococcus aureus* and aerobic streptococci should be started until conclusive culture results are obtained. Antibiotic agents are appropriate against Gram-negative organisms for suspected severe infection. There is limited evidence for the use of topical antimicrobial treatments. For soft tissue infections, the following agents should be considered: penicillins, cephalosporins, carbapenems, metronidazole, clindamycin, linezolid, daptomycin, fluoroquinolones, or vancomycin, but not tigecycline [38].

Intravenous antibiotic administration is only indicated in severe infections (bacteraemia), as most mild to moderate infections will respond to oral antibiotics with a high bioavailability. Antibiotic treatment alone is insufficient for managing diabetes-related foot ulcers and additional interventions are also necessary, including sharp debridement, drainage of purulent discharge, and appropriate offloading [38].

Wounds with extensive bone and soft tissue involvement require deep and aggressive debridement to remove non-viable tissue and provide drainage of purulent discharge [38]. Complete surgical excision can significantly reduce the number of days taken to heal compared with ulcers managed more conservatively [38].

Osteomyelitis

Osteomyelitis frequently affects the forefoot, with over 90% of infections occurring at this site, 5% in the midfoot, and 5% in the hindfoot; however, osteomyelitis can occur in any bone. Forefoot osteomyelitis has a better prognosis than midfoot or hindfoot osteomyelitis [13]. Early and accurate diagnosis is vital to ensure treatment with a suitable antibiotic agent and reduce the risk of minor and major amputation [13].

A useful clinical sign suggesting osteomyelitis in a digit is a sausage-shaped swelling. The probe-to-bone test is a useful tool in the evaluation of osteomyelitis. The procedure involves inserting a blunt probe into the soft tissue deficit. A hard endpoint (solid or gritty) indicates a positive finding. The anatomical location and the performer's expertise may affect reliability. A positive probe-to-bone test finding in a high-risk individual indicates a high probability of osteomyelitis. A negative probe-to-bone test result in a low-risk person indicates a low probability of osteomyelitis [13].

The gold standard for the diagnosis of osteomyelitis is bone biopsy, which provides histological and microbiological findings [13]. A combination of the probe-to-bone test, C-reactive protein and/or procalcitonin levels, erythrocyte sedimentation rate (ESR), and plain X-rays should be carried out in suspected osteomyelitis (Figure 53.8) [34]. If a diagnosis cannot be reached, advanced imaging studies such as magnetic resonance imaging scan, 18F-fluorodeoxyglucose positron emission tomography/computed tomography (CT), or leucocyte scintigraphy (with or without CT) may be required [39]. Clinically relevant bone microorganisms should be sent to histopathology for culture and sensitivity as early as possible [13].

Antibiotic therapy should be based on the likely or proven causative pathogen(s) and their susceptibilities; the clinical severity of the infection; published evidence of efficacy of the agent for diabetic foot infections; risk of adverse events, including collateral damage to the commensal flora; likelihood of drug interactions; and agent availability [38]. Individuals with osteomyelitis have a higher rate of recurrence after initial treatment and a longer time to healing compared to soft tissue infections [38].

Surgical resection of the infected portion of bone once all conservative options have failed has been the mainstay for treating osteomyelitis, but increasing evidence from case series and a randomized controlled trial reports that osteomyelitis localized to one or two phalanges may be successfully treated with antibiotics alone. There is no evidence base to advise the optimal duration of antibiotic therapy for osteomyelitis, but a recent trial suggests that six weeks' antibiotic therapy may be sufficient [13]. Osteomyelitis in the diabetic foot is often due to long-standing non-healing ulcers and has an associated high risk of minor and major amputation [13].

Figure 53.8 This radiograph displays two main abnormalities: changes of osteomyelitis and septic arthritis involving the first metatarso-phalangeal joint, with destruction of the distal first metatarsal and proximal area of the proximal phalanx of the great toe; and chronic changes of Charcot neuroarthropathy in the first cuneiform/metatarsal area.

Negative pressure

Negative-pressure devices significantly reduce wound-closure times and improve the healing rates of foot ulcers with no increase in complications [40]. Increased perfusion and granulation tissue are the reported benefits from cell deformation [40]. A recent systematic review confirmed that there was some evidence to support the use of negative-pressure devices in surgical wounds [40].

Hyperbaric oxygen

Although hyperbaric oxygen therapy is not recommended specifically for treating diabetes foot wounds [41], initial trials of topical oxygen treatment have shown promise in treating diabetes-related foot ulcers and further studies are ongoing [42].

Surgical management

Surgical management is based on expert opinion and at best case series reports. Surgical interventions may be considered if conservative options have failed and may include Achilles' tendon lengthening, metatarsal head resection, internal/external fixation, and flexor-extensor tendon lengthening. Tissue fillers can also be used for loss of fatty pad; however, evidence is limited and surgical intervention poses increased risks [39]. Surgery should only be considered once all non-surgical options have been explored, as 75% of wounds will heal without any form of surgical intervention [39].

Charcot neuroarthropathy

Charcot neuroarthropathy is a devastating complication of diabetic neuropathy, which can result in extensive bone and joint destruction, increased risk of ulceration, infection, and amputation if not properly managed (Figure 53.9) [43]. Active Charcot neuroarthropathy characteristically presents with localized swelling, erythema, and increased temperature ($>2^{\circ}\text{C}$ compared to the contralateral foot) to the affected foot. In individuals with peripheral neuropathy, pain may not always be present and is only reported in 50% of individuals with diabetes [43]. Therefore individuals presenting with the characteristic symptoms in the context of a history of peripheral neuropathy and/or renal failure should be considered to have Charcot neuroarthropathy until proven otherwise. Advanced presentations of Charcot neuroarthropathy may be characterized by a foot deformity, particularly a *rocker-bottom* deformity.

Management

Immobilization until complete resolution of the active phase is required. Total contact casting or removable walkers are suitable; however, if total contact cast is used, it must be replaced every 1–2 weeks to adjust for limb volume changes from oedema reduction and to assess for any complications secondary to immobilization [34]. Bilateral Charcot neuroarthropathy is reported in 30% of cases [34]; it is thought that immobilization of one foot may increase the load on the contralateral foot, predisposing to bilateral active Charcot neuroarthropathy. Therefore prophylactic support with appropriate footwear and insoles is recommended for the contralateral foot to minimize the risk of bilateral active Charcot neuroarthropathy [34].

Periodic follow-up radiographs are required to monitor the progression of Charcot neuroarthropathy and changes in the architectural alignment of the foot [34]. Three-monthly reviews are required for such high-risk individuals to monitor the development of recurrent or new episodes, along with other foot complications [43]. If the correct diagnosis is made in the active phase of Charcot neuroarthropathy and conservative treatment is successful, surgery may be avoided [43] and the risk of ulceration and amputation reduced. Surgical management is considered in the inactive phase of Charcot neuroarthropathy where joint instability has failed. Surgical intervention is generally avoided during the active phase of Charcot neuroarthropathy due to a high risk of secondary infection [43].

Figure 53.9 X-ray of chronic Charcot foot demonstrating neuroarthropathic changes in the midfoot with peri-talar destruction.

Conclusion

Peripheral neuropathy plays a central role in the development of foot lesions through the loss of protective sensation, as the absence of pain renders the foot highly vulnerable to trauma without

awareness. The International Working Group on the Diabetic Foot reported on the details required in the planning and reporting of intervention studies in the prevention and management of foot diabetic disease. Guidelines for the prevention and treatment of diabetes-related foot disease are invaluable in creating the standards of care necessary to achieve a reduction in amputations.

Sexual Function in Men and Women with Diabetes

Kirsty Winkley¹, Camilla Kristensen¹, Jackie Fosbury², and David Price³

¹ King's College London, London, UK

² Sussex Community NHS Foundation Trust, Brighton, UK

³ Morriston Hospital, Swansea, UK

Key points

- The prevalence of erectile dysfunction in men with diabetes increases with age and is about 35–50% overall.
- Penile erection occurs as a result of engorgement of the erectile tissue following vascular smooth muscle relaxation in the corpus cavernosum mediated by nitric oxide (NO), which is derived from both parasympathetic nerve terminals and the vascular endothelium.
- Erectile dysfunction in diabetes is largely due to failure of NO-mediated smooth-muscle relaxation secondary to endothelial dysfunction and autonomic neuropathy.
- Erectile dysfunction is an early indicator of endothelial dysfunction and a marker of increased cardiovascular risk.
- Sildenafil and other phosphodiesterase 5 (PDE5) inhibitors act by inhibiting the breakdown of cyclic guanosine monophosphate, the second messenger in the NO pathway, and hence enhance erections under conditions of sexual stimulation.
- PDE5 inhibitors are safe and effective and can be used to treat erectile dysfunction in a diabetes clinic or general practice.
- Other options for treating erectile dysfunction in diabetes are intracavernosal injection therapy, transurethral alprostadil, vacuum therapy, and surgical insertion of penile prostheses.
- In women with diabetes, sexual dysfunction is twice as common than in women without diabetes and women may not be aware diabetes is a cause.
- Sexual dysfunction is associated with high and low blood glucose levels, depression, and body image issues in women with diabetes.
- There are no licensed pharmacological treatments for women with diabetes and sexual dysfunction, although PDE5 inhibitors may have some benefit. There have been no published studies on psychological interventions for women with diabetes and sexual dysfunction.
- Contraceptive advice is essential in diabetes, as unplanned pregnancies carry an increased risk of morbidity and fetal abnormalities. Most forms of contraception are safe and effective in women with diabetes, but the oral contraceptive pill is recommended, as it is reliable and well tolerated.
- Hormone replacement therapy should be considered on a short-term basis in all women with an appropriate indication, particularly if they have diabetes. It has no adverse effects on glycaemic levels or lipid profiles.

Male erectile dysfunction

Erectile dysfunction is one of the commonest clinically apparent complications in men with diabetes. It can cause distress, but is usually treatable. It may also be a marker of cardiovascular risk, and so it is a condition that all diabetes professionals should be aware of and understand.

Physiology of erectile function

Tumescence is a vascular process under the control of the autonomic nervous system. The erectile tissue of the corpus cavernosum behaves as a sponge, and erection occurs when it becomes engorged with blood. Dilatation of the arterioles and vasculation of the corpus cavernosum leads to compression of the outflow venules against the rigid tunica albuginea (Figure 54.1) [1, 2]. Hence smooth-muscle relaxation is the key phenomenon in this

process, as it leads to increased arterial inflow and reduced venous outflow [3, 4]. The process is under the control of parasympathetic fibres, which were previously known as non-adrenergic, non-cholinergic neurones, as the neurotransmitter was unknown; however, it is now clear that nitric oxide (NO) is the agent largely responsible for smooth-muscle relaxation in the corpus cavernosum. It is both produced in the parasympathetic nerve terminals and generated by NO synthase in the vascular endothelium. Within the smooth-muscle cell of the corpus cavernosum, NO stimulates guanylate cyclase, leading to increased production of the second messenger, cyclic guanosine monophosphate (cGMP), which induces the activation of protein kinase G. This inhibits calcium release, which leads to smooth-muscle relaxation (Figure 54.2) [5, 6]. Neuronally derived NO is important in initiation, whereas NO from the endothelium is responsible for maintenance of erection [7].

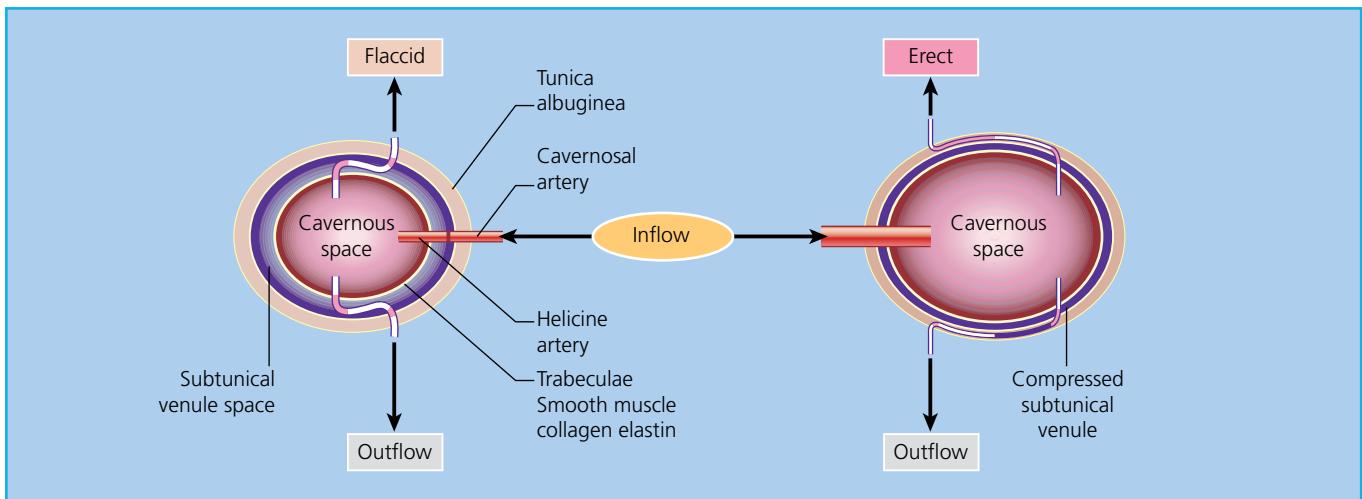

Figure 54.1 Diagrammatic representation of the corpus cavernosum. During tumescence, dilatation of the helicine and cavernosal arteries produces expansion of the cavernous space and compression of the outflow venules against the rigid tunica albuginea.

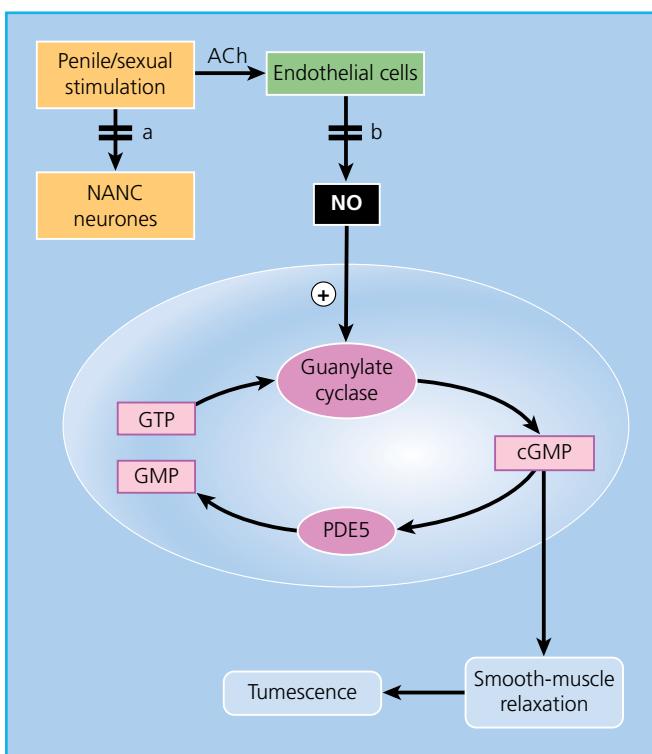

Figure 54.2 Pathophysiology of erectile function in diabetes. Diagrammatic representation of the pathways leading to the relaxation of a corpus cavernosal smooth-muscle cell. In diabetes there are defects in nitric oxide-mediated smooth-muscle relaxation due to neuropathy of (a) the NANC fibres and (b) endothelial dysfunction. ACh, acetylcholine; cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate; GMP, guanosine monophosphate; NANC, non-adrenergic, non-cholinergic neurones; NO, nitric oxide; PDE5, phosphodiesterase type 5.

Pathophysiology of erectile dysfunction in diabetes

In men with diabetes, erectile dysfunction is due to failure of NO-induced smooth-muscle relaxation from both autonomic neuropathy and endothelial dysfunction [8]. Many men with diabetes report that in the early stages they do not have a problem achieving an erection but that they cannot maintain it. This suggests that in

these individuals failure of endothelium-derived NO occurs before significant autonomic neuropathy.

Other potential abnormalities may contribute to the development of erectile dysfunction in diabetes: endothelium-derived hyperpolarizing factor (EDHF) plays a role in endothelium-dependent relaxation of human penile arteries [9] and EDHF-mediated endothelium-dependent relaxation is significantly impaired in penile resistance arteries in men with diabetes [9]. Impaired EDHF responses might therefore contribute to the endothelial dysfunction of diabetic erectile tissue.

Increased oxygen free-radical levels in diabetes may reduce the vasodilator effect of NO. In particular, the formation of products of non-enzymatic glycation to produce advanced glycation end-products (AGEs) generates reactive oxygen species, which impairs NO bioactivity [10, 11]. AGEs play a role in the development of microvascular and macrovascular disease in diabetes [12]. In animal models, inhibition of AGE formation improves endothelium-dependent relaxation and restores erectile function in diabetic rats [13, 14].

Other pathophysiological changes known to occur in diabetes may contribute to erectile dysfunction, including non-enzymatic glycation of proteins, which impairs endothelium-dependent relaxation of the aorta in rats [15, 16]. Other factors, not limited to diabetes, may also contribute to the development of erectile dysfunction in men with diabetes. Structural changes associated with large-vessel disease are commonly associated with erectile dysfunction in diabetes. However, this is usually associated with functional changes of widespread endothelial dysfunction in diabetes, and it is difficult to separate the relative importance of the two factors.

Testosterone has a central role in the physiology of erectile function and in the regulation of male sexual behaviour and attitudes. Hypogonadism is a well-established, and treatable, cause of erectile dysfunction. In experimental studies, androgen deficiency leads to a reduction in smooth-muscle and structural abnormalities in the erectile tissue [17, 18]. In recent years, there has been interest in a potential association between reduced levels of testosterone and type 2 diabetes and the metabolic syndrome. However, it is controversial whether there is a causal link between diabetes and hypogonadism, and this will be discussed later in this chapter.

Other factors contributing to erectile dysfunction in diabetes
In addition to endothelial dysfunction and autonomic neuropathy, erectile dysfunction is associated with other conditions common in diabetes, such as hypertension and large-vessel disease [19]. A cross-sectional study of 550 Chinese men reported that in the 318 men with diabetes and erectile dysfunction the prevalence of diabetes complications – that is, cardiovascular disease, neuropathy, and nephropathy – was 1.7 times greater than for men with diabetes and no erectile dysfunction [20]. Furthermore, men with diabetes are more likely to be taking medications that can impair erectile function (Box 54.1). Antihypertensive agents are commonly reported to be associated with erectile dysfunction, although much of the evidence is anecdotal; β -blockers, aldosterone receptor blockers, and thiazide diuretics are the most commonly reported culprits [21]; the α -blockers perhaps have the least risk [22]. Finally, it should be remembered that there are many other potential causes of erectile dysfunction unrelated to diabetes, from which men with diabetes are not immune (Box 54.2).

Box 54.1 Medications associated with erectile dysfunction

Antihypertensives

- Thiazide diuretics
- β -blockers
- Calcium channel blockers
- Angiotensin-converting enzyme (ACE) inhibitors
- Central sympatholytics (methyldopa, clonidine)
- Aldosterone receptor antagonists

Antidepressants

- Tricyclics
- Monoamine oxidase inhibitors
- (NB: Selective serotonin reuptake inhibitors can cause ejaculatory problems)

Antipsychotics

- Phenothiazines
- Haloperidol

Hormones

- Luteinizing hormone-releasing hormone (goserelin, buserelin)
- Oestrogens (stilbestrol)
- Antiandrogens (cyproterone)

Miscellaneous

- 5 α -Reductase inhibitors (finasteride)
- Statins (simvastatin, atorvastatin, pravastatin)
- Cimetidine
- Digoxin
- Metoclopramide

Drugs of abuse

- Alcohol
- Tobacco
- Marijuana
- Amphetamines
- Anabolic steroids
- Barbiturates
- Opiates

Box 54.2 Conditions associated with erectile dysfunction

Psychological disorders

- Anxiety about sexual performance
- Psychological trauma or abuse
- Misconceptions
- Sexual problems in the partner
- Depression
- Psychoses

Vascular disorders

- Peripheral vascular disease

Hypertension

- Venous leak
- Pelvic trauma

Neurological disorders

- Stroke
- Multiple sclerosis
- Spinal and pelvic trauma
- Peripheral neuropathies

Endocrine and metabolic disorders

- Diabetes
- Hypogonadism
- Hyperprolactinaemia
- Hypopituitarism
- Thyroid dysfunction
- Hyperlipidaemia
- Renal disease
- Liver disease

Miscellaneous

- Surgery and trauma
- Smoking
- Drug and alcohol abuse
- Structural abnormalities of the penis

Clinical aspects of erectile dysfunction in diabetes

Erectile dysfunction becomes more prevalent with age. In a population-based study in Massachusetts, USA, the prevalence of complete erectile failure was reported to be 5% in men in their 40s and 15% in those over 70 years of age [19]. In younger sexually active men aged 18–31 years ($n = 2660$) in the Growing Up Today study, mild erectile dysfunction was present in 11.3% and moderate to severe in 2.9% [23]. By contrast, a systematic review and meta-analysis of 145 studies including 88 577 men with diabetes demonstrated a much higher prevalence of 52.5% overall (95% confidence interval [CI] 48.8 to 56.2), 37.5% for men with type 1 diabetes, and 66.3% for men with type 2 diabetes [24]. The prevalence in men with diabetes also increases with age. In a survey of men attending a hospital diabetes clinic in the UK, the prevalence of erectile dysfunction increased from 13% among 30-year-olds to 61% among men aged over 60 years [25] (Figure 54.3). Overall the prevalence was 38%. The prevalence of erectile dysfunction in diabetes in a general practice population was even higher, at 55% [19]. These data suggest that erectile dysfunction is the commonest clinically apparent complication of diabetes in men.

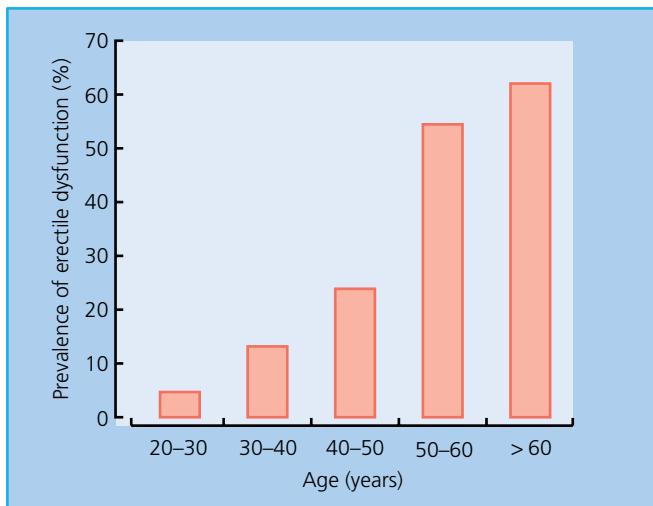

Figure 54.3 Prevalence of erectile dysfunction by age of men attending a hospital diabetes clinic. Source: Data from Price et al. 1991 [25].

Conversely, diabetes is a common finding in men presenting with erectile dysfunction. Approximately 20% of men seen in erectile dysfunction clinics have diabetes, of whom ~5% were previously diagnosed [26, 27].

The presence of other medical conditions increases the risk of erectile dysfunction. A population-based survey of 600 men in Brazil, Italy, Japan, and Malaysia examined the prevalence of erectile dysfunction and its relationship to other diseases and lifestyles. The prevalence of erectile dysfunction among men with diabetes rose from 25% at age 40–44 to 70% at age 65–70 years [28]. Cardiovascular disease increased the risk of erectile dysfunction. The prevalence was 31.7% in men with diabetes only, 40% in men with diabetes and heart disease, and 46.5% in those with diabetes and hypertension. Men with diabetes who smoked and reported below-average levels of physical activity had a fourfold increase in the prevalence of erectile dysfunction.

Erectile dysfunction as a risk factor for cardiovascular disease

There is convincing evidence of an association between erectile dysfunction and both cardiovascular disease [29, 30] and mortality [31]. This may be because they share common risk factors. Increased waist measurement and reduced physical activity, both important risk factors for ischaemic heart disease, considerably increase the risk of erectile dysfunction [32–34].

The association between erectile dysfunction and cardiovascular disease may be due to more than shared risk factors and may arise because they are both manifestations of endothelial dysfunction, which has a key role in the pathogenesis and progression of atherosclerosis [35]. It is clear that the endothelium has important and complex endocrine and paracrine functions, and one of its most important products is NO (previously known as endothelium-derived relaxing factor). NO derived from both nerve terminals and the vascular endothelium has a central role in the physiology of erection. Therefore, there are theoretical grounds to believe that erectile dysfunction might be an early marker of endothelial dysfunction and hence an important risk factor for cardiovascular disease, and there is evidence to support this case in animal studies [36] and humans [37, 38].

Hence the association between erectile dysfunction and increased cardiovascular risk may be a case of shared *common soil*, in particular endothelial dysfunction and microvascular disease. In practical terms, this means that cardiovascular risk should be assessed in any man with erectile dysfunction whether he has diabetes or not. A man with type 2 diabetes and erectile dysfunction has approximately double the risk of developing coronary heart disease compared with a similar man without erectile dysfunction [29].

Smoking and alcohol consumption

Smoking greatly increases the risk of developing erectile dysfunction. A follow-up of the Massachusetts Male Aging Study reported that cigarette smoking almost doubled the risk of developing erectile dysfunction after about seven years [19]. A similar finding was reported by the large Health Professionals' Follow-up Study [32]. Smoking appears to exert its effects via the NO signal transduction pathway [39].

In contrast to tobacco, it is well-established that moderate alcohol consumption is associated with a reduced risk of a cardiovascular event. It is interesting that drinking alcohol in moderation also appears to reduce the risk of developing erectile dysfunction [40], whereas men with alcohol dependence are more likely to experience it [41].

Quality-of-life issues

That erectile dysfunction can significantly worsen a man's quality of life is beyond doubt and treating erectile dysfunction improves quality of life. A large study of men with type 2 diabetes reported that erectile problems were associated with a dramatic increase in depressive symptoms [42]. In another series in general practice, 45% of men with diabetes stated that they thought about their erectile dysfunction all or most of the time, 23% felt that it severely affected their quality of life, and 10% felt that it severely affected their relationship with their partner [43]. More recently, a study of 100 men with diabetes, of whom 90% had type 1 diabetes, demonstrated that 66% had erectile dysfunction and almost 50% of them had not sought help [44]. The same study also reported high rates of depressive symptoms, anxiety, and relationship difficulties in those experiencing sexual issues [44]. A systematic review of randomized trials of erectile dysfunction treatment reported improvements in self-esteem, confidence, and depression scores after treatment [45].

Assessment and investigation of erectile dysfunction in diabetes

Clinical assessment

If health professionals do not start the conversation to ask about erectile dysfunction and the man raises the subject, it is likely he is anxious about the problem. However, once the subject has been broached, men with erectile dysfunction and their partners (if present) do not usually have any difficulty discussing the problem. A description of the nature of the erectile dysfunction should be obtained, to ensure that the man is experiencing erectile dysfunction and not another related problem, such as premature ejaculation (Box 54.3). General physical examination may give clues as to the aetiology of erectile dysfunction and the choice of treatment (Box 54.4). The suggested investigations of erectile dysfunction in diabetes are listed in Box 54.5. These cover psychological issues, hypogonadism, cardiovascular issues, and urological problems. Comorbid depression is common in people with diabetes [46] and

Box 54.3 Key features in the history of erectile dysfunction in diabetes

Onset usually gradual and progressive

Earliest feature often inability to sustain erection long enough for satisfactory intercourse

Erectile failure may be intermittent initially

Sudden onset often stated to indicate a psychogenic cause, but little evidence to support this

Preservation of spontaneous and early-morning erections does not necessarily indicate a psychogenic cause

Loss of libido consistent with hypogonadism but not a reliable symptom

Men with erectile dysfunction often underestimate their sex drive for a variety of reasons

Box 54.4 Key physical signs on examination

Any features of hypogonadism

Manual dexterity – may preclude physical treatment

Protuberant abdomen

External genitalia:

Presence of phimosis

Testicular volume

Peyronie's disease

Balanitis

Box 54.5 Investigation of erectile dysfunction in diabetes

Serum testosterone if libido reduced or hypogonadism suspected (ideally taken at 9 a.m.)

Serum prolactin and luteinizing hormone if serum testosterone subnormal

Assessment of cardiovascular status if clinically indicated:

ECG

Serum lipids

Glycated haemoglobin, electrolytes, if clinically indicated

Psychological screening:

Depression

Anxiety

Urological assessment if clinically indicated

the consultation provides an opportunity to address other health issues. For the reasons outlined earlier, consideration should be given to assessing the man's cardiovascular status. The consultation also provides an opportunity to address the management of the man's diabetes.

General advice

As erectile dysfunction increases with age, most men with diabetes and their partners seeking treatment for erectile dysfunction are middle-aged. Diabetes healthcare professionals can offer an effective service for the treatment of erectile dysfunction in the absence of psychosexual counsellors [49–52]. It is important that the cause of the erectile dysfunction is explained, as many men will blame themselves. They should be advised that if they wish to resume sexual relations they will require long-term treatment, as spontaneous return of erectile function in diabetes occurs only rarely [53].

Treating erectile dysfunction in an attempt to save a failing relationship is rarely successful and may make the situation worse. The assistance of a suitably qualified psychosexual counsellor should be considered in this situation. Referral to a counsellor should also be considered if there is evidence of depression, anxiety, loss of attraction between partners, or marked performance anxiety. Any other medical problems should be addressed. Improving metabolic management may help general well-being, but suboptimal glycaemic levels should not be used as a reason to refuse or delay treatment. Men who smoke should be advised to stop for reasons of general health, although there is no good evidence that stopping smoking will improve erectile function in a man with diabetes.

Many men with diabetes will be taking medication known to cause erectile dysfunction. However, changing the treatment in an attempt to improve sexual function rarely works and may cause delays and frustration for the man. It is therefore not advisable unless there is a strong temporal relationship between starting treatment and the onset of erectile dysfunction.

Treatment options

The advent of effective oral therapies has transformed the management of erectile dysfunction. These should be offered as first-line therapy to men with diabetes, and the other treatment options should be reserved for those in whom oral therapy is contraindicated or ineffective.

Oral agents

Phosphodiesterase 5 inhibitors

Phosphodiesterase type 5 (PDE5) is an enzyme found in smooth muscle, platelets, and the corpus cavernosum. During tumescence, there is an increase in the intracellular concentration of NO, which produces smooth-muscle relaxation via the second messenger cGMP. This is broken down in turn by PDE5. Hence PDE5 inhibitors can enhance erections under conditions of sexual stimulation.

Sildenafil was the first PDE5 inhibitor and is a highly effective treatment for erectile dysfunction in men with and without diabetes [54, 55]. The first large study of 532 men with erectile dysfunction of mixed aetiology was published in 1998. In the group given sildenafil, 69% of all attempts at intercourse were successful, compared with 22% in those given placebo [56]. Other studies in men with erectile dysfunction of mixed aetiology have shown success

depression is associated with onset of erectile dysfunction in men with diabetes [47]; poor self-esteem and anxiety may follow these comorbid problems, exacerbating the problem of erectile dysfunction [48]. Few investigations are needed, but it is worth excluding other treatable causes of erectile dysfunction; in practical terms, hypogonadism is the only treatable one. The relationship between diabetes and hypogonadism is a matter of debate (see later), but gonadal function should be assessed in all men with diabetes and erectile dysfunction. Some men presenting with erectile dysfunction will not have attended any form of clinic for many years, and so

rates between 65% and 77% [56,57]. Studies of sildenafil have reported success rates of ~70% in hypertension [58], 76% in spinal cord injury [59], 63% in spina bifida [60], and 40% following radical prostatectomy [61].

In men with diabetes, the success rates for sildenafil are between 56% and 59% [58,62]. A study in older men reported success rates of 69% overall and 50% in men with diabetes [63]. Most of these studies of sildenafil have been short term, but a trial examining the long-term efficacy of sildenafil in men with erectile dysfunction due to a variety of causes reported that only 52% continued to use it after two years [64]. This figure may seem surprisingly low, but it is certainly considerably higher than for any other type of erectile dysfunction treatment.

Other phosphodiesterase type 5 inhibitors

There are currently four PDE5 inhibitors licensed for treatment: sildenafil, tadalafil, vardenafil, and avanafil, with two new additional agents, mirodenafil and udenafil, that are not yet widely available. Their key characteristics are listed in Table 54.1 and adverse effects from the key trials of PDE5 inhibitors in men with diabetes are given in Table 54.2 [65–70].

All four PDE5 inhibitors have similar efficacy and safety profiles. Their side-effect profiles differ slightly, but the most notable difference is the longer half-life of tadalafil. Thus a single dose of tadalafil offers the potential to restore erectile function to normal for two days and thereby remove the need for medication to be taken each time prior to sexual activity. The choice between this form of treatment and on-demand dosing is largely a matter of individual choice. Patient preference studies of agents with differing dosing instructions are difficult to perform in a blinded fashion, but these have generally shown a preference for tadalafil over sildenafil [71–75].

Adverse effects

Adverse effects related to PDE5 inhibitors are headache, dyspepsia, and flushing. Headache and flushing might be expected, as the inhibitors are vasodilators. Dyspepsia is usually mild and may be due to relaxation of the cardiac sphincter of the stomach. Abnormal vision is experienced by ~6% of men taking sildenafil; this may be because the drug has some activity against PDE6, which is a retinal enzyme. Back pain and muscle cramps are particularly an adverse effect of tadalafil. In all studies, the discontinuation rate due to adverse effects was low.

Cardiovascular safety of phosphodiesterase type 5 inhibitors

The launch of sildenafil, the first PDE5 inhibitor, was soon followed by case reports of cardiovascular events and deaths associated with its use. However, PDE5 inhibitors are not associated with increased cardiovascular risk [76–79]. Restoring sexual function is not completely without risk, as sexual activity, like any form of physical activity, can precipitate cardiovascular events in those at risk. A large case-control study reported that the risk of a cardiovascular event in the two hours after intercourse was increased 2.5-fold in healthy men and 3-fold if there was a history of previous myocardial infarction [80]. Although the absolute risk remains small, the issue of cardiovascular safety must be addressed in all men before treating erectile dysfunction. Jackson et al. suggested a classification scheme for assessing cardiovascular risk in men undergoing treatment for erectile dysfunction; those with the highest risk should be referred for specialist cardiac evaluation, whereas the lowest-risk group could be managed in primary care [79].

Drug interactions with phosphodiesterase type 5 inhibitors

PDE5 inhibitors can be used safely in men taking a wide range of drugs, but there are several potential important interactions. They are contraindicated in the presence of any nitrate therapy (including

Table 54.1 Characteristics of available phosphodiesterase type 5 inhibitors.

Agent	Dosage (mg)	Onset of action (min)	Half-life (h)	Duration (h)
Sildenafil	25, 50, or 100 PRN	30–60	3–5	<12
Vardenafil	5, 10, or 20 PRN	30–60	4–5	<10
Tadalafil	10 or 20 PRN or 5 daily	60–120	17.5	<36
Avanafil	50, 100, or 200 PRN		3	<6

PRN, as needed.

Table 54.2 Adverse effects of phosphodiesterase type 5 inhibitors (%).

Effect	Sildenafil [62–65]	Tadalafil [56, 66, 67]	Vardenafil [68, 69]	Avanafil [70]
Headache	8.1–9.3	8.0–21	5–11	11.5
Flushing	7.4–8.1	3.0–9.0	5.4–10	4
Back pain	2.5	4.6–9.0	0	1
Dyspepsia	2.7–3.0	4.1–17	2.3	3
Nasal congestion	2.7–4.1	2.0–5	10	3

Diarrhoea	2.5	0.8		
Abnormal vision	1.4	0		1
Muscle cramps	4.1	3–7		0

The prevalence quoted for each adverse effect is for the top dose used in each study.

nicorandil), as the combination can cause profound hypotension. A man taking nitrates seeking treatment for erectile dysfunction can be offered alternatives to PDE5 inhibitors or the nitrates can be stopped or changed to an alternative therapy. Nitrates are a symptomatic treatment with no prognostic implications and so this is possible in most cases, but it should be done in consultation with a cardiologist in all but the most straightforward cases.

Nitrate therapy should not be given within 24 hours of taking sildenafil, avanafil, or vardenafil and at least 48 hours of taking tadalafil. If angina develops during or after sexual activity following the use of a PDE5 inhibitor, the man should be advised to discontinue any sexual activity and to stand up, as this reduces the work of the heart by reducing venous return.

PDE5 inhibitors should be used with caution in men who take α -blockers because the combination may lead to symptomatic hypotension in some men. The individuals should be stable on α -blocker therapy before initiating a PDE5 inhibitor at the lowest dose [77].

How to use phosphodiesterase type 5 inhibitors

These agents should be taken orally about one hour before sexual activity. This period can be shortened if the drug is taken on an empty stomach. After the one-hour period, there is a *window of opportunity* when sexual activity can take place. For sildenafil, avanafil, and vardenafil, this is at least four hours, but it may be over eight hours [77]. For tadalafil, the window of opportunity may last 48 hours. Men with diabetes usually require the maximum recommended dose and should be advised that the drug only works in conjunction with sexual stimulation.

Tadalafil can be prescribed as a daily 5 mg dose rather than on an as-required basis. Many men find this more acceptable as it obviates the need to *plan for sex*. It is effective when taken in this way [81] and may be slightly more effective than as-required tadalafil [82], but it is more expensive.

Management of non-responsiveness of phosphodiesterase type 5 inhibitors

It is difficult to predict whether a man will respond to a PDE5 inhibitor. Failure to respond is more likely in men with long-standing and severe erectile dysfunction [37,45]. However, no single factor precludes a successful outcome, and in practical terms it is worth trying a PDE5 inhibitor in all men with erectile dysfunction unless there is a contraindication. It is important that men are advised on how to take their medication properly. Intercourse success rates reach a plateau after eight attempts, so men should try at least eight times with a PDE5 inhibitor at the maximum recommended dose before being considered a non-responder [83].

Even with the maximum dose taken correctly, a large proportion of men with diabetes will not respond to PDE5 inhibitors. Treating any underlying hypogonadism may improve the outcome in this situation, but most men should be offered an alternative treatment.

Hypogonadism

The relationship between diabetes, metabolic syndrome, and hypogonadism has been the subject of considerable interest in recent years. The combination of overweight, sexual dysfunction, fatigue, and borderline low serum testosterone in a middle-aged man with type 2 diabetes is a common clinical problem. The term *late-onset male hypogonadism* has been coined to describe this condition. Pharmaceutical companies have been quick to promote research in this area as they look to widen the market for testosterone products. Reduced serum testosterone is more common in men with the metabolic syndrome and type 2 diabetes [84,85]. Conversely,

hypogonadism is associated with a near doubling of the risk of diabetes [86]. However, a causal relationship between the two has not been established and there are many confounding factors. The US Endocrine Society Clinical Practice Guidelines offer clear advice on the management of hypogonadism. It should only be treated if there are symptoms associated with hypogonadism (such as erectile dysfunction) and unequivocal biochemical evidence of hypogonadism [87,88]. There is certainly insufficient evidence to support treating hypogonadism to improve glucose tolerance or cardiovascular risk.

However, a serum testosterone should always be measured in men with diabetes and erectile dysfunction, particularly in those who do not respond to PDE5 inhibitors. Hypogonadism due to confirmed pituitary or testicular disease may be an uncommon finding in this situation, but it usually responds well to treatment with testosterone. In the more common group of men with late-onset male hypogonadism, testosterone replacement may improve erectile dysfunction as a sole treatment [89] and enhance the response to PDE5 inhibitors [90,91].

Other oral therapies

Various oral agents have been tried as treatments for erectile dysfunction in the past, including apomorphine, trazodone, yohimbine, and phentolamine. The data on all of them are limited and none has stood the test of time. They have been supplanted by the PDE5 inhibitors and probably have little role in the management of erectile dysfunction in diabetes.

Intracavernosal injection therapy

Intracavernosal self-injection using phentolamine was first described in 1983 by Brindley [92], although the French urologist Virag [93] reported the use of papaverine slightly earlier. Although papaverine was more effective than phentolamine, it was an unlicensed treatment and was superseded by alprostadil (prostaglandin E), which was licensed for the treatment of erectile dysfunction in 1996.

Alprostadil is supplied in a self-injection pen device, which is easy to use (Figure 54.4). Most studies show that self-injection therapy has a disappointingly high long-term discontinuation rate [94–96]. Self-injection treatment carries a small risk of priapism (a sustained unwanted erection). Although an infrequent complication, priapism is important, as it must be treated within six hours by aspirating blood from the corpus cavernosum. Men undertaking self-injection must be warned of this potential problem and given instructions on what to do should it occur (Box 54.6).

Figure 54.4 Alprostadil self-injection pen device.

Box 54.6 Instructions to medical staff for treating prolonged erections due to prostaglandin E₁

Do not delay treatment beyond six hours.

Using an aseptic technique, aspirate 20–25 ml of blood from the corpus cavernosum (19- or 21-gauge butterfly needle). Repeat this on the opposite side of the penis if detumescence does not occur.

If still unsuccessful, inject 0.5–1.0 ml of a 300 g/l solution of phenylephrine every 5–10 min (maximum dosage 5 ml) into the corpus cavernosum. If necessary, this may be followed by further aspiration of blood through the same needle. Extreme caution is necessary in men taking monoamine oxidase inhibitors, as a hypertensive crisis may result. Use carefully in those with coronary heart disease, uncontrolled hypertension, or cerebral ischaemia. Monitor pulse rate and blood pressure throughout.

If this is unsuccessful, refer for urgent surgical treatment, such as a shunt procedure.

Transurethral alprostadil

Many men find injection therapy unacceptable because it requires injecting the penis, and transurethral administration of the vasoactive agent appears largely to overcome this problem. The principle is simple: a slender applicator is inserted into the urethra to deposit a pellet containing alprostadil in polyethylene glycol. This gradually dissolves, allowing the prostaglandin to diffuse into the corpus cavernosum. In a placebo-controlled study of 1511 men with erectile dysfunction of mixed aetiology, 65% were able to have intercourse using this system [97]. The results in the 240 men with diabetes in the study were similar [98]. Penile pain was reported in 10.8% and hypotension in 3.3% of the men receiving alprostadil. Priapism and penile fibrosis were not reported. As with most non-oral erectile dysfunction treatments, long-term usage has been disappointing [99].

Topical alprostadil cream

Alprostadil is also available as a cream, which is applied around the urethral meatus. It contains dodecyl 2-N,N-dimethylaminopropionate, a novel penetration enhancer to allow the prostaglandin to reach the erectile tissue. Published data are limited, but it seems to be well tolerated and as effective as transurethral alprostadil [100].

Vacuum therapy

Vacuum devices became widely available in the 1970s. They comprise a translucent tube, placed over the penis, and an attached vacuum pump (Figure 54.5). Air is pumped out of the tube and the negative pressure draws blood into the erectile tissue, producing tumescence. A constriction band (which has previously been placed over the base of the tube) is slipped off to remain firmly around the base of the penis to maintain the erection, and the tube is removed. The devices require some practice and dexterity, but most couples use them satisfactorily. Trials of vacuum therapy have reported success rates of ~70% in men both with and without diabetes, suggesting that it is an effective treatment, provided that couples are prepared to use it [101–103].

Vacuum devices are safe and effective treatments, and inexpensive to use after an initial outlay (in the UK) of ~£100–250. The side effects are discomfort from the constriction band, failure to

Figure 54.5 Typical vacuum device with constriction rings.

ejaculate, and a cold penis. Many couples find the use of vacuum devices unacceptable, and since the introduction of newer treatments their use has declined. They still have a role, however, in men who do not respond or who cannot use other treatments. Vacuum devices have the advantage over other erectile dysfunction treatments that they do not need repeat prescriptions and visits to a pharmacist for continued use.

Surgery

In spite of recent advances in the management of erectile dysfunction, some men will not be able to use the available treatment options. There will therefore always be a limited role for surgery.

The surgical options available are as follows:

- Insertion of penile prostheses.
- Corrective surgery for associated Peyronie's disease or post-injection corporal fibrosis.
- Venous and arterial surgery.

Discussion of vascular and corrective surgery of the penis is best left to a specialist urology textbook, but a general practitioner or diabetes healthcare professional needs to know which men might benefit from referral for insertion of a penile prosthesis. This form of surgery is best reserved for those in whom conventional treatments have failed and who are keen to resume full sexual activity.

Counselling of the man, and whenever possible his partner, is important, particularly about the choice of prosthesis. The man's or couple's wishes are important factors in device selection, as is the cost of the prosthesis. Men must be warned regarding postoperative pain or discomfort and the potential need for reoperation. They will need to restrict physical activity and refrain from intercourse for 4–6 weeks after the operation. They should be warned about the possible complications of infection, erosion, and prosthesis failure, and that these problems usually require device removal. It is also important that the man and his partner are aware that the erection produced by a prosthesis is different from a normal erection, depending very much on the type of prosthesis chosen. It is useful to show examples of the prostheses and to describe how they are inserted and the mechanism of action.

There is uncertainty as to whether men with diabetes are at higher risk of infection than those without diabetes after insertion of a penile prosthesis, but there is a consensus that, should infection occur, it is more serious [104]. Good preoperative diabetes management is important to minimize the risk. Most published series of well-selected groups of men who have undergone penile prosthesis

insertion have reported acceptable results, with good levels of patient satisfaction [105].

Organization of the management of erectile dysfunction

Traditionally, erectile dysfunction was managed in a dedicated clinic, often run by a urologist. The advent of effective oral therapies has made the management much simpler, so that erectile dysfunction in diabetes can usually be managed by any diabetologist or general practitioner. A physician considering treating erectile dysfunction will have to decide whether to run a separate clinic or to see the men in a routine diabetes clinic. Such a decision will depend on local resources and circumstances, but it is certainly possible to manage erectile dysfunction in a diabetes clinic. If this is to be done, it is advisable to have information literature on erectile dysfunction available for men with diabetes. A great deal of useful patient information is produced by pharmaceutical companies and national diabetes organizations such as Diabetes UK, both in printed form and online. It is often wise to let the man read this and to consider the matter, with treatment being started at a subsequent visit.

Managing erectile dysfunction in primary care

There are considerable advantages to the treatment of erectile dysfunction in primary care. A general practitioner is more likely to know and understand a man's particular circumstances. Men may feel more comfortable seeking help from their family practitioner than from a hospital specialist or sexual therapist. Little specialized equipment is required, and so there is no reason why interested general practitioners should not effectively treat the majority of men presenting with erectile dysfunction.

As with many disorders encountered in primary care, the general practitioner may choose to manage the problem in a standard consultation with the man. Others may choose to refer their individuals with diabetes to a fellow partner or colleague with a particular interest in erectile dysfunction or to their practice nurse, who may have received appropriate training in the assessment of men with erectile dysfunction.

When a man presents with erectile dysfunction, there is an opportunity to consider other health issues and screen for underlying causes. Erectile dysfunction is often associated with conditions that benefit from early detection such as diabetes, hypertension, and hyperlipidaemia. It is therefore important to consider general health issues and to address lifestyle factors.

Specialist erectile dysfunction service

Although most men with erectile dysfunction will be managed in primary care, there is still a role for a specialist service. It is likely that these clinics will mainly treat men who have failed to respond to oral therapies and that they will maintain expertise in the use of other treatments, such as intracavernosal injection therapy and vacuum devices, referring the men when necessary to urological surgeons for penile prosthesis insertion. Many specialist clinics are run by specialist nurses.

Female sexual dysfunction

Female sexual dysfunction is a common problem and is associated with a range of biopsychosocial factors. Diabetes is a known cause of sexual dysfunction in women, but this is rarely discussed in diabetes consultations.

Physiology of sexual function

The female sexual response has a cognitive and emotional response as well as a physical response [106]. These are reflected in the four phases of the sexual response proposed by Masters and Johnson in 1966 [107]. Physical response involves increased blood flow to the genital region; increased heart rate, blood pressure, and respiration; vaginal lubrication; and nipple erection. Female genitalia refer to the external structure of the vulva, which includes the mons pubis, clitoris and bulbs, labia majora, and labia minora (Figure 54.6) [108]. The internal genitalia includes the vagina. The glans clitoris is visible externally, but the clitoris extends internally and the clitoral bulbs surround the urethra and extend around the vaginal walls. The structure of the genitalia includes two distinct vascular tissues:

- Erectile tissue similar to male genitalia in the clitoris and clitoral bulbs, which engorge with blood during sexual arousal.
- Non-erectile vascular tissue in the glans clitoris and labia minora.

The walls of the vagina enlarge with increased blood flow during sexual arousal, but also comprise non-erectile tissue. For normal sexual response there needs to be adequate blood supply to the external and internal genitalia, together with normal function of the sensory and autonomic nervous system. Clitoral erectile tissue function is dependent on the NO/cGMP pathway in the same way as erectile function is governed in men [109].

The first stage of the sexual response is desire, and the second is arousal. However, women may not experience distinct phases [110]. Arousal can be induced both mentally and physically, and can involve all the senses either individually or in combination. The third stage is orgasm, although there is a lack of consensus as to how this is induced and its involvement in reproductive fitness, male and female satisfaction, and brain activity involvement. The final stage is resolution or satisfaction.

Physiology of sexual dysfunction

Sexual activity is associated with multiple health benefits, such as improved quality of life, quality of social relationships, and mental well-being, and it is a good form of exercise. However, female sexual dysfunction is common and affects women of all ages [111, 112]. In physiological terms, female sexual dysfunction may occur because of reduced vasocongestion of the vulva and vagina, leading to impaired arousal and reduced vaginal lubrication. According to the World Health Organization [113], there are four categories of female sexual dysfunction: sexual desire disorder, sexual arousal disorder, orgasmic dysfunction, and sexual pain disorder. However,

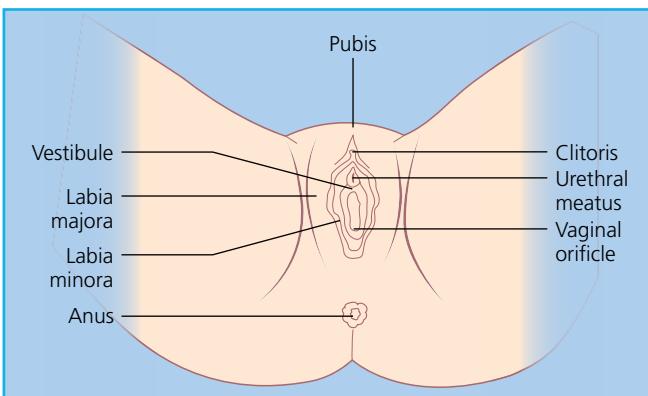

Figure 54.6 Female genitalia.

the fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) [114] reduced these to three by combining the first two:

- *Female sexual interest/arousal disorder*: a lack of sexual interest or failure to become aroused.
- *Female orgasmic disorder*: difficulty achieving orgasm.
- *Genito-pelvic pain/penetration disorder*: dyspareunia or vaginismus.

For diagnosis of these specific categories of sexual dysfunction, each should be present for 75–100% of the time and for a minimum period of six months and cause significant distress. The three categories of sexual dysfunction are largely consistent with the International Classification of Diseases 11 (ICD-11) and the Fourth International Consultation on Sexual Medicine (ICSM) is consistent with DSM-5 [115, 116]. Some female sexual disorders may overlap and the exact cause may be difficult to distinguish, as it can incorporate psychological, interpersonal, and physical factors [117].

The factors affecting sexual dysfunction were summarized by Khajehei et al. [118], who suggest five categories:

- Medical-surgical conditions, e.g. lower urinary tract problems, voiding problems, endometriosis, diabetes.
- Obstetrics and gynaecology, e.g. childbirth, breastfeeding, menopause, hysterectomy.
- Psychological, e.g. depression, anxiety, mental health problems.
- Lifestyle, e.g. physical activity, smoking, alcohol and drug use.
- Other factors, e.g. sexual orientation, practice, abuse, negative body image.

However, other associated factors suggested by DSM-5 and ICD-11 not listed here can include relationship or partner factors (Box 54.7).

Pathophysiology of female sexual dysfunction in diabetes

Women with diabetes are at increased risk of sexual dysfunction, but prevalence rates vary between studies. In premenopausal women with type 1 diabetes prevalence rates are 20–44% [119–123] and in mixed pre- and postmenopausal studies of women with type 1 diabetes rates are 42% [122]. For postmenopausal women with type 2 diabetes rates are also high, at 42–75% [122]. Compared with women without diabetes, women with type 1 diabetes or type 2 diabetes are twice as likely to have sexual dysfunction, as demonstrated in a systematic review and meta-analysis of 26 observational studies [124]. Women with diabetes and higher body mass index (BMI) are also more likely to report sexual dysfunction when measured by the validated self-report Female Sexual Function Index (standardized mean difference [SMD] –0.90, 95% CI –1.00 to –0.81) [124]. In women with type 1 diabetes, Enzlin et al. demonstrated that those who met the cut-off for depression on the Beck Depression Inventory were at greater risk of sexual dysfunction [125].

For women with diabetes, high or low blood glucose levels are associated with reduced vaginal lubrication, painful sex, and inability to orgasm [126, 127]. High rates of depression, known to be double that of general population samples [46], also have an impact on sexual function. Issues related to body image and scarring, injection sites, or wearing of medical devices may affect confidence to engage in sexual activity [128]. Furthermore, diabetes-related fatigue, fear of hypoglycaemia during sex, and the need to test blood glucose levels frequently may add to the general inconvenience of self-managing diabetes and maintaining sexual activity [129]. Such issues are all likely to affect relationships with a partner [130].

Box 54.7 Conditions associated with female sexual dysfunction

Psychological disorders

- Anxiety
- Depression
- Stress
- Obsessive compulsive disorder
- Psychiatric problems
- Fear of childbirth
- Fear of sexually transmitted disease

Gynaecological trauma

- Sexual abuse
- Genital mutilation
- Trauma caused by childbirth
- Menopause
- Hormonal imbalance
- Hysterectomy
- Ovariectomy
- Endometriosis
- Uterine fibroids

Urological conditions

- Painful bladder symptoms
- Lower urinary tract problems
- Urinary incontinence
- Leakage of urine during sexual activity

Social factors

- Relationship factors

- Hypopituitarism

Lifestyle

- Physical activity
- Smoking
- Drug abuse
- Alcohol abuse

Other medical conditions

- Hypertension
- Cancer
- Inflammatory disease

Clinical aspects of sexual dysfunction for women with diabetes

There is a general consensus that failure of arousal is more common, occurring in 14–45% of women with diabetes [125, 131]. In contrast, studies have reported conflicting results on the prevalence of orgasmic disorder [125, 132] and genito-pelvic pain in diabetes [126]. It would be reasonable to summarize the results of all the studies by saying that sexual dysfunction is

more common in women with diabetes and is mainly characterized by failure of arousal, although orgasmic problems and dyspareunia may also occur.

Sexual dysfunction as a risk factor for cardiovascular disease in women with diabetes

In women with diabetes, sexual dysfunction is emerging as a risk factor for cardiovascular disease via its impact on autonomic neuropathy. The main evidence for this comes from the 16/17-year follow-up of the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) study. Among 153 women with type 1 diabetes and sexual dysfunction, there were increased odds of developing cardiovascular autonomic neuropathy (CAN) (odds ratio [OR] 1.52, 95% CI 0.89 to 2.61) [133].

Atherosclerosis may be relevant to sexual function in women with diabetes. Clitoral colour Doppler ultrasound is a novel technique to assess the pulsatility index (PI), which measures the resistance to blood flow in the vascular structures and increased resistance and suggests micro-atherosclerosis. Clitoral colour Doppler ultrasound was used to measure sexual functioning in a clinic population of 71 women seeking treatment. Clitoral PI was statistically higher in women who were obese or had metabolic syndrome after adjustment for confounders [134]. Clitoral PI markers of metabolic syndrome, specifically degree of insulin resistance (higher homeostasis model assessment [HOMA] index) and triglyceride levels, were associated with increased PI. Increased clitoral PI was also associated with reduced arousal on the Female Sexual Function Index domain. Similar findings might be anticipated in a population of women with type 2 diabetes. The lack of research in this area means that we do not know if treatment can improve clitoral PI or if PI can be used to predict cardiovascular events.

Sexual dysfunction and peripheral neuropathy in women with diabetes

Sexual dysfunction, such as problems with orgasm and vaginal lubrication, is associated with central nerve damage, as in spinal cord injury. Sensory or peripheral nerve damage may also be a problem for women with diabetes. There is an increased incidence of sexual dysfunction for women who have diabetes-related peripheral neuropathy [135]. Women with diabetes demonstrate less physiological arousal compared with those without diabetes when viewing erotic stimuli [136]. Similarly, sensation in the vagina and clitoris is reduced in women with diabetes [137].

Smoking and alcohol consumption

Although smoking and alcohol consumption are associated with erectile dysfunction in men with diabetes, there is no evidence of an association for women with type 1 diabetes or type 2 diabetes. In a cross-sectional study of 524 women with diabetes in Jordan, sexual dysfunction was associated with age, BMI, duration of diabetes, presence of coronary artery disease, nephropathy, and retinopathy, but not directly with smoking [138].

Quality of life and psychological issues

In a study of 595 women with type 2 diabetes, depression, defined as antidepressant use or prior psychological counselling for depression, was independently associated with sexual dysfunction on the Female Sexual Function Index [139]. Furthermore, in a study by Enzlin et al. [125], women with type 1 diabetes who reached the cut-off for depressive symptoms on the Beck Depression Inventory

were four times more likely to have sexual dysfunction (37.7% vs 8.3%, $p < 0.001$). More recently, Barnard et al. [44] replicated a survey study originally conducted by Meekings et al. 1998 [140], with a population of 258 women with diabetes recruited via social media. More than 50% of the sample had problems with painful sex and orgasm. Free text responses indicated that diabetes had a negative impact on relationships with a partner, including lack of sexual interest [44].

Assessment and investigation of sexual dysfunction in diabetes

Clinical assessment

Female sexual dysfunction is rarely discussed in the diabetes clinic. Women rarely complain of sexual dysfunction and may not know that diabetes is a cause. Furthermore, women may feel embarrassed to discuss sexual issues, and diabetes healthcare professionals may also be unaware of the association with diabetes and/or feel ill-equipped to raise the topic. One way to identify the issue in a routine consultation could be to use self-report questionnaires or clinician checklists. The validated 19-item Female Sexual Function Index determines sexual function according to six domains including: sexual desire, arousal, lubrication, orgasm, satisfaction, and dyspareunia (pain) [141]. It is scored on a five-point scale, with higher scores indicating less sexual dysfunction. Shorter measures include the Brief Sexual Symptom Checklist for women (BSSC-W). Measures such as these may form the basis of more detailed discussion within the clinical setting [142].

Investigation of sexual dysfunction

Formal investigation of sexual dysfunction once identified should involve detailed medical history taking, including medical, physical, and psychological factors. It is important to determine prior sexual abuse, genital mutilation, or trauma caused by childbirth. Physical examination should be conducted by a gynaecologist. Review of medications to identify those that may exacerbate sexual function (Box 54.8) and screening of depression, anxiety, and body image are important. Blood tests may identify underlying disorders in addition to diabetes diagnosis, for example prolactin and testosterone to determine low/high levels of circulating sex hormones and thyroid function test to determine an additional underlying endocrine cause.

General advice

Women with diabetes rarely complain of sexual problems and diabetes health professionals rarely ask. In physiological terms, the female equivalent of male erectile dysfunction is reduced vasocongestion of the vulva and vagina, leading to impaired arousal and reduced vaginal lubrication. Failure to achieve an erection makes sexual intercourse impossible, but reduced vaginal lubrication can be overcome with simple treatments such as lubricating creams and may not even be considered to be abnormal by a postmenopausal woman. However, women may be suffering in silence and diabetes healthcare professionals may need to acquire skills to enable them to start the conversation. Optimization of blood glucose levels may improve symptoms of sexual dysfunction and this is therefore an important first step to support women. Other diabetes-related issues such as those to do with body image or the inconvenience of managing diabetes to maintain a sexual relationship might also be best discussed within a diabetes consultation, and will only happen if healthcare professionals are proactive in discussing the topic with women.

Box 54.8 Medications associated with female sexual dysfunction**Antihypertensives**

- β-blockers
- Thiazide diuretics
- Central sympatholytics (methyldopa, clonidine)
- Aldosterone receptor agonists

Antidepressants

- Selective serotonin reuptake inhibitors (SSRIs)
- Monoamine oxidase (MAO) inhibitors
- Tricyclic antidepressants

Antipsychotics

- Barbiturates
- Benzodiazepines
- Lithium

Hormones

- Danazol
- Gonadotrophin-releasing hormone (GnRH) agonists
- Hormonal contraceptives
- Anti-androgens
- Tamoxifen
- Gonadotrophin-releasing hormone (GnRH) analogues

Miscellaneous

- Statins
- Anticholinergics
- Antihistamines
- Digoxin
- Chemotherapeutic agents

Substance misuse

- Smoking
- Amphetamines
- Opiates

Organization of the management of sexual dysfunction

Female sexual dysfunction if identified can be managed in a dedicated clinic, but this is currently not generally offered in the diabetes clinic. Nevertheless, it may be possible to offer a service to women and some UK National Health Service (NHS) services have successfully integrated a discussion of sexual dysfunction into clinics with support from a diabetes psychotherapy service [147]. There are now a few useful patient information leaflets that could be made available to women and may prompt them to discuss their issues within their diabetes consultation. For example, more information and/or leaflets can be found on the webpages for Diabetes UK and Diabetes Health and Wellness Foundation [127].

Management of female sexual dysfunction

Many women attending a diabetes clinic will be over 50 years of age and some will have problems associated with the menopause, including vaginal dryness and dyspareunia. It can be difficult to distinguish the effects of the menopause from those of diabetes, but in practical terms the treatment is the same. Topical oestrogen or simple lubricant gels are usually effective. Managing loss of libido in women with diabetes is more complex and beyond the scope of this book. It is much more likely to be due to psychosocial and relationship, rather than somatic, problems. Similarly, anorgasmia is complex and best left to a specialist, although it is worth remembering that selective serotonin reuptake inhibitor antidepressants are a common cause.

The mechanism of action of PDE5 inhibitors suggests that they might improve arousal and vaginal lubrication. However, trials of PDE5 inhibitors for this purpose in women with and without diabetes have shown conflicting results. Measures of genital vasocongestion and clitoral blood flow have been reported to improve, but the impact on self-reported measures of sexual satisfaction has been disappointing [148, 149]. PDE5 inhibitors probably have little role in the management of sexual dysfunction in women with diabetes.

For postmenopausal women and sexual dysfunction, tibolone is a systemic hormone replacement therapy (HRT) that has demonstrated an improvement in sexual dysfunction on the Female Sexual Function Index, specifically improved vaginal lubrication and reduced dyspareunia [150, 151]. Tibolone is a synthetic steroid that has similar function to progesterone, oestrogen, and testosterone.

Treatment options

There is limited research on treatment of sexual dysfunction in women with diabetes. Most research has focused on pharmacotherapy, specifically PDE5 inhibitors and bupropion, an atypical antidepressant (norepinephrine-dopamine reuptake inhibitor, NDRI). PDE5 inhibitors have been tested in premenopausal women with type 1 diabetes with sexual arousal disorder, and demonstrated subjective improvements in arousal, desire and enjoyment of sexual activity, and objective measures of clitoral blood flow [143]. PDE5 inhibitors have not been tested in women with type 2 diabetes, although they have been used to treat pulmonary hypertension [144]. There is a single study suggesting that bupropion may improve sexual dysfunction in women with type 2 diabetes who were depressed [145]. However, there are no licensed treatments for women with diabetes and sexual dysfunction.

Psychological interventions

There are no published studies of psychological interventions for women with diabetes and sexual dysfunction. However, a systematic review and meta-analysis of 15 studies of women without diabetes with sexual dysfunction demonstrated improvements in orgasmic disorder ($d = 0.46$, 95% CI 0.07 to 0.86) [146].

Genitourinary infections in women with diabetes

Vaginal candidiasis is a common finding in women with diabetes if there is hyperglycaemia, because yeasts thrive in a glucose-rich environment. Severe infection can be irritating, painful, and can interfere with sexual intercourse. Infections typically respond to conventional antifungal creams and pessaries; resistant cases usually respond to a single oral dose of fluconazole. To reduce chance of reinfection, attempts should be made to optimize blood glucose levels. The male partner may also need treatment for candidiasis for the same reason.

Other genital infections also occur in women with diabetes, but probably no more frequently than in the general population. These cases should be referred to the appropriate genitourinary service.

Contraception

Contraception and family planning are especially important in women with diabetes. Suboptimal glycaemic levels during the first

trimester of pregnancy is associated with an increased risk of fetal morbidity and mortality [152–155]. It is essential that women with diabetes are supported to plan their pregnancies with diabetes prior to conception (Chapter 71).

Contraindications to pregnancy

As medical and obstetric care has improved, the list of contraindications to pregnancy in women with diabetes has shrunk (Chapter 71). If pregnancy is contraindicated, sterilization should be considered.

Method of contraception

Few diabetes organizations make any recommendation on the preferred method of contraception to be used in women with diabetes. The American Diabetes Association's recent Standards of Medical Care in Diabetes recommend that effective contraception is particularly important, but the options and recommendations are largely the same as those for women without diabetes [156]. This is true, but certain factors, in particular impact on risk factors and carbohydrate tolerance, should be taken into consideration before choosing any particular method.

Hormonal contraception

The oral contraceptive pill (OCP) remains one of the popular methods of contraception in women with diabetes in high-income countries [157]. It is simple to use and reliable. If properly used, it has the lowest failure rate for any contraceptive method, apart from sterilization [158]. Unfortunately, OCPs are associated with female sexual dysfunction, specifically arousal problems [159]. Long-acting reversible contraceptives are now recommended as first line for adolescents and young women by the American College of Obstetrics and Gynaecologists [160] and the American College of Paediatrics [161], whereas the UK National Institute of Health and Care Excellence (NICE) guidance refers to individual choice [162]. There is no evidence on their use in adolescents with diabetes [163] and there have been concerns about the safety of hormonal contraception in women with diabetes.

Hormonal contraception, carbohydrate tolerance, micro- and macrovascular risk

There is no evidence that hormonal contraceptives affect carbohydrate tolerance or metabolic management in women with diabetes. A Cochrane review of studies examining the impact of steroidal contraception in women without diabetes reported that there was minimal impact on carbohydrate metabolism and no major differences between different types of hormonal contraceptives [164]. In women with type 1 diabetes or type 2 diabetes, a more recent Cochrane review reported that neither combined nor progestin-only contraceptives had a significantly different effect than non-hormonal contraception on glucose levels, lipid metabolism, or complications [165]. A small impact of hormonal contraception on glucose levels cannot be ruled out, but in practical terms this should not deter their use in women with diabetes.

The cardiovascular safety of hormonal contraception is not beyond doubt, because most reported studies were flawed or small and a large definitive study examining the effects on cardiovascular morbidity and mortality in women with diabetes is needed. When considering prescribing hormonal contraception to a woman with diabetes, the same factors should be considered as in a woman without diabetes. Smoking, hypertension, age, and vascular disease should be considered and the risks weighed for the individual

woman. The World Health Organization's published criteria for contraceptive use provide useful practical advice on the choice of contraception in women with diabetes [166].

Once the risks have been assessed, any combined or progestin-only contraceptive can be used in women with type 1 diabetes or type 2 diabetes and the individual's preference should be considered. Any woman taking hormonal contraception should be reviewed regularly for assessment of blood pressure and serum lipids.

Combined hormonal contraceptive preparations carry an increased risk of venous thromboembolism. The risk is probably greatest (50–80% increase) with the *third-generation* progestins, desogestrel and gestodene, compared with preparations containing levonorgestrel [167]. The risk remains very small, however, and these are still safe preparations. There is no evidence that progestin-only contraceptives are associated with an increased risk of thrombosis.

Intrauterine contraceptive device

The intrauterine contraceptive device (IUD) is a safe and effective form of contraception in women with diabetes. Early concerns about the risk of pelvic inflammatory disease in diabetes were largely unfounded, with no increased risk of pelvic inflammatory disease in women with type 1 diabetes [168] or type 2 diabetes [169]. Similarly, early suggestions of an increased failure rate for IUDs in women with diabetes have not been borne out [168].

Barrier methods

Since the advent of acquired immune deficiency syndrome (AIDS), the condom has been widely advocated to reduce the risk of transmission of sexually transmitted diseases. It has a higher failure rate than OCPs and IUDs and for this reason is not recommended if pregnancy is contraindicated. For high-risk individuals, many genitourinary clinics recommend a combination of the OCP and condoms to minimize the risk of pregnancy and sexually transmitted diseases, a technique known as *double Dutch*.

Emergency contraception

Three methods of emergency contraception are licensed in the UK and are available in many other countries: progestogen-only and combined oestrogen–progesterone pills, and the copper IUD. The hormonal preparations can be taken up to 72 hours after unprotected intercourse, but are most effective if taken within 24 hours [170]. Nausea was reported in 23% and vomiting in ~6% of the women who used the progestrone-only regimen. Women with type 1 diabetes should be warned of these potential side effects. Little work on the use of these agents in women with diabetes has been published, but they may have a role in the prevention of unplanned pregnancies occurring at a time of hyperglycaemia.

Hormone replacement therapy

Few areas of medicine have gone through as many changes in perception in modern times as HRT. It was used as a treatment for osteoporosis and menopausal symptoms, but had become regarded as a potential treatment to reduce cardiovascular risk, largely based on observational studies. In 2001, a survey of general practitioners and hospital doctors in the UK suggested that the majority would advise HRT for women with diabetes as prophylaxis for cardiovascular disease [171]. Attitudes changed almost overnight, however,

following the publication of the Women's Health Initiative trial in 2002 [170]. This was a large, randomized study of combined oestrogen and progesterone HRT that was stopped early because of increased adverse outcomes, including cardiovascular disease, stroke, thromboembolism, and breast cancer. Further evidence has accumulated and now HRT is viewed largely as a short-term treatment for menopausal symptoms that does not increase cardiovascular risk, but is not without risk. Many women with diabetes are postmenopausal, and so diabetes professionals need to be aware of the potential risks and benefits.

Hormone replacement therapy and glucose tolerance

HRT does not worsen glucose tolerance in women with or without diabetes and may produce a slight amelioration. In women without diabetes, oestradiol and low-dose conjugated oestrogens are associated with an improvement and no effect on insulin sensitivity, whereas higher doses of conjugated oestrogens and alkylated oestrogens may cause deterioration of glucose tolerance [173–175].

In postmenopausal women with diabetes, oestradiol improves the fasting blood glucose concentration and glycated haemoglobin [176]. A larger observational study of over 15 000 women with type 2 diabetes also reported that HRT was associated with an improvement in glycated haemoglobin (HbA_{1c}) [177]. The NICE guideline for the treatment of the menopause concluded that there was no adverse effect or benefit on fasting blood glucose or HbA_{1c} at three or six months' follow-up for women with type 2 diabetes treated with HRT [178]; however, as the five studies had a small sample size, the evidence was deemed low to very low quality. A Cochrane review concluded that there is little or no evidence for women with type 1 diabetes [179].

Hormone replacement therapy and lipids

Like glucose tolerance, the effect of HRT on lipid profiles appears to be at worst neutral and may be slightly beneficial. In women without diabetes, oestrogens reduce total and low-density lipoprotein (LDL) cholesterol and increase high-density lipoprotein (HDL) cholesterol and triglyceride levels [180,181]. Transdermal oestrogen preparations have a beneficial effect on plasma lipids, reducing LDL cholesterol and triglycerides and increasing HDL cholesterol [181].

The effect of HRT on lipid profiles in women with diabetes has been reported in several studies. In a small, randomized crossover study of women with overweight and type 2 diabetes, conjugated oestrogen therapy reduced central obesity, HbA_{1c} , and total cholesterol, and improved physical functioning [183]. In another small, randomized crossover study, conjugated oestrogens reduced total and LDL cholesterol and increased HDL cholesterol in women both with

and without diabetes. The addition of medroxyprogesterone acetate abolished the increase in HDL in both groups. There was no apparent effect on fasting glucose or insulin levels [184]. In the largest study, 61 postmenopausal women received combined HRT in a randomized crossover design. HRT reduced total and LDL cholesterol, but there was no change in serum HDL or triglyceride levels [185].

Hormone replacement therapy and blood pressure

HRT can be prescribed to postmenopausal women with hypertension under careful supervision. One of the few studies of HRT and blood pressure in diabetes suggested that it can be prescribed without any adverse effect on ambulatory blood pressure measurements in hypertensive and normotensive women [186].

Hormone replacement therapy and ischaemic heart disease

Early case-control studies suggested that HRT reduces the risk of ischaemic heart disease in postmenopausal women by 30–50% [187, 188]. Subsequent clinical trials, nevertheless, reported very different results, and a reasonable summary of subsequent studies would be that there is no evidence that HRT reduces cardiovascular risk, but it probably does not increase it [189, 190]. It is, however, associated with an increase in thromboembolic disease. No large studies on the effect of HRT on the risk of ischaemic heart disease in women with diabetes have been reported. Therefore, when managing a postmenopausal woman with diabetes, guidance for the general population should probably be followed. Recently published guidance from NICE provides useful practical advice [178]. In brief, HRT should be considered as a short-term treatment for menopausal symptoms. Cardiovascular risk factors are not a contraindication provided that they are adequately managed. Transdermal preparations should be considered if there is a history of thromboembolic disease.

Hormone replacement therapy and osteoporosis

Women with type 1 diabetes have reduced bone mineral density at the time of diagnosis [191]. Although women with type 2 diabetes might be expected to be protected from osteoporosis because of their increased tendency to obesity, they are at increased risk of hip fracture (Chapter 59). A very large prospective cohort study of postmenopausal women in Iowa reported that women with diabetes had a 1.7-fold higher risk of hip fracture than women without diabetes [192]. Hence the benefits of HRT in reducing the risk of osteoporotic fractures would appear to be at least as great in women with diabetes as in those without diabetes, and HRT should be considered for postmenopausal women with diabetes with osteoporosis.

Clinical Enteric Neuroscience Translational and Epidemiological Research (CENTER), Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN, USA

Key points

- Diabetic enteropathy refers to all the gastrointestinal complications of diabetes, which can affect the entire gastrointestinal tract.
- Gastrointestinal symptoms in diabetes include dysphagia, dyspepsia, gastroparesis, abdominal pain, constipation, diarrhoea, and faecal incontinence. Some gastrointestinal disturbances (e.g. delayed gastric emptying) are often asymptomatic.
- Although these gastrointestinal symptoms are not uncommon among people with diabetes in clinical practice, the prevalence of gastrointestinal manifestations among such people in the community is not substantially higher than in the general population.
- These gastrointestinal manifestations can reduce quality of life and nutrition and also impair glycaemic management.
- These symptoms are attributed to gastrointestinal sensorimotor dysfunction resulting primarily from extrinsic and intrinsic nerve (i.e. enteric) dysfunction.
- The investigations are tailored to the presenting symptoms and require tests to exclude an organic disorder (e.g. gastric outlet obstruction in gastroparesis), to confirm gastrointestinal sensorimotor dysfunction (e.g. delayed gastric emptying), and to identify complications (e.g. small intestinal bacterial overgrowth).
- The management of gastrointestinal symptoms in diabetes relies primarily upon improving glycaemic management and symptomatic measures, in addition to attention to the individual's state of hydration and nutrition.

Although most attention has traditionally been focused on the stomach, diabetes can affect the entire gastrointestinal tract. The term *diabetic enteropathy* refers to all the gastrointestinal complications of diabetes. Gastrointestinal involvement may be asymptomatic or manifest as symptoms, such as dysphagia, heartburn, nausea, vomiting, abdominal pain, constipation, diarrhoea, and faecal incontinence. These manifestations may affect quality of life, impair nutrition, and affect glycaemic management.

incontinence) was not significantly different between individuals with either type 1 diabetes or type 2 diabetes and age-matched people without diabetes [4]. However, people with type 2 diabetes and men with type 1 diabetes used laxatives more frequently than people without diabetes. Moreover, that study and a Finnish population-based study reported that people with type 1 diabetes had a lower prevalence of heartburn [5]. In contrast to these studies, a study in Australia found that the prevalence of several upper and lower gastrointestinal symptoms was higher in 423 people with predominantly (95%) type 2 diabetes than in people without diabetes [6].

Compared with those studies, which were anchored by symptoms alone (i.e. not by diagnostic tests), the cumulative 10-year incidence of gastroparesis has been estimated at 5.2% in type 1 diabetes and 1% in type 2 diabetes in a community sample of people with diabetes [7]. In that study, gastroparesis was documented by physician diagnosis based on delayed gastric emptying with scintigraphy, or by symptoms and retained food at endoscopy. However, because gastroparesis was identified only in people who presented for care, people who had an asymptomatic delay in gastric emptying may not have been identified. Hence, the estimated incidence and prevalence of gastroparesis are critically dependent on definition [8].

Studies of the natural history of gastroparesis have been limited by relatively small numbers of participants, potential referral bias, or short follow-up periods. One study suggested that delayed

Epidemiology of diabetes-related enteropathy

Studies in selected groups, often from tertiary referral centres, suggest that gastrointestinal symptoms are common in diabetes [1, 2]. However, these studies are prone to selection and other biases, which are avoided by studies conducted among people with diabetes in the community, where the prevalence of gastrointestinal symptoms is either not different from or only slightly higher than for people without diabetes. In the Rochester Diabetic Neuropathy Study, only 1% of people with diabetes had symptoms of gastroparesis and only 0.6% had nocturnal diarrhoea [3]. In another study from Olmsted County, Minnesota, USA, the prevalence of gastrointestinal symptoms (i.e. nausea and/or vomiting, dyspepsia, heartburn, irritable bowel syndrome, constipation, and faecal

gastric emptying and symptoms are both relatively stable over 12 or 25 years [9]. In a clinic-based study, diabetic gastroparesis was associated with severe symptoms, nutritional compromise, impaired glucose management, and a poor quality of life, independent of other factors such as age, tobacco use, alcohol use, or type of diabetes [10]. Several studies have investigated the association between diabetic gastroparesis and mortality or morbidity [11–18]. For example, among 86 people with diabetes, of whom 56% had delayed emptying of solids and 28% had delayed emptying of liquids, ~25% had died by follow-up at least nine years later. Gastroparesis was not associated with mortality after adjustment for other disorders [11]. However, this study did not ascertain the relationship between diabetic gastroparesis and other medical conditions. In another study that compared three parallel cohorts of people with diabetes (i.e. 94 with symptoms and delayed gastric emptying, 94 with classic symptoms of delayed gastric emptying but normal scintigraphy, and 94 with no symptoms of gastroparesis), diabetic gastroparesis was associated with cardiovascular disease, hypertension, retinopathy, and increased hospitalization [12]. Compared with those with gastrointestinal symptoms alone, people with diabetic gastroparesis also had more hospital days; mortality was also greater, but differences were not statistically significant. In the National Institute of Diabetes, Digestive and Kidney Diseases Gastroparesis Clinical Research Consortium, the incident death rate for a cohort of 358 people with gastroparesis was 0.015 deaths per person-year. The death rate was significantly higher in 50 people with type 1 diabetes and 59 with type 2 diabetes compared with idiopathic ($n = 249$) cases (0.0266 vs 0.0094 deaths per person-year) and in those with delayed (73%) compared with normal (27%) gastric emptying (0.0189 vs 0.0031 deaths per person-year) [19].

Taken together, these data suggest that gastrointestinal manifestations are common among people with diabetes presenting for care. However, in the general population, the prevalence of gastrointestinal manifestations is not substantially higher among people with diabetes, perhaps partly because the prevalence of gastrointestinal symptoms among people without diabetes in the community is relatively high, approaching 20%, mostly attributable to functional gastrointestinal disorders (e.g. irritable bowel syndrome). Among people with gastrointestinal symptoms, the gastric emptying assessment can identify those with a worse prognosis. Whether this increased morbidity is driven by gastroparesis is unknown.

Data on long-term natural history in the community are available from an epidemiology study in the UK [20]. Ye et al. utilized the Clinical Practice Research Datalink (CPRD) database, an anonymized data source of general practitioner records with 4.4 million active patients comprising 7% of the entire UK population and representative in terms of age, sex, ethnicity, and body mass index (BMI) [20]. They estimated an overall prevalence of gastroparesis of 13.8 per 100 000 persons and an incidence of 1.9 per 100 000 person-years [20]. This estimate is comparably lower than a report from Olmsted County, Minnesota, the only other reported population-based study of gastroparesis [21]. In both studies, diabetes-related and idiopathic were the most prevalent forms of gastroparesis. In some [20, 21], but not all [12] studies, mortality appeared to be higher in individuals with both diabetes and gastroparesis. Associated morbidity in those with diabetic gastroparesis (estimated by Charlson morbidity index) was associated with mortality [20], but the relationship of the classical diabetic triopathy (neuropathy, nephropathy, and retinopathy) to gastroparesis or mortality was not assessed.

Pathophysiology

Gastrointestinal dysmotility in diabetes is caused by extrinsic (i.e. sympathetic and parasympathetic) neural dysfunction, hyperglycaemia, and hormonal disturbances. More recently, a role for intrinsic (i.e. enteric) neuronal dysfunction, resulting from loss of excitatory and inhibitory neurons and interstitial cells of Cajal (ICC), has also been implicated [22]. Neural dysfunction has been attributed to several mechanisms (e.g. oxidative stress), described in what follows and detailed elsewhere [23].

Normal gastrointestinal motor functions

Gastrointestinal motor function is primarily controlled by the intrinsic or enteric nervous system (i.e. the 'little brain' in the digestive tract) and modulated by the extrinsic (i.e. parasympathetic and sympathetic) nervous system (Figure 55.1) [25]. While intrinsic and extrinsic controls are independent, the prevertebral ganglia integrate afferent impulses between the gut and the central nervous system and provide additional reflex control of the abdominal viscera. The parasympathetic arm is excitatory to non-sphincteric muscle and inhibits sphincters. The sympathetic component has opposite effects. The enteric nervous system consists of 100 million neurons that are organized in distinct ganglionated plexi, including the submucous plexus that is primarily involved in absorption and secretion, and the myenteric plexus that regulates motility. The ICC serve as pacemakers and also convey messages from nerves to smooth muscle. As with the somatic and autonomic nerves elsewhere, the gut's autonomic and enteric nervous system can be affected in diabetes. Derangements of the extrinsic nerves at any level may alter gastrointestinal motility and secretion [26].

Gastrointestinal digestion and absorption require gastrointestinal motility, gastric and pancreatic secretion, and gastrointestinal hormonal release, which in turn modulate motor, secretory, and absorptive functions in the upper gut [27]. Traditionally, these processes are considered in three phases – that is, cephalic, gastric, and intestinal – which are integrated and overlap. Normally liquids, particularly non-caloric liquids, empty rapidly from the stomach in a linear fashion. In contrast, gastric emptying of solids follows an exponential pattern. During the first 45-minute post-prandial period (i.e. the lag phase), the gastric antrum grinds solids into particles smaller than 2 mm in size so they can be emptied through the pylorus. During the lag phase, the stomach relaxes or accommodates, providing room for digestion to occur (Figures 55.2 and 55.3). Thereafter, solids are emptied in a linear fashion, with ~50% emptying in two hours and 100% emptying in four hours.

Pancreatobiliary secretions and mechanical processes ensure small intestinal digestion, which precedes absorption. The small intestine transports solids and liquids at approximately the same rate; the head of a column of liquid chyme may reach the caecum as early as 30 minutes after ingestion. As a result of the lag phase for the transport of solids from the stomach, liquids typically arrive in the colon before solids. However, it takes about 150 minutes for half the solid and liquid chyme of similar caloric density (assuming solids are presented in a triturated form to the small bowel) to traverse the small bowel. Complex carbohydrates or fat in the distal small intestine exert feedback control of proximal small intestinal motility (i.e. the small intestinal brake). Chyme is transferred from the ileum to the colon in intermittent boluses. On average, it takes 36 hours, with an upper limit of 65 hours, to transfer contents from the caecum to the rectum. Compared with the stomach and small

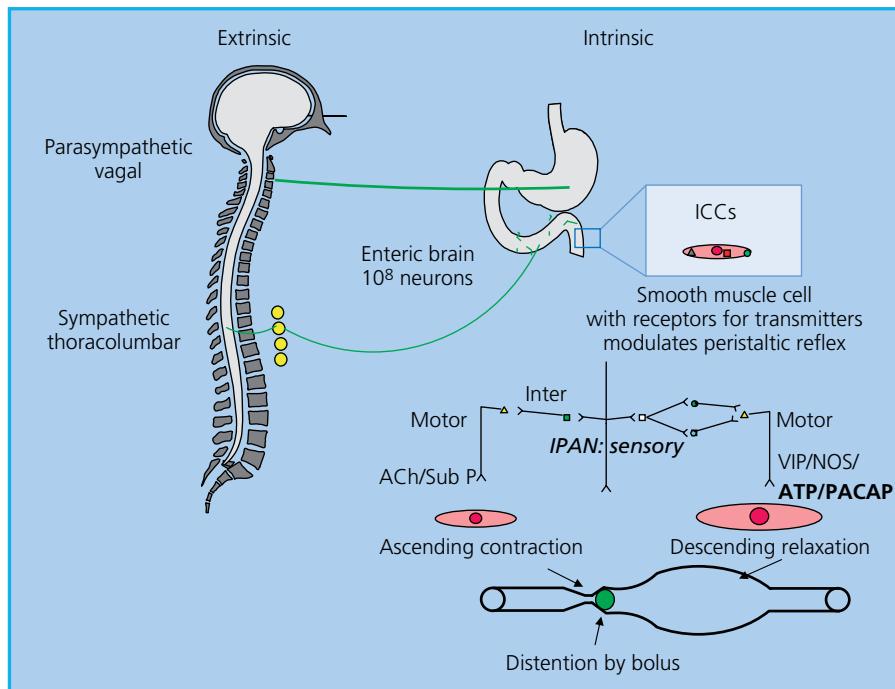

Figure 55.1 Control of gastrointestinal motility. Note that the extrinsic or autonomic nervous system modulates the function of the enteric nervous system, which controls smooth-muscle cells through excitatory (i.e. acetylcholine [Ach], substance P [SubP]) or inhibitory (nitric oxide [NO], vasoactive intestinal peptide [VIP], pituitary adenylate cyclase activating peptide [PACAP]) neurotransmitters. ICCs, interstitial cells of Cajal; IPAN, intrinsic primary afferent neurons; NOS, nitric oxide synthase. Source: Adapted by permission from Camilleri and Phillips 1989 [24].

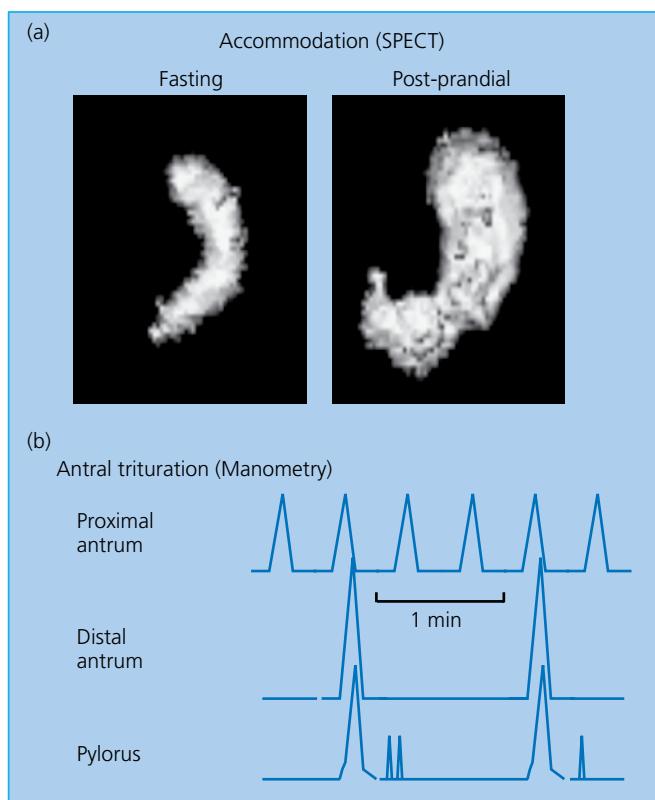

Figure 55.2 Assessment of gastric motor functions. (a) Gastric accommodation can be assessed by measuring the post-prandial change in gastric volume using single photoemission computed tomography (SPECT). The stomach wall is labelled with intravenous [^{99m}Tc]pertechnetate. Food is subsequently transferred to the antrum. (b) Manometry demonstrates that the distal antrum and pylorus contract synchronously to grind food into smaller particles. Only particles 2 mm or smaller can be emptied through the pylorus.

intestine, colonic transit is relatively prolonged, permitting digestion (i.e. of fibre) and absorption (i.e. of water and electrolytes) to be completed.

Pathophysiology of diabetes-related enteropathy: insights from animal studies

In animal models, extrinsic neural dysfunction has been primarily ascribed to a loss of myelinated and unmyelinated fibres, without much neuronal loss [28, 29]. The loss of nerve fibres is often multi-focal, suggestive of ischaemic injury. Within the enteric nervous system, reduced neuronal staining and, to a lesser extent, neuronal loss, particularly inhibitory neurons expressing nitric oxide synthase (NOS), have been described in several animal models of diabetes [23]. In theory, this reduction in nitrenergic inhibitory functions may contribute to impaired gastric accommodation and accelerated intestinal transit in diabetes. Reduced sympathetic inhibition may also contribute to accelerated intestinal transit. Since nitric oxide (NO) is a mediator of pyloric relaxation, loss of NOS may impair pyloric relaxation and thereby retard gastric emptying. Loss of ICC, documented in several animal models and case reports of diabetes, may also contribute to gut dysmotility [22, 30]. In addition, loss of ICC and increase in CD45 and CD68 immunoreactivity are the commonest enteric neuropathological abnormalities in diabetic and idiopathic gastroparesis [31, 32].

Several mechanisms, including apoptosis, oxidative stress, advanced glycation end-products, and neuroimmune mechanisms, may be responsible for neuronal loss and gut dysmotility [23]. The loss of ICC has been attributed to a reduction in haem-oxygenase (HO-1) and other protective mechanisms against hyperglycaemia [22]. The effects of diabetes on neuronal morphology and functions are reversible. Insulin or pancreas transplantation improved glycaemia and the axonopathy affecting autonomic nerves in rats with diabetic autonomic neuropathy [33]. Insulin also restored expression of NOS and gastric emptying in animal

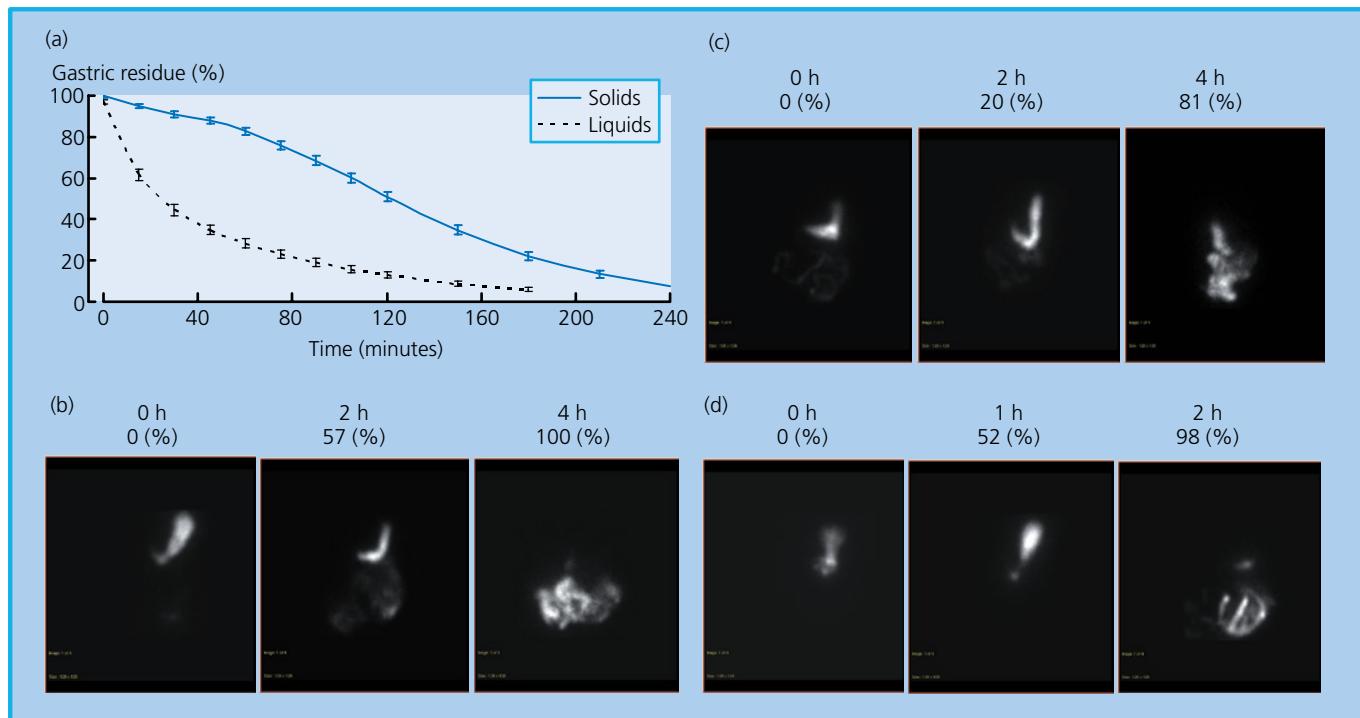

Figure 55.3 Assessment of gastric emptying by scintigraphy. Normally liquids are emptied in a linear manner, whereas solid emptying has an exponential profile, characterized by an initial lag phase, followed by a more rapid, linear emptying (a). The lag phase corresponds to the time required for antral trituration and gastric accommodation, during which ~10% of solids are emptied (b–d). Representative

examples of normal, delayed, and accelerated gastric emptying, respectively, of an egg meal, labelled with ^{99m}Tc , in people with diabetes. At time 0 (i.e. the first image in each panel), the entire meal was in the stomach. Thereafter, the normal ranges for gastric emptying are 11–39% at 1 h, 40–76% at 2 h, and 84–98% at 4 h.

models of diabetes, and insulin and insulin-like growth factors prevented the loss of ICC in cultures [34, 35]. Since ICC do not express receptors for either hormone, these effects are perhaps mediated by smooth-muscle secretion of stem cell factor, which is the most important growth factor for ICC, rather than directly by insulin and insulin-like growth factors [22]. Overexpression of glial cell line-derived neurotrophic factor, a trophic factor for enteric neurons, in transgenic mice reversed hyperglycaemia-induced apoptosis of enteric neurons and improved gastric emptying and intestinal transit [36]. The effects of hyperglycaemia on enteric neurons (apoptosis) appear to be counterbalanced by the positive effects on ICC (increased kit expression) and cholinergic responses, as observed in obese, leptin receptor knockout mice [37]. Therefore, the overall effects of hyperglycaemia are unclear from a mechanistic perspective.

Modulation of M2 macrophages and oxidative stress in gastroparesis

Macrophage-based immune dysregulation is associated with delayed gastric emptying in diabetic mice [38]. The biochemical mechanism leading to loss of these different pacemaker cells is considered to be oxidative stress, and the depletion of anti-inflammatory resident M2 macrophages expressing HO-1 is believed to be the underlying pathobiology. Loss of anti-inflammatory macrophages and increased expression of genes associated with pro-inflammatory macrophages have been reported in full-thickness gastric biopsies from people with gastroparesis. It has also been demonstrated that abnormalities in the enteric neural control, including disorders of

different pacemaker cells (ICC and platelet-derived growth factor receptor α [PDGFR α] fibroblast-like cells) and alterations in numbers of nitrergic neurons and CD206-positive macrophages, are associated with idiopathic or diabetic gastroparesis manifesting as delayed gastric emptying [31, 32].

Based on transcriptomic studies of full-thickness gastric body biopsies from people with gastroparesis and deep RNA sequencing and reverse transcription polymerase chain reaction (RT-PCR), many differentially expressed genes involved in immune functions such as cytokines and interleukins were actually downregulated, and there were no significant differences in enrichment of genes associated with M1 or M2 macrophages in the diabetic gastroparesis and diabetic control samples [39, 40].

In addition, proteomic studies [41] of full-thickness gastric antrum biopsies obtained from 9 people with diabetic gastroparesis and 5 individuals without diabetes revealed the following proteins to be underexpressed: trefoil factor 2 (TFF2), fatty acid-binding protein (FABP3 heart), glycerol-3-phosphate dehydrogenase (GPD1 [NAD(+)]), trypsin-1 (PRSS1), interleukin-1 receptor type 2 (IL-1R2), granulocyte colony-stimulating factor 3 (CSF3), carbonic anhydrase 3 (CA3), and α -2-HS-glycoprotein (AHSG), as well as carbonic anhydrase 1 (CA1). The only protein overexpressed was calcium/calmodulin-dependent protein kinase type II subunit- β (CAMK2B). These proteins are involved predominantly in tissue repair, cellular metabolism, or translation of ligand-receptor interaction to cellular function. Thus, other than responses to the cytokine interleukin-1 (IL-1/IL-1R2) and IL-6 (CSF3), which are downregulated, there do not appear to be consistent immune- or inflammation-related

abnormalities in proteins expressed in the antrum, which is the locus of significantly reduced function (antral hypomotility) in diabetic gastroparesis.

Pathophysiology of diabetes-related enteropathy in humans

Gastric dysfunction

In over 100 individuals who underwent gastric motor function tests to investigate the cause of upper gastrointestinal symptoms, approximately a quarter of the individuals had either abnormal gastric emptying, reduced gastric accommodation, abnormalities in both emptying and accommodation, or normal motor functions [42].

After initial evidence suggesting that there was no significant relationship of abnormal gastric emptying and symptoms and responses to prokinetics, two systematic reviews and meta-analyses have reported that when measured optimally (≥ 3 h, solid-phase meal), delayed gastric emptying was significantly associated with symptoms (early satiety and fullness) [42], and improvement in gastric emptying was associated with significant improvement in symptoms [43].

Neuropathy

Diabetes is associated with accelerated or delayed gastric emptying, increased and reduced gastric sensation, and impaired gastric accommodation (Figure 55.4) [45]. A vagal neuropathy can cause antral hypomotility and/or pylorospasm, which may delay gastric emptying [46]. The pathophysiology of rapid gastric emptying in diabetes is less well understood. Conceivably, impaired gastric accommodation resulting from a vagal neuropathy [47] may increase gastric pressure and thereby accelerate gastric emptying of liquids. However, the relationship between rapid gastric emptying and impaired gastric accommodation has not been substantiated. The relationship between vagal neuropathy and impaired post-prandial accommodation is unclear, since accommodation may be

preserved even in persons with diabetes with vagal neuropathy [48]; this may reflect non-vagal adaptive mechanisms involving enteric neurons [49]. Some people with diabetes and gastroparesis also have small intestinal dysmotility, more frequently characterized by reduced than by increased motility [50]. Small bowel dysmotility may also contribute to gastric stasis.

Hyperglycaemia

Acute hyperglycaemia delays gastric emptying in healthy individuals and in people with type 1 diabetes [51–55]. These effects may be explained by hyperglycaemia-induced suppression of antral motility and migrating motor activity (i.e. the intestinal ‘house-keeper’) [56–58]. However, the effects of acute hyperglycaemia on gastric emptying are modest. Indeed, even in type 1 diabetes, severe acute hyperglycaemia (i.e. 16–20 vs 4–8 mmol/l) prolonged the gastric emptying half-time by only 17 minutes (i.e. from 124 to 141 minutes). Acute modulation of blood glucose within the physiological post-prandial range (4–8 mmol/l) can also delay gastric emptying to a lesser extent [54]. Cross-sectional studies suggest that higher glycated haemoglobin (HbA_{1c}) concentrations are associated with a higher prevalence of gastrointestinal symptoms and slower gastric emptying among people with diabetes in the community [6, 59]. Although strict glycaemic management improves neural, renal, and retinal functions in diabetes, the impact on gastric emptying is unclear [60]. Improved glycaemic levels did not improve gastric emptying one week later in 10 people with type 2 diabetes [61]. Likewise, overnight and sustained (six months) improvements in glycaemic levels did not affect gastric emptying in 30 individuals with suboptimally managed diabetes [62]. In addition to hyperglycaemia, electrolyte imbalances due to diabetic ketoacidosis (e.g. hypokalaemia) and uraemia may also aggravate impaired motor function in persons with diabetes.

Recent studies have formally appraised the contribution of hyperglycaemia to impaired gastric emptying. Although acute, severe, and chronic hyperglycaemia can delay gastric emptying, there is limited evidence that delayed gastric emptying is an independent risk factor for elevated HbA_{1c} or hypoglycaemia in

GI manifestation of diabetes	Associated disease	Clinical presentation
Gall bladder motility ↓ antral hypomotility pylorospasm		Gallstones Gastric stasis, bezoars
↓ Gastric accommodation		Dyspepsia
↓ α_2 -adrenergic tone in enterocytes	Exocrine pancreatic insufficiency	Diarrhoea, steatorrhoea intestinal pseudo-obstruction
Small bowel (SB) dysmotility Colonic dysmotility	Celiac sprue	Gastric or SB stasis or rapid SB transit
Anorectal dysfunction sensory neuropathy IAS-sympathetic EAS-pudendal neuropathy	SB bacterial overgrowth Bile acid mal-absorption	Constipation, or diarrhoea Disordered defaecation or faecal incontinence

diabetes, based on a systematic review of the literature [55]. Among 78 participants with type 1 diabetes followed for 20 years in the Epidemiology of Diabetes Interventions and Complications (EDIC) study, delayed gastric emptying was associated with early and long-term hyperglycaemia (i.e. the HbA_{1c} at entry into the Diabetes Control and Complications Trial (DCCT) approximately 27 years previously, the duration of diabetes before DCCT entry, and mean HbA_{1c} over 27 years during DCCT-EDIC) [63].

Iatrogenic gastroparesis: opioids and glucagon-like peptide 1 receptor agonists

A confounding factor to the diagnosis of diabetic gastroparesis is the increased use of opioid medications for abdominal pain [64]. Among 583 individuals in the NIH Gastroparesis Consortium database, 41% were taking opioids, which included 33% on potent morphine-like agents. Moreover, the indication for the opioid was abdominal pain for 61% of the individuals. These persons also had higher symptom scores, greater levels of gastric retention, worse quality of life, increased hospitalization, and increased use of antiemetic and pain modulator medications compared with non-users or those using weaker opioids (e.g. tramadol, tapentadol, codeine, or propoxyphene) [65]. It has been proposed that such individuals receive a therapeutic trial with a peripherally active mu-opioid receptor antagonist to differentiate the relative contributions of the opioid and underlying disease to the gastroparesis [7, 64]. Opioids induce multiple actions that lead to gastric emptying delay or gastroparesis, including antral hypomotility and pylorospasm [66].

Iatrogenic gastroparesis may result from treatment with amylin analogues such as pramlintide [67] or glucagon-like peptide 1 (GLP-1) receptor agonists such as liraglutide and exenatide. Effects of the latter have been documented in the literature in the gastric emptying of liquids [68, 69], with clinically relevant delays in the gastric emptying of solids [70]. Short-acting GLP-1 receptor

agonists (e.g. GLP-1, exenatide, lixisenatide) delay gastric emptying to a greater extent [71, 72] than the longer-acting agents (liraglutide, exenatide once weekly, and semaglutide) [73].

Diabetic diarrhoea

It is useful to categorize the pathophysiology of diabetic diarrhoea into conditions that are or are not associated with malabsorption (Figure 55.5). Involvement of sympathetic fibres, which normally inhibit motility and facilitate absorption via α₂-adrenergic receptors, can result in accelerated small intestinal transit and cause diarrhoea [74]. Artificial sweeteners such as sorbitol may also contribute to diarrhoea. People with rapid ileal transit may have bile acid malabsorption [75, 76], and deconjugated bile acids induce colonic secretion.

Features suggestive of malabsorption such as anaemia, macrocytosis, or steatorrhoea should prompt consideration of bacterial overgrowth, small bowel mucosal disease, or pancreatic insufficiency. Small intestinal dysmotility predisposes to bacterial overgrowth, which can cause bile salt deconjugation, fat malabsorption, and diarrhoea. Although type 1 diabetes is associated with coeliac disease, most people with coeliac disease and type 1 diabetes in the community are asymptomatic [77]. Chronic pancreatic insufficiency may result from pancreatic atrophy, disruption of cholinergic enteropancreatic reflexes, or elevated serum hormonal levels of glucagon, somatostatin, and pancreatic polypeptide, which reduce pancreatic enzyme secretion [78]. However, the association between chronic pancreatic insufficiency and diabetes is uncommon. Moreover, because there is sufficient pancreatic reserve, only 10% of pancreatic function is sufficient for normal digestion.

Faecal incontinence

Loose stools and anorectal dysfunction contribute to faecal incontinence in diabetic diarrhoea. Compared with continent persons with diabetes and people without diabetes, people with diabetes

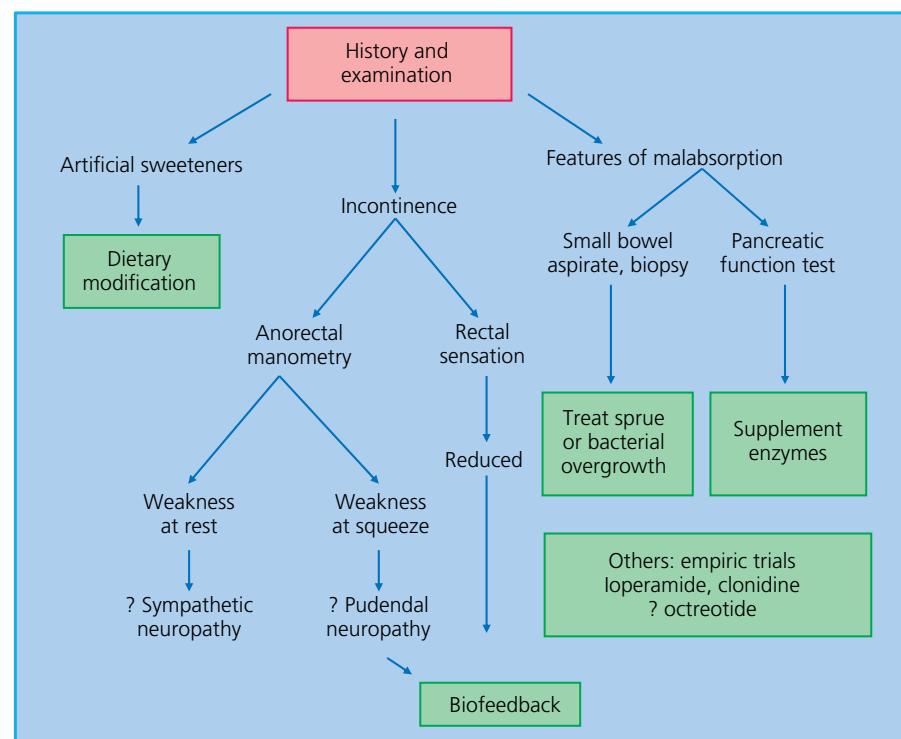

Figure 55.5 Management of diarrhoea in diabetes mellitus. Source: Adapted by permission from Camilleri 1996 [44].

and faecal incontinence have a higher threshold for rectal perception of balloon distension (i.e. reduced sensation) [79, 80]. A sympathetic neuropathy may impair internal anal sphincter function, causing reduced anal resting pressure. A pudendal neuropathy may result in reduced anal squeeze pressure.

Constipation

The mechanisms of constipation in diabetes have not been carefully studied and are poorly understood. Clinical observations suggest that, similar to idiopathic chronic constipation, both colonic dysmotility and anorectal dysfunctions (i.e. impaired anal sphincteric relaxation during defaecation) may contribute to constipation in diabetes [81]. Persons with colonic dysmotility have an impaired colonic contractile response to a meal and delayed colonic transit [82]. People with reduced rectal sensation may not perceive the desire to defaecate. Compared with euglycaemia, acute hyperglycaemia inhibited the colonic contractile response to gastric distension and proximal colonic contraction elicited by colonic distension in healthy people without diabetes [83]. However, acute hyperglycaemia did not significantly affect fasting or post-prandial colonic tone, motility, compliance, and sensation, or rectal compliance and sensation in healthy people [84].

In addition to these factors, it is also important to consider the role of psychological factors in the perception and impact of gastrointestinal symptoms. Indeed, psychosomatic symptoms are significantly associated with the reporting of gastrointestinal symptoms [4]. A systematic review of 42 studies observed that diabetes is associated with depression; the prevalence of depression among persons with diabetes (i.e. 9–27%) is approximately two-fold greater than in individuals without diabetes [85]. The severity of the depression is associated with the magnitude of hyperglycaemia in type 1 diabetes and type 2 diabetes [86] and with the prevalence of complications of diabetes (i.e. retinopathy, nephropathy, neuropathy, macrovascular complications, and sexual dysfunction) [87]. Among 200 936 persons with depression, 74 160 (36.9%) had diabetes, of whom 57 418 (28.6%) had complications [88]. Among individuals with depression, the incidence of serious psychiatric outcomes was greater in persons with (6.7%) than without diabetes (3.3%). In the National Institutes of Diabetes and Digestive and Kidney Disorders (NIDDK) Gastroparesis Consortium study, nearly 50% of the participants had clinically significant anxiety and moderate to severe depression [89]. Taken together, these findings underscore that depression is common, often severe, and may contribute to the expression of gastrointestinal sensorimotor dysfunctions in diabetes.

Several medications for the treatment of diabetes have gastrointestinal side effects: metformin can cause diarrhoea, and, among other medications, verapamil and anticholinergic agents can cause constipation.

Clinical manifestations

Dysphagia and heartburn

Oesophageal dysmotility, typically characterized by impaired peristalsis with simultaneous contractions, is common, may cause dysphagia, and may be related to cardiovascular autonomic neuropathy [90]. The amplitude of peristaltic contractions and basal lower oesophageal sphincter pressures is generally normal. Symptoms of gastroesophageal reflux are also common, particularly in persons

with impaired gastric emptying who have vomiting. Rarely, recurrent vomiting may lead to Mallory–Weiss tears and bleeding.

Dysphagia and heartburn should prompt upper gastrointestinal endoscopy to exclude reflux and other incidental mucosal diseases (e.g. candidiasis, neoplasms). Although manometry may reveal oesophageal peristaltic disturbances in persons with significant dysphagia that is not explained by a structural lesion, it is unlikely to alter management, except rarely in people in whom another disorder (i.e. achalasia) is responsible for the dysphagia. Because of the high prevalence of coronary atherosclerosis in diabetes, testing for coronary artery disease should be considered when necessary in those with chest pain.

Dyspepsia and gastroparesis

Although gastroparesis refers to a syndrome characterized by symptoms (i.e. nausea, vomiting, early satiation after meals, and impaired nutrition) and objective evidence of markedly delayed gastric emptying, gastric retention may be asymptomatic [91], perhaps because of the afferent dysfunction associated with vagal denervation [92]. Nausea and vomiting typically occur in episodes lasting days to months, or in cycles. Nausea and vomiting may be associated with impaired glycaemic management and often cause hypoglycaemia, perhaps because delivery of food into the small bowel for absorption is not sufficient to match the effects of exogenous insulin.

Consistent with the concept of a paralysed stomach, the term gastroparesis should be restricted to people with markedly delayed gastric emptying. When the delay in gastric emptying is not severe, the term diabetic dyspepsia is perhaps more appropriate. Dyspepsia is characterized by one or more, generally post-prandially, upper gastrointestinal symptoms (i.e. bloating, post-prandial fullness, and upper abdominal pain). Typically, vomiting is not severe, but significant weight loss secondary to reduced caloric intake is not unusual in people with dyspepsia. In addition to delayed gastric emptying, impaired gastric accommodation and abnormal (i.e. increased or decreased) gastric sensation may also contribute to symptoms in diabetes [93, 94]. Nonetheless, the distinction of dyspepsia from gastroparesis is challenging, since there is no official distinction between moderately and severely delayed gastric emptying. Clinical experience suggests that gastric emptying of <65% at four hours reflects a significant delay, as it is often associated with nutritional consequences, thus resulting in the need for nutritional supplementation, jejunal feeding, or gastric decompression [95].

Gastric retention may be asymptomatic in some people, possibly owing to afferent dysfunction in the setting of vagal denervation, and delayed gastric emptying may be associated with recurrent hypoglycaemia in people without upper gastrointestinal symptoms.

People with diabetic gastroparesis frequently have long-standing type 1 diabetes with complications (i.e. retinopathy, nephropathy, peripheral neuropathy, and other forms of autonomic dysfunction including abnormal pupillary responses, anhidrosis, gustatory sweating, orthostatic hypotension, erectile dysfunction, retrograde ejaculation, and dysfunction of the urinary bladder) (Table 55.1). By contrast, earlier studies suggested that rapid gastric emptying of liquids is a relatively early manifestation of type 2 diabetes [96–100]. Clinicians have relied on the manifestations of complicated diabetes and on certain symptoms (e.g. vomiting of undigested food eaten several hours previously and weight loss) and signs (e.g. a gastric succussion splash or features of an autonomic neuropathy) to predict delayed gastric emptying in people with diabetes who present with upper gastrointestinal symptoms. However, several

studies have shown that symptoms are of limited utility for predicting delayed gastric emptying in diabetes [101–107]. Similarly, the type and duration of diabetes, HbA_{1c} levels, and extraintestinal complications were, in general, not useful for discriminating normal from delayed or rapid gastric emptying. However, significant

weight loss and a neuropathy were risk factors for delayed and rapid gastric emptying, respectively [108]. In summary, upper gastrointestinal symptoms in persons with diabetes may result from accelerated gastric emptying, often in association with vagal neuropathy and impaired proximal gastric accommodation. Hence, it is essential to measure gastric emptying in people with upper gastrointestinal symptoms.

People with diabetic gastroparesis may have other features caused by autonomic neuropathy. Table 55.2 provides a summary of commonly performed autonomic tests.

In people with upper gastrointestinal symptoms, an upper endoscopy is necessary to exclude peptic ulcer disease and neoplasms, either of which can cause gastric outlet obstruction. Upper endoscopy may reveal gastric bezoars, which suggest antral hypomotility. Metabolic derangements, such as diabetic ketoacidosis or uraemia, and medications, particularly opiates, calcium channel blockers, and anticholinergic agents, may contribute to dysmotility. Rarely, people with gastroparesis present with retrosternal or epigastric pain, and cardiac, biliary, or pancreatic disease may be considered. Recent data also show that upper gastrointestinal symptoms may be associated with impairment of gastric accommodation [41]; this can be measured radiologically using single

Table 55.1 Symptoms and signs of autonomic dysfunction.

Sympathetic	Parasympathetic
Failure of pupils to dilate in the dark	Fixed, dilated pupils
Fainting, orthostatic dizziness	Lack of pupillary accommodation
Constant heart rate with orthostatic hypotension	Sweating during mastication of certain foods
Absent piloerection	Decreased gut motility
Absent sweating	Dry eyes and mouth
Impaired ejaculation	Dry vagina
Paralysis of dartos muscle	Impaired erection
	Difficulty with emptying urinary bladder
	Recurrent urinary tract infections

Table 55.2 Commonly performed autonomic tests.

Test	Physiological functions tested	Rationale	Comments/pitfalls
Sympathetic function			
Thermoregulatory sweat test (% surface area of anhidrosis)	Preganglionic and postganglionic cholinergic	Stimulation of hypothalamic temperature control centres	Cumbersome, whole-body test
Quantitative sudomotor axon reflex test (sweat output, latency)	Postganglionic cholinergic	Antidromic stimulation of peripheral fibre by axonal reflex	Needs specialized facilities
Heart rate and blood pressure responses			
Orthostatic tilt test	Adrenergic	Baroreceptor reflex	Impaired responses if intravascular volume is reduced
Postural adjustment ratio	Adrenergic	Baroreceptor reflex	Impaired responses if intravascular volume is reduced
Cold pressor test	Adrenergic	Baroreceptor reflex	Impaired responses if intravascular volume is reduced
Sustained hand grip	Adrenergic	Baroreceptor reflex	Impaired responses if intravascular volume is reduced
Plasma norepinephrine response to Postural changes	Postganglionic adrenergic	Baroreceptor stimulation	Moderate sensitivity, impaired response if intravascular volume is reduced
Intravenous edrophonium	Postganglionic adrenergic	Anticholinesterase 'stimulates' postganglionic fibre at prevertebral ganglia	False negatives caused by contributions to plasma norepinephrine from many organs
Parasympathetic function			
Heart rate (RR) variation with deep breathing	Parasympathetic	Vagal afferents stimulated by lung stretch	Best cardiovagal test available, but not a test of abdominal vagus
Supine/erect heart rate	Parasympathetic	Vagal stimulation by change in central blood volume	Cardiovagal test
Valsalva ratio (heart rate, max/min)	Parasympathetic	Vagal stimulation by change in central blood volume	Cardiovagal test
Gastric acid secretory or plasma pancreatic polypeptide response to modified sham feeding or hypoglycaemia	Parasympathetic	Stimulation of vagal nuclei by sham feeding or hypoglycaemia	Abdominal vagal test, critically dependent on avoidance of swallowing food during test
Nocturnal penile tumescence	Pelvic parasympathetic ⁷	Integrity of S2–4	Plethysmographic technique requiring special facilities
Cystometrographic response to bethanechol	Pelvic parasympathetic	Increase in intravesical pressure suggests denervation supersensitivity	Tests parasympathetic supply to bladder, not bowel

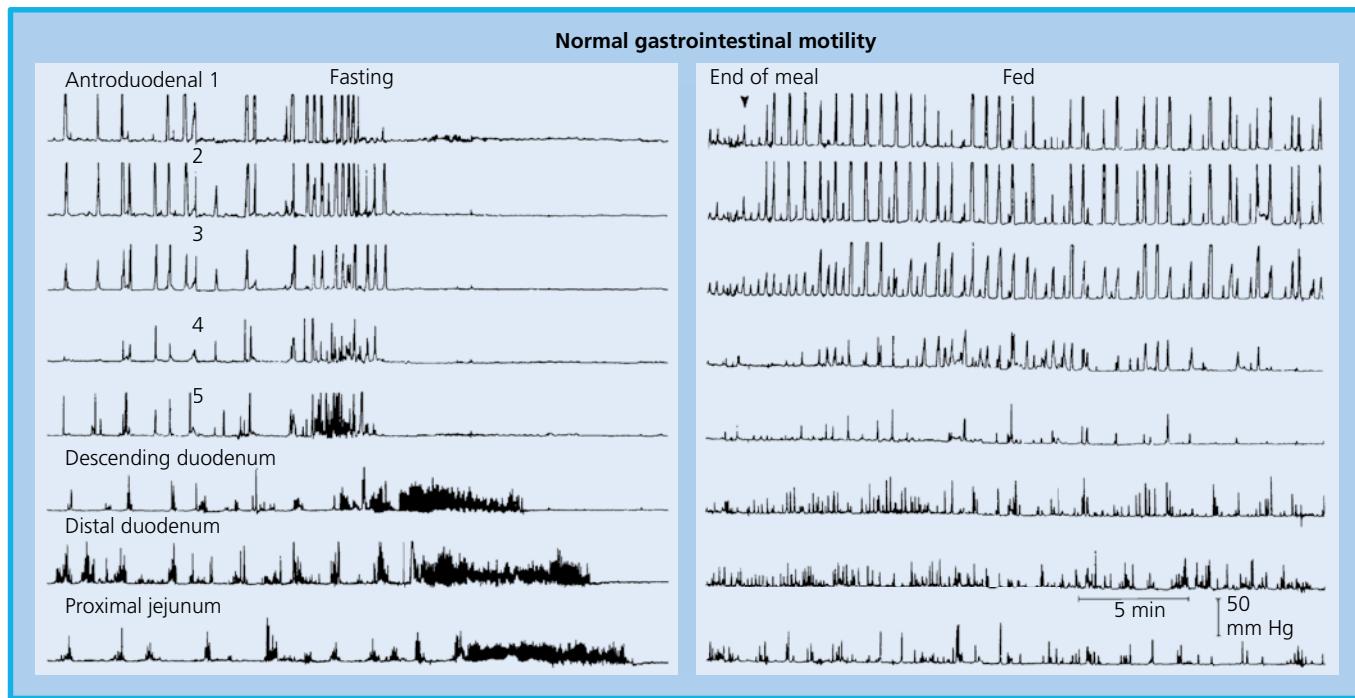

Figure 55.6 Normal manometric profile (fasting and post-prandial). The migrating motor complex characteristic of the fasting state is demonstrated by the presence of quiescence (phase I), intermittent activity (phase II), and an activity front (phase III). The post-prandial profile shows high-amplitude, irregular, but persistent phasic pressure activity at all levels. Source: Reproduced by permission from Malagelada et al. 1986 [114].

photoemission computed tomography (SPECT) or magnetic resonance imaging (MRI). Simpler approaches more widely available are a nutrient drink test (in which the maximum tolerated caloric load of less than 750 kcal would suggest impaired accommodation [110] and 206 kcal is diagnostic of impaired accommodation [111]), or a water load test where a volume ingested over five minutes is measured [111].

Barium X-rays of the small intestine or enterography with computed tomography should be considered only when the clinical features raise the possibility of small intestinal obstruction. Gastric emptying of solids should be quantified by scintigraphy or stable isotope breath test [112, 113], and antroduodenal manometry may be considered in selected circumstances. Measurements of pressure profiles in the stomach and small bowel can confirm motor disturbances and may facilitate the selection of patients for enteral feeding (Figure 55.6). People with gastroparesis due to predominant antral hypomotility as a result of diabetic enteropathy may tolerate feeding delivered directly into the small bowel, whereas those with a more generalized motility disorder may not.

Diarrhoea and constipation

The term *diabetic diarrhoea* was first coined in 1936 by Bargen at the Mayo Clinic to describe unexplained diarrhoea associated with severe diabetes [115]. Diabetic diarrhoea is typically chronic, may be episodic, and can be severe. Diarrhoea can occur at any time, but is often nocturnal and may be associated with anal incontinence, which may indicate internal anal sphincter dysfunction. Persons with diarrhoea commonly have symptoms of delayed gastric emptying such as early satiety, nausea, and vomiting.

Constipation may occur in isolation or alternate with episodes of diarrhoea. Many physicians regard constipation to be synonymous with infrequent bowel movements. It is important to characterize

symptoms because many people have misconceptions about normal bowel habits. For example, it is not necessary to have a bowel movement daily – the normal range varies from three bowel movements every week to every day. Moreover, by constipation, people refer to one or more of a variety of symptoms (i.e. infrequent stools, hard stools, excessive straining during defaecation, a sense of anorectal blockage during defaecation, the need for anal digitation during defaecation, and a sense of incomplete evacuation after defaecation) [116]. Some of these symptoms (e.g. a sense of anorectal blockage during defaecation) may suggest disordered evacuation. A careful rectal examination during relaxation and straining is needed to exclude rectal mucosal lesions and to detect the presence of rectal prolapse, rectocele, and disordered defaecation. Normally, voluntary contraction is accompanied by upward and anterior motion of the palpating finger towards the umbilicus as the puborectalis contracts. Conversely, the puborectalis should relax and the perineum should descend (by 2–4 cm) during simulated evacuation. The rectal examination may suggest features (i.e. reduced or increased perineal descent, paradoxical contraction of puborectalis) of defaecatory disorders.

Abdominal pain

People with diabetes are obviously susceptible to the usual causes of abdominal pain seen in the general population. There is an increased prevalence of gallstones because of altered gallbladder contractility and of mesenteric ischaemia caused by generalized atherosclerosis. However, there is little evidence that altered gallbladder contractility *per se* (i.e. in the absence of gallstones) causes symptoms. Thoracolumbar radiculopathy may result in pain in a girdle-like distribution that does not cross the midline. Specific tests are indicated if the clinical features of pain suggest these disorders. It is essential to elicit a careful history.

Diagnostic tests

Suspected gastric dysfunction

Typically, diagnostic testing is primarily guided by symptom pattern and severity. However, since persons with delayed gastric emptying are often asymptomatic, gastric emptying assessments should also be considered in those with unexplained hypoglycaemia. After initial testing to identify disturbances of transit, more detailed testing with intraluminal techniques (i.e. manometry and/or a barostat) may be useful for characterizing motor dysfunction and guiding therapy. Delayed gastric emptying can be documented by scintigraphy, stable isotope breath test, or the presence of a large amount of retained food in the stomach. Barium studies and scintigraphy using labelled liquid meals are of limited value for identifying dysmotility because the gastric emptying of liquids and semi-solids (e.g. mashed potatoes) frequently is normal, even in the presence of moderately severe symptoms. The tests that are available to measure gastric emptying non-invasively are summarized in Table 55.3.

Assessment of solid emptying by means of a radiolabel that tags the solid phase of the meal is a more sensitive test with a well-defined normal range. The proportion of radioisotope retained in the stomach at two and four hours distinguishes normal function from delayed gastric emptying with a sensitivity of 90% and a specificity of 70% [118]. The importance of obtaining scans for four hours after a meal cannot be overemphasized. Since gastric emptying is slow initially, it is not accurate to extrapolate emptying from scans taken for a shorter duration. Another useful test for measuring solid-phase gastric emptying utilizes a standardized meal with a biscuit enriched with ^{13}C , a substrate containing the stable isotope. When metabolized, the proteins, carbohydrates, and lipids of the *Spirulina platensis* or the medium-chain triglyceride, octanoate, give rise to respiratory CO_2 that is enriched in ^{13}C . Measurement of $^{13}\text{CO}_2$ breath content (a reflection of the amount of biscuit remaining in the stomach) by isotope ratio mass spectrometry allows the estimation of gastric emptying half-life [112, 113].

The wireless motility capsule using the SmartPill™ (Medtronic, Minneapolis, MN, USA) has been approved by the US Food and Drug Administration (FDA) for the evaluation of gastric emptying and colonic transit time in people with suspected slow transit

constipation, and for the measurement of pH, temperature, and pressure throughout the gastrointestinal tract [119]. It is a safe and practical alternative to gastric electrical stimulation [120]. Sensed data are transmitted by the single-use capsule to a receiver worn by the patient, and pH values from 0.5 to 9.0, pressure activity, and temperature are recorded. Gastric emptying time is defined as the time from capsule ingestion to a rise in pH from gastric baseline to >4.0, marking the passage of the capsule from the antrum to the duodenum. Normal emptying of the capsule should occur within five hours of ingestion. If it does not occur within six hours, a maximum gastric emptying time value of six hours is assigned [119]. The gastric emptying results with the wireless motility capsule are not as accurate as those using scintigraphy with a digestible solid meal. However, its advantages include point-of-care use in ambulatory settings and avoidance of the pitfalls of gastric electrical stimulation, such as radiation exposure, need for a gamma camera, and lack of standardized practices across centres [119]. The utility of the wireless motility capsule testing has been enhanced with data showing that pressure profile measurements recorded by the capsule can differentiate persons with diabetic gastroparesis from healthy individuals by the significantly lower numbers of contractions and motility indices [121].

Healthy individuals and (more likely) persons with gastroparesis may not have a phase III migrating motor complex contraction within six hours, when the next meal is given, and capsule emptying may be inhibited by the suspension of the migrating motor complex by the meal. Other limitations include possible difficulty with capsule ingestion and the potential for capsule retention or obstruction. Use of the capsule is contraindicated in children and those with a known history of oesophageal stricture.

For people with severe upper gastrointestinal symptoms, antro-pyloroduodenal manometry is a specialized technique that assesses pressure profiles in the stomach and small bowel and also guides management. Manometry may also reveal hypomotility of the gastric antrum and/or an intestinal neuropathy (Figures 55.6 and 55.7). Individuals with selective or dominant abnormalities of gastric function may be able to tolerate enteral feeding (delivered directly into the small bowel), unlike those with a more generalized motility disorder. Manometry may also reveal excessive tonic and phasic pressure activity at the pylorus [123]. Pyloric dysfunction is documented with a functional luminal imaging probe performed during endoscopy,

Table 55.3 Non-invasive measurements of gastric emptying.

Feature	Gastric emptying by scintigraphy	Stable isotope breath test	Wireless pressure and pH capsule
Indication/function measured	Gastric emptying	Gastric emptying	Emptying and pressure amplitude
Device, assembly or special requirements	External gamma camera and isotope-labelled meal	Breath collection vials and stable isotope-labelled meal	Intraluminal capsule with miniaturised strain gauge and pH measurement
Placement of device	–	–	Capsule swallowed
Performance/versatility/interpretation	Excellent, standardized meals, data acquisition and interpretation	Becoming standardized Performance related to mathematical analysis	Standard acquisition, delayed emptying fairly valid; pressures of unclear significance
Duration of study	Typically 4 h, could be added to small bowel and colon transit	3–4 h	6 h, could be added to small bowel and colon transit
Availability/potential use	+	+++	+
Costs	++	+	++

The '+' signs signify the lowest (+) to the highest (++) availability or potential use.

which assesses diameter, distensibility, and compliance of the pylorus [124]. It has been proposed that this measurement might facilitate selection of those for pyloric interventions for gastroparesis.

Gastric accommodation in response to meal ingestion may be impaired in diabetes [41, 125]. This may contribute to the gastrointestinal symptoms of nausea, bloating, and early satiety. Imaging of the stomach wall using ^{99m}Tc -pertechnetate allows measurement of gastric volume after meal ingestion.

Investigation of constipation

For persons with constipation, tests of colonic transit, anorectal manometry, and rectal balloon expulsion provide a useful start to investigation. Anorectal manometry and the rectal balloon expulsion test generally suffice to diagnose or exclude defaecation disorders; MRI or barium proctography is required only in selected cases. Colonic transit is often delayed in people with defaecatory disorders. Therefore, in those with slow colonic transit, slow transit constipation can only be diagnosed after excluding defaecatory disorders. Intraluminal assessments of colonic phasic motility (by manometry) and tone (by barostat) often reveal other dysfunctions (e.g. impaired contractile responses to a meal) and/or pharmacological stimuli (e.g. bisacodyl or neostigmine) in persons with slow-transit constipation. Colonic transit can be characterized by radiopaque markers, which, depending on the technique, take 5–7 days, or by scintigraphy, which takes 24–48 hours. Both techniques are equally accurate for identifying slow or rapid colonic transit.

Small intestinal dysmotility may manifest as one or more of the following features: abnormal migrating motor complexes, failure to convert from fasting to post-prandial motor pattern, and/or features of a vagal neuropathy (i.e. excessive number of fasting migrating motor complexes or persistent post-prandial migrating motor complexes). Assessment of stool fat provides a useful differentiation point for diabetic diarrhoea, as it indicates malabsorption as the pathophysiology leading to diarrhoea. An upper endoscopy provides an opportunity to obtain duodenal aspirates for bacterial overgrowth

and small bowel biopsy to exclude coeliac disease. Lactose or glucose hydrogen breath tests rely on substrate metabolism by bacterial overgrowth in the small intestine, with hydrogen release in breath excretion. However, studies have shown that the early peak is frequently due to rapid delivery of the substrate to the colon, with bacterial metabolism by normal colonic flora rather than small bowel bacterial overgrowth [126]. To reduce the potential impact of this confounding factor (i.e. rapid intestinal transit), a more restricted definition to diagnose small intestinal overgrowth may be preferable; that is, an early hydrogen peak (20 ppm), due to small intestinal bacteria, occurring at least 15 minutes before the later prolonged peak, corresponding to the passage of the remaining lactulose into the colon. However, even with more restricted definitions, the sensitivity and specificity of the lactulose hydrogen breath test in detecting small bowel bacterial overgrowth have been reported to be only 68% and 44%, respectively, and for the glucose breath test 62% and 83%, respectively [126].

Management

The principles of management are to address fluid and nutritional requirements, improve glycaemic management, and treat symptoms [127].

Gastroparesis and dyspepsia

The first step in the management of gastroparesis is to educate the person to use a small particle diet, aided with cooking of non-digestible fibre and homogenization of solids to a small particle size [128]. Although nutritional requirements and symptoms can be addressed to a variable extent in persons with mild and compensated gastroparesis, those with severe gastroparesis often require hospitalization for one or more of the following measures: intravenous hydration and correction of metabolic derangements (ketacidosis, uraemia, hypoglycaemia, hyperglycaemia), nasoenteric

decompression, and/or enteral nutrition to manage vomiting and nutritional requirements [95]. Parenteral nutrition may become necessary in cases of malnutrition. Bezoars may be mechanically disrupted during endoscopy, followed by gastric decompression to drain residual non-digestible particles.

Erythromycin, at a dose of 3 mg/kg body weight intravenously every eight hours, can accelerate gastric emptying [129, 130]. When oral intake is resumed, treatment with oral erythromycin, 250 mg three times a day for 1–2 weeks, is worthwhile. The prokinetic effects of erythromycin are limited by tachyphylaxis. Anecdotal findings suggest that erythromycin may be effective if courses are separated by a drug-free period, lasting for example two weeks. Hyperglycaemia interferes with the prokinetic effect of intravenous erythromycin on gastric emptying in people with and without diabetes [39]. Since both liquids and homogenized solids are more readily emptied from the stomach than solids, liquid or blended food is better tolerated. Frequent monitoring of blood glucose is essential during this phase; however, improved glycaemia did not improve gastric emptying in people with suboptimally controlled type 2 diabetes [62].

For individuals with severe gastroparesis who do not respond to the measures outlined, it may be necessary to bypass the stomach with a jejunal feeding tube. This procedure should be preceded by a trial of nasojejunal feeding for a few days, with infusion rates of at least 60 ml/h of iso-osmolar nutrient. It is preferable to place jejunal feeding tubes directly into the jejunum either by endoscopy or, if necessary, by laparoscopy or mini-laparotomy, rather than via percutaneous endoscopic gastrostomy tubes. Such tubes allow restoration of normal nutritional status, but they are not without adverse effects. There is no evidence to suggest that gastrectomy relieves symptoms or enhances quality of life. People with gastroparesis often have concomitant small intestinal denervation, which is likely to cause persistent symptoms after gastrectomy [50, 131].

If the individual remains symptomatic, other prokinetic agents may be considered as adjuncts. In the USA the only available medication is metoclopramide, a peripheral cholinergic and antidopaminergic agent. During acute administration, it initially enhances gastric emptying of liquids in diabetic gastroparesis, but its symptomatic efficacy is probably related to its central antiemetic effects. However, its long-term use is restricted by a decline in efficacy and by a troubling incidence of central nervous system side effects. Therefore, it is preferred to prescribe a dose of 10 mg three times a day, administered 30 minutes before meals, for a short duration; the higher dose is 20 mg three times a day. A systematic review of trials concluded that there was limited evidence to support the use of domperidone, which is another dopaminergic antagonist not approved for use in the USA [132]. Endoscopic injection of botulinum toxin into the pylorus was not effective in controlled studies primarily of idiopathic gastroparesis [133, 134]. The neurokinin 1 (NK1) antagonist aprepitant, 125 mg/d, improved secondary outcomes but not severity of nausea in a four-week multicentre, double-masked trial of 126 participants with nausea and vomiting (57% with delayed gastric emptying) [135]. New medications in development for diabetic gastroparesis are relamorelin [136] (a pentapeptide ghrelin agonist) and tradipitant [137] (an NK1 antagonist).

Relamorelin (RM-131) is a novel pentapeptide ghrelin receptor agonist with greater potency in increasing gastric emptying in animal pharmacology studies than other ghrelin mimetics [138]. In two randomized, double-blind, placebo-controlled, crossover studies conducted in 10 people with type 2 diabetes or type 1 diabetes and prior documentation of delayed gastric emptying, relamorelin

accelerated the gastric half-emptying time of solids [139, 140]. In a phase II study of persons with type 1 diabetes, relamorelin reduced upper gastrointestinal symptoms, with the most impressive effects being observed in those with high baseline vomiting [141]. In individuals with chronic constipation, relamorelin also accelerated colonic transit [142].

Although the FDA recognizes gastric electrical stimulation as a humanitarian use device for refractory gastroparesis, its use for this indication is controversial. Although published data suggest that the device reduces vomiting frequency only when the device is on, data submitted to the FDA indicated that electrical stimulation reduced vomiting frequency to a similar extent with the device turned off or on, suggesting a placebo response [143, 144]. Moreover, the device is expensive and does not accelerate gastric emptying. Between 10% and 20% of individuals have device-related complications. Recent data from a large European multicentre study showed reduced frequency of refractory vomiting in persons with and without diabetes; however, this was not associated with acceleration of gastric emptying or improved quality of life [145].

Pyloromyotomy performed either laparoscopically or endoscopically is increasingly offered to individuals with diabetic gastroparesis as well as to persons with idiopathic or postsurgical gastroparesis. At least four systematic reviews and meta-analyses [146–149] that appraised approximately 10 open-label clinical trials have demonstrated improvement in Gastroparesis Cardinal Symptom Index as well as gastric emptying by scintigraphy in the overall appraisal of gastric per oral endoscopic myotomy (G-POEM). Nevertheless, sham controlled studies are required, and the impact on outcomes of comorbidity including vagal dysfunction, antral hypomotility, and objective evidence of pyloric dysfunction requires further elucidation [150].

Diabetic diarrhoea

Diabetic diarrhoea is treated symptomatically with loperamide, preferably administered 30 minutes before meals, in the dose range of 2–16 mg/d. Consumption of artificial sweeteners that contain the osmotically active sugar substitute sorbitol should be reduced. Second-line approaches are clonidine, 0.1 mg orally [151] or by patch, in those who do not experience significant postural hypotension. Amitriptyline, which has anticholinergic effects, may reduce intestinal cramping and transit. Octreotide (25–50 µg subcutaneously 5–10 minutes before meals) delays small intestinal transit [152] and may also reduce secretory diarrhoea associated with rapid intestinal transit [153]. Although it was suggested that octreotide reduces small bowel bacterial overgrowth in chronic intestinal pseudo-obstruction [154], the study assessed bacterial overgrowth by breath testing. Indeed, by delaying small intestinal transit, octreotide may predispose to bacterial overgrowth. Regulating stool consistency may also improve faecal continence. In addition, pelvic floor retraining with biofeedback therapy can improve rectal sensation and enhance coordination between perception of rectal distension and contraction of the external anal sphincter [80]. However, biofeedback therapy is less effective in people with markedly reduced rectal sensation. A descending colostomy may be required and may improve the quality of life in those with severe diarrhoea associated with faecal incontinence.

Constipation

For people without pelvic floor dysfunction, chronic constipation can be generally managed with pharmacological agents (i.e. osmotic and stimulant laxatives) [155]. Pelvic floor retraining by biofeedback

therapy is the cornerstone for managing defaecatory disorders; laxatives are used as an adjunct to pelvic floor retraining [156]. Fibre supplementation, either with dietary supplementation or with fibre products (e.g. psyllium, 15–18 g/d), should be considered in people with inadequate fibre intake. Of the osmotic laxatives, polyethylene glycol (up to 17 g in 225 ml of water once or twice a day) is a widely used and safe over-the-counter agent. Although lactulose is a poorly absorbed disaccharide, lactulose syrup contains small amounts of absorbable sugars and may increase hyperglycaemia. Magnesium compounds are safe, but individuals with impaired renal function may develop magnesium retention. Bisacodyl or glycerine suppositories are useful rescue agents in people who have not had a bowel movement for two days. If possible, suppositories should be administered 30 minutes after a meal to synergize pharmacological therapy with the physiological response to a meal. By activating chloride channels and inducing colonic secretion,

lubiprostone accelerated colonic transit in healthy individuals and improved symptoms in functional constipation [157, 158] and diabetes and constipation [159].

The anticholinesterase pyridostigmine is efficacious in relief of constipation in individuals with diabetes and constipation, and the effect is also observed in those with autonomic neuropathy [160, 161]. Several other medications are available for the treatment of chronic constipation [162], although they have not been formally or specifically tested in persons with diabetes.

Key points

- The background to the present chapter is a need to present the past decades' scientific discoveries on the relationship between diabetes and oral health.
- The aim is to emphasize the importance of good oral health, which is now to be considered part of the therapeutic modalities for prevention and treatment of diabetes.

- The chapter deals with the association of diabetes with various oral diseases, including gingivitis, periodontitis, caries, hyposalivation, candidal infection, and cancer; of these, periodontitis is the most important for daily clinical management of individuals with diabetes.

Recent decades have significantly widened the perspectives of the association of medical diseases with diseases of the oral cavity, the interaction of oral tissues with diabetes probably being best documented. Hyperglycaemia, and even slightly elevated blood glucose levels, adversely affects oral health, with manifestations including widely different diseases and conditions, which include gingivitis and periodontitis, caries, candidal infection, decreased saliva secretion, and oral cancer. Oral infections associated with local and systemic inflammatory responses, on the other hand, adversely affect blood glucose levels [1].

inflammation limited to the gingival soft tissue. Gingivitis affects 50–90% of the adult population [3, 4] and is characterized by common signs of inflammation in the tooth-surrounding soft tissue, including redness and oedema (Figure 56.2). Bleeding is common during oral hygiene procedures and chewing in individuals with gingivitis, but pain is uncommon, which is why the inflammatory process may run an unnoticed course. Providing there is sufficient oral hygiene with tooth brushing and interdental cleaning, the dental biofilm can be removed, and the inflammatory lesion resolved without leaving permanent damage to the tooth-supporting tissues. However, without adequate biofilm removal, the condition may progress to periodontitis.

Gingivitis and periodontitis

Most scientific data deal with interactions of periodontal diseases and diabetes, which is probably most important, because it is bidirectional and may have serious consequences for the course of both diseases. Several reviews have focused on the bidirectional association of periodontitis with diabetes, and a recent consensus report and treatment guidelines summarize the outcome of a joint workshop on periodontal diseases and diabetes by the International Diabetes Federation (IDF) and the European Federation of Periodontology (EFP) [2].

Gingivitis

The periodontal tissues are shown in Figure 56.1. Since the surface of teeth is not constantly renewed, as occurs for other surfaces of the human organism, there is an obvious possibility for bacterial accumulation with biofilm formation (plaque) on the dental surfaces. The biofilm typically accumulates along the gingival margin and if not mechanically removed, it grows and invades the gingival crevice. In response to the biofilm formation, gingivitis is a reversible

Periodontitis

Periodontitis, which is always preceded by gingivitis, is a common multifactorial inflammatory disease initiated by the accumulation of opportunistic pathogenic bacteria in biofilms formed at the tooth surface below the gingival margin [2] (Figure 56.1). The outcome of the inflammatory process includes deepening of the gingival crevice, resulting in formation of a gingival pocket with an anaerobic environment. The associated dysbiosis of the biofilm microbiota, invading the gingival pocket, leads to a non-resolving and destructive inflammatory response [5, 6]. Population studies have revealed a prevalence of around 50% in its mildest forms in adults, rising to more than 60% in individuals aged more than 65 years [7, 8]. Radiographic bone loss and clinical registrations corresponding to periodontitis in a recent Scandinavian study have been observed in as much as 72.4%. The prevalence of periodontitis increases after 40 years of age, with severe forms occurring primarily after 60 years of age [9]. Severe periodontitis affects around 11% of the adult global population [10] and is a major cause of tooth loss,

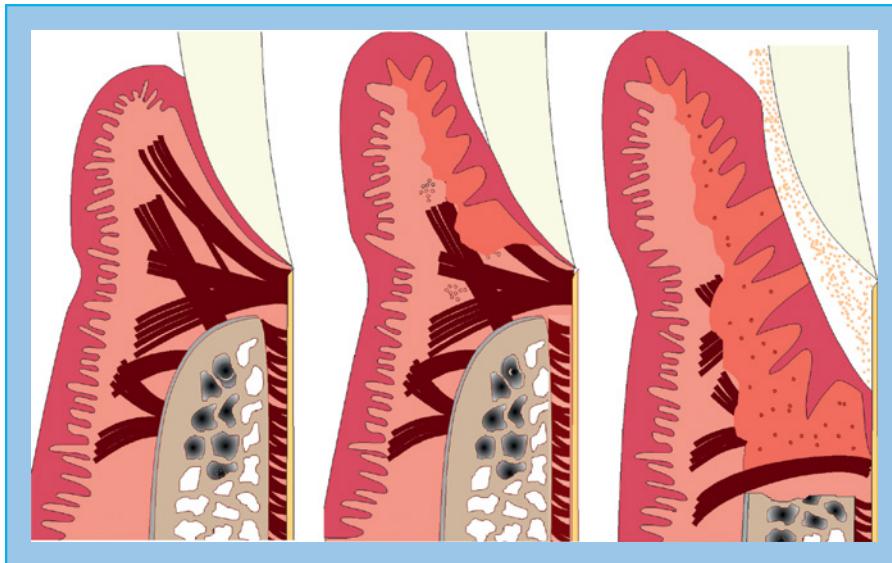

Figure 56.1 Schematic drawing of the periodontal soft and hard tissue close to the gingival margin: em, enamel; den, dentin; bone, alveolar bone; gin, gingival soft tissue with epithelial attachment to enamel in the healthy periodontum; root, root covered by cementum with periodontal ligament attaching the root to the alveolar bone. In gingivitis the gingiva is inflamed with oedema and the architecture of the

epithelial attachment is changed. In periodontitis the gingival connective tissue, the periodontal ligament, and the supporting alveolar bone are undergoing degradation. There is a bacterial biofilm in the gingival pocket, and through ulcerations in the pocket epithelium bacteria have direct access to the connective tissue and the circulation. Source: © Palle Holmstrup.

Figure 56.2 Gingivitis with redness and slight swelling of marginal gingiva.

nutritional compromise, altered speech, low self-esteem, and poor quality of life [11, 12]. Periodontitis is considered the second most prevalent oral disease worldwide [13], and is the fourth most frequent illness on the Disease Global burden list [14].

The disease results in degradation of the periodontal tissues with irreversible attachment loss (Figure 56.3), including loss of alveolar bone and deepened gingival pockets with ulcerations (Figure 56.1), associated with inflammation and microbial dysbiosis. The inflammatory processes account for the tissue breakdown, which may result in gingival retraction visible as elongated teeth. As the result of alveolar bone loss (Figure 56.4) the affected teeth may loosen, change position, and ultimately, if left untreated, they may be lost (Figures 56.5 and 56.6) [15].

Determined by several factors including oral hygiene, periodontal care attendance, lifestyle, tobacco habits, medical diseases, and genetics, the individual susceptibility to periodontitis varies greatly.

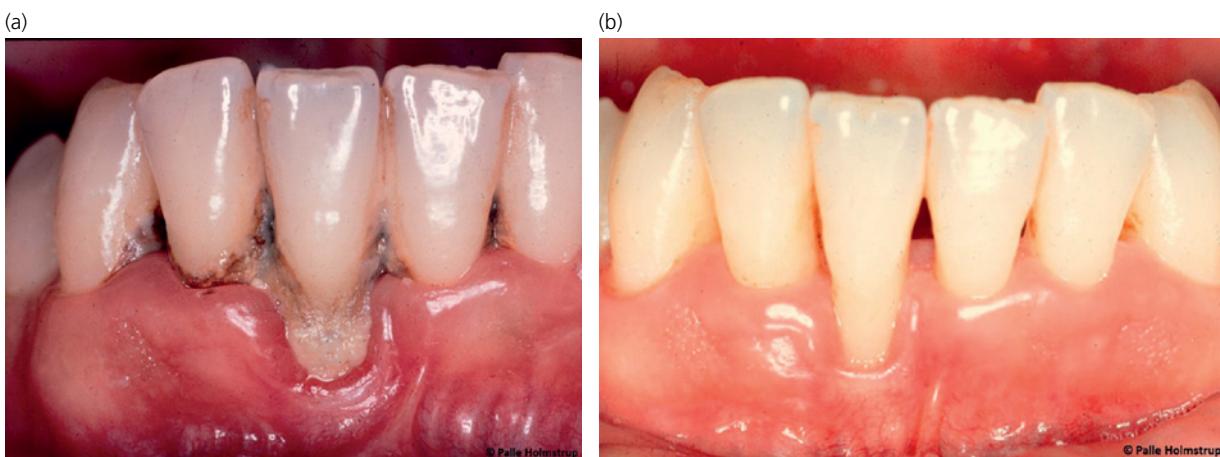

Figure 56.3 (a) Periodontitis with plaque covering dental calculus at the exposed root surface. Interdental papillae are lost, and the gingival margin shows irregular oedematous condition with retraction. (b) The same individual as in (a) after periodontal treatment. There is no longer inflammation, but the periodontal tissue degradation is irreversible.

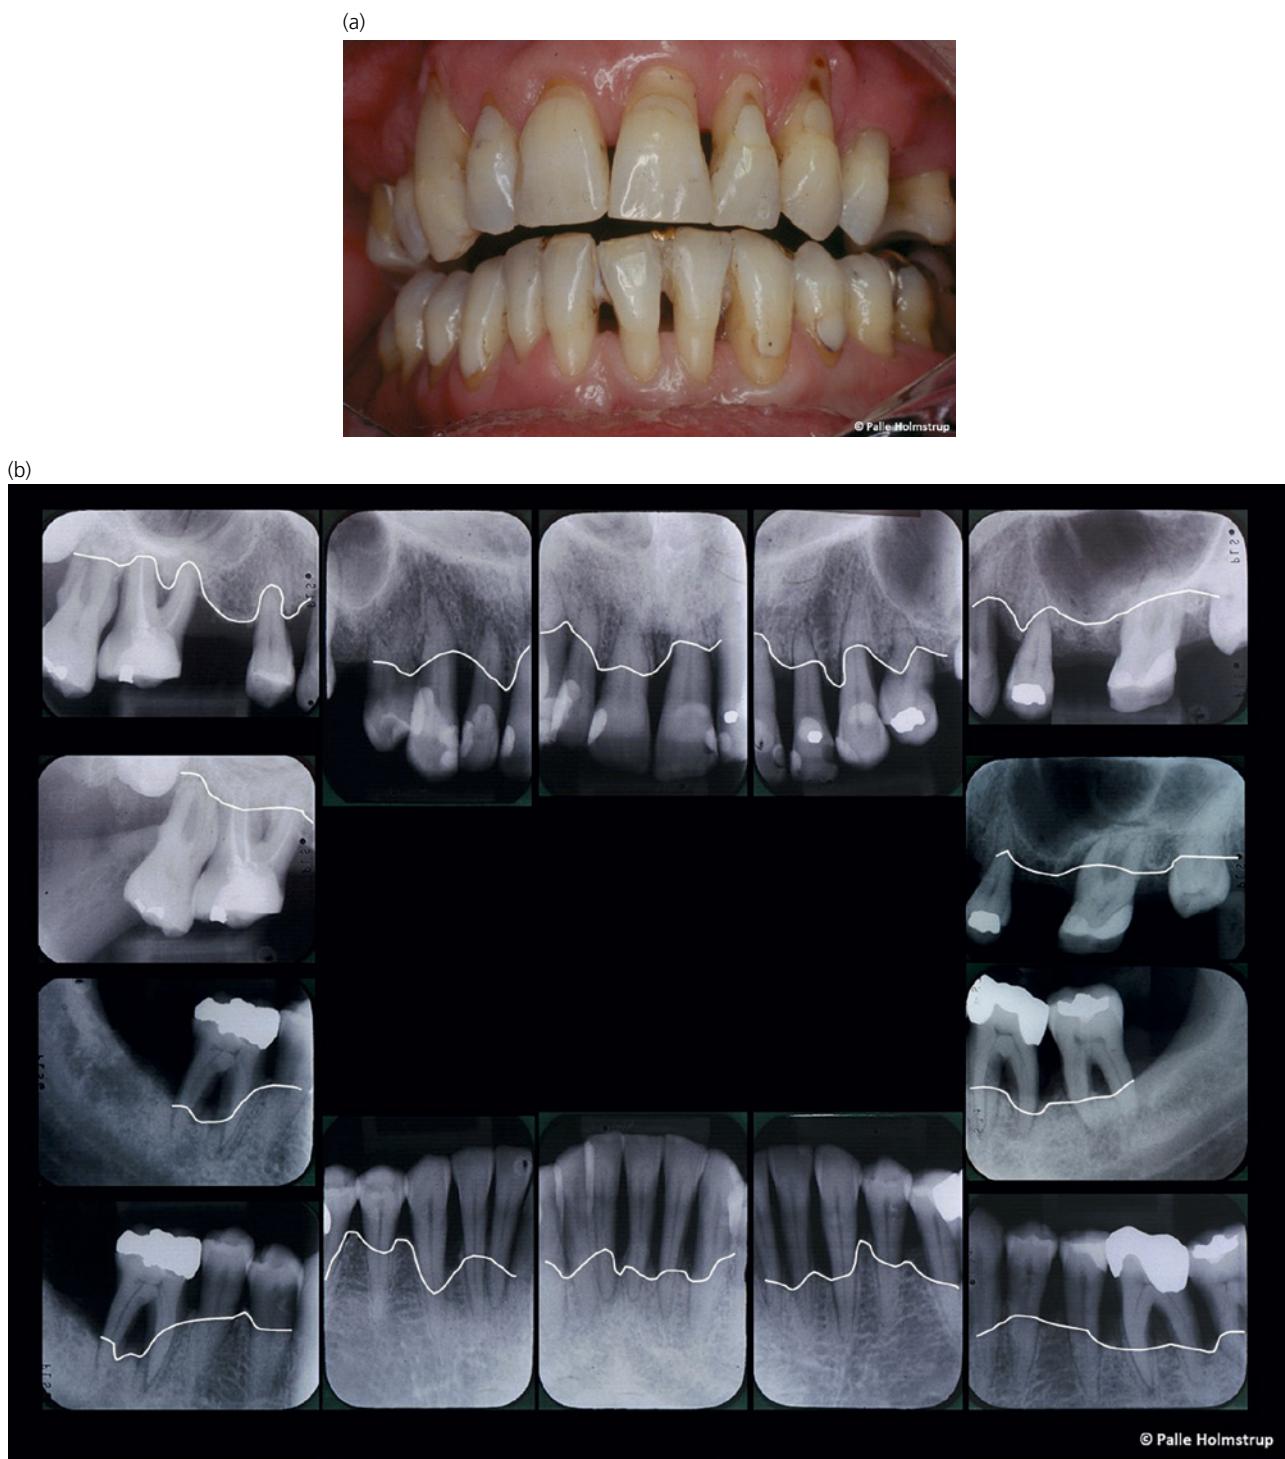

Figure 56.4 (a) A 47-year-old person with severe periodontitis causing elongated teeth due to loss of tooth-supporting tissue. (b) The same person as in (a). X-rays demonstrate major loss of alveolar bone due to severe periodontitis. Margin of bone marked with white line. While the pristine level of the bone margin is approximately 2 mm from the crown of the teeth, the supporting bone around several teeth is limited to the periapical part of the root.

It has been demonstrated in a twin study that genetics may account for as much as half of the tissue destruction [16].

An important characteristic of periodontitis is the deepened gingival pockets, the epithelial lining of which becomes ulcerated due to inflammation (Figure 56.1). Thereby bacteria from the pockets can penetrate the gingival soft tissue including the vessels, resulting

in bacteraemia. This happens as a consequence of everyday procedures like chewing, tooth brushing, and flossing in individuals with periodontitis [17].

Due to its vague clinical symptoms, such as gingival oedema and bleeding, the course of periodontitis is often unnoticed by the patient until tooth loosening and changed position occur (Figure 56.5).

Figure 56.5 Severe periodontitis has caused displacement of the teeth with diastemata between upper incisors. Calculus on lower incisors.

Figure 56.6 Severe periodontitis with major loss of supporting tissue, elongated teeth, exposure of roots, and loosening. Accumulation of plaque on the root surfaces.

These are often the reason for seeking treatment. Professional root scaling with removal of biofilm and calculus is essential to stop progression of the disease. In cases with deep pockets, surgical periodontal treatment aiming at achieving improved clinical attachment levels and reducing pocket depths may be needed.

Association of diabetes with gingivitis and periodontitis

Numerous studies and reviews have described the association of diabetes with oral diseases [2, 18–21]. The incidence of gingivitis is particularly high in children and adolescents with newly discovered

type 1 diabetes, and in individuals with diabetes with glycated haemoglobin ($\text{HbA}_{1\text{c}}$) values above 10% (86 mmol/mol) [22, 23]. Also, a higher incidence of plaque and gingivitis has been found in adolescents with both well- and dysregulated type 1 diabetes than in adolescents without diabetes [24]. In addition, children with type 1 diabetes and type 2 diabetes, respectively, generally have an increased gingival bleeding tendency through puberty, after which it appears to decrease [25].

Several cross-sectional and longitudinal studies have demonstrated that both individuals with type 1 diabetes and those with type 2 diabetes have an increased risk and severity of periodontitis compared to individuals without diabetes, and periodontitis is often mentioned as the sixth complication of diabetes [20, 26–39]. The overall risk of periodontitis in persons with diabetes has been estimated to increase by a factor of 2–3 [26]. An additional important characteristic of periodontitis in individuals with diabetes is a poorer outcome of periodontal therapy [27].

In type 1 diabetes, increased incidence and severity of periodontitis are associated with elevated $\text{HbA}_{1\text{c}}$, but in addition age (>32 years), duration of diabetes (>10–24 years), tobacco smoking, presence of late diabetes-related complications, and dental care habits seem to be important to the development and progression of periodontitis [22, 28].

The level of metabolic control determines the susceptibility to progression from gingivitis to periodontitis, and elevated $\text{HbA}_{1\text{c}}$ is an important determinant of periodontal breakdown in both individuals with type 1 diabetes and those with type 2 diabetes [29–31], with a direct correlation between periodontal health and $\text{HbA}_{1\text{c}}$ in persons with type 2 diabetes [19, 31–33]. Thus, well-managed diabetes is a prerequisite for maintaining periodontal health [34]. Moreover, the prevalence of periodontal sites with moderate to severe attachment loss also depends on the duration of diabetes [35]. Figure 56.7 illustrates the greater prevalence of moderate or severe periodontitis in people with sub-optimally or well-managed diabetes compared to individuals without diabetes. It appears that the prevalence of moderate or severe periodontitis in individuals with diabetes is about double that of those without and triple in the youngest group aged 30–44 years with sub-optimally managed diabetes compared to those without diabetes [36, 37].

To reduce the unrecognized course of periodontitis with tissue loss, it is advisable to establish a system that enables easy access to routine periodontal examination of persons with diabetes [1, 38].

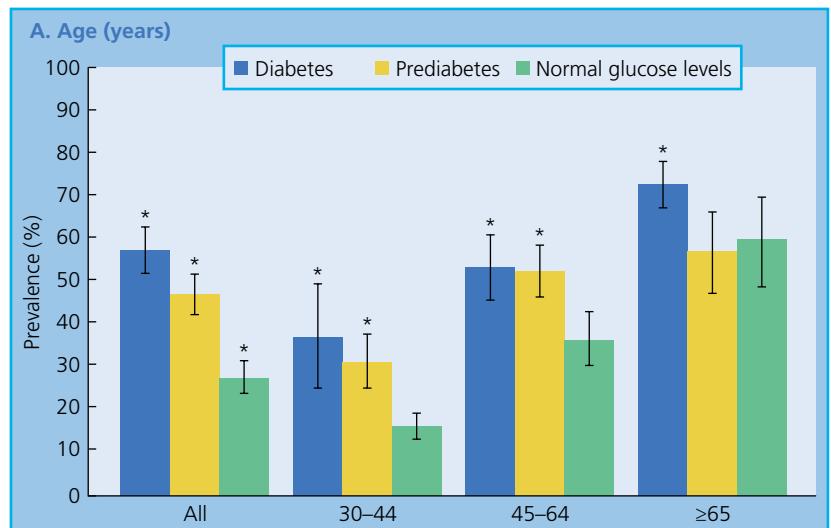

Figure 56.7 There is a greater prevalence of moderate or severe periodontitis in people with sub-optimally or well-managed diabetes compared to individuals without diabetes. Source: Reproduced by permission from Borgnakke et al. 2017 [36].

Dental health education and surveillance may be particularly important in this population, since sub-optimal metabolic management is often associated with poor oral hygiene [39].

Several studies and reviews have shown that periodontitis adversely affects blood glucose levels even with increased HbA_{1c} in individuals without diabetes [40, 41]. Elevated HbA_{1c} levels were more frequently seen in individuals examined in the dental clinic with periodontitis than in those without [42]. Thus, the more severe the periodontal condition, the poorer glycaemic status becomes, and the more diabetes-related complications are seen [2, 41, 43–45]. Analyses of data from a nationwide database in Taiwan have shown that people with severe periodontitis and in need of surgical treatment after confounder adjustment had a 23% increased risk of developing overt type 2 diabetes within a period of two years [46]. Studies from other countries have confirmed this finding [41]. Further clear evidence of the significance of periodontitis for the course of diabetes comes from clinical studies on the effect of periodontal treatment in individuals with diabetes (see later).

The counterpart to periodontitis around dental implants is denoted peri-implantitis. It is characterized by tissue breakdown including bone resorption around dental implants, with possible disintegration of the implant, and hyperglycaemia may also be associated with an increased risk of peri-implantitis like periodontitis [47, 48].

It can be concluded that well-managed diabetes does not imply an increased risk of attachment loss, but it is a challenge that both periodontitis and type 2 diabetes have a quiet, insidious course, and that many people do not know that they have periodontitis, pre-diabetes, or overt type 2 diabetes. Because the bidirectional interaction of the two diseases has a major impact on the affected individuals, dentists and medical doctors should be aware of the interaction of the diseases.

Pathogenic mechanisms linking diabetes and periodontitis

Diabetes and periodontitis, like several other inflammatory diseases, share several risk indicators including socioeconomic factors and smoking [49]. They also possess pathogenic similarity in their shared inflammatory background, which is why inflammatory interaction of the two diseases is an obvious possible driver of their mutual interaction.

A dysregulated immune system is central to the pathogenesis of diabetes and its associated complications. Systemic changes in cytokine levels have an impact on the pathogenesis of type 2 diabetes, which is associated with several physiological, nutritional, and metabolic changes, including hyperglycaemia, production of advanced glycation end-products (AGEs), hyperlipidaemia, and increased adiposity [50]. These mechanisms can contribute to the deterioration of the individual's periodontal condition [51]. Persistent hyperglycaemia results in glycation of proteins and eventually conversion to AGEs, which may lead to immune dysregulation with a long-lasting inflammatory state and a weakened self-limitation and resolution of immune responses, which are characteristic of periodontitis [51].

Many studies have investigated pathogenic pathways by which diabetes may have an impact on the course of periodontitis [52–55]. These include studies showing an impact of the level of hyperglycaemia in people with normoglycaemia or pre-diabetes as well as those with diabetes on the composition of the periodontal microbiota [56–58].

Clinical and animal studies have demonstrated elevated gingival levels of several factors that may all potentiate tissue destruction in people with sub-optimally managed diabetes. These include interleukin 1β (IL1-β), tumour necrosis factor α (TNF-α), IL-6, receptor activator of nuclear factor kappa B ligand (RANKL)/osteoprotegerin (OPG), and reactive oxygen species (ROS). In addition, individuals with diabetes and periodontitis exhibit high levels of both circulating TNF-α, C-reactive protein (CRP), and ROS, and successful periodontal treatment reduces these levels [55].

The binding of AGE to its receptor (RAGE) may result in the synthesis of pro-inflammatory cytokines, activation of nuclear transcription factor-κB (NF-κB), and production of ROS [59], all of which may result in increased cellular apoptosis, reduced bone formation, and increased bone resorption, as thoroughly reviewed [52–54]. A summarizing model of a mechanism of diabetes-related bone loss in periodontitis is presented in Figure 56.8 [52, 60].

Interaction of AGEs with toll-like receptors (TLRs) has been described, and increased expression of TLR2, TLR4, and TLR9 has been found in periodontitis-affected tissues of individuals with diabetes, compared to similar tissue from people without diabetes [61]. Further investigations of the TLR-mediated pathways in diabetes and periodontitis are obviously needed.

The role of neutrophils in the development of periodontitis in general is considered protective, and impaired neutrophil function may account for an increased susceptibility to periodontitis. Indeed, neutrophil function in individuals with diabetes and periodontitis has been studied intensively. The outcome of studies based on peripheral neutrophils may conceivably differ from that of neutrophils located in periodontal tissues. However, signs of compromised neutrophil function have been found in persons with type 2 diabetes and periodontitis [62].

Although an impact of periodontitis on diabetes may appear obvious, there is still limited evidence to understand the mechanistic pathways of periodontitis's influence on diabetes, while most is still speculative. Most studies demonstrate that circulating pro-inflammatory mediators are elevated in individuals with diabetes and periodontitis, in particular TNF-α, CRP, and mediators of oxidative stress. Taken together, these mediators may affect glycaemic levels [2].

High levels of CRP in individuals with both diabetes and periodontitis have been associated with increased HbA_{1c}, and since periodontitis itself may account for higher levels of CRP, the additional systemic inflammation associated with periodontitis may be responsible for the increased HbA_{1c} in individuals with diabetes and periodontitis [40]. Insulin resistance in people with periodontitis and diabetes may also be promoted by hyperreactive neutrophils producing ROS, which, in turn, may stimulate pro-inflammatory pathways [63]. An obvious similarity of the two diseases also includes an increased level of oxidative stress [64].

Experimental studies in rodents have provided insight into the possible interactions between periodontitis and diabetes [65]. Interestingly, ligature-induced periodontitis has been shown to deteriorate metabolic control in rats with type 2 diabetes, with an increase in glucose tolerance of 30% and an increase in IL-1β in adipose tissue compared to rats with diabetes, but without periodontitis [66]. In pre-diabetic rats with ligature-induced periodontitis glucose tolerance was also significantly impaired, which suggests that periodontitis may facilitate the development of overt diabetes [67]. Moreover, the pre-diabetic rats with periodontitis developed renal alterations including kidney hypertrophy and a tendency for increased glomerular volume [68].

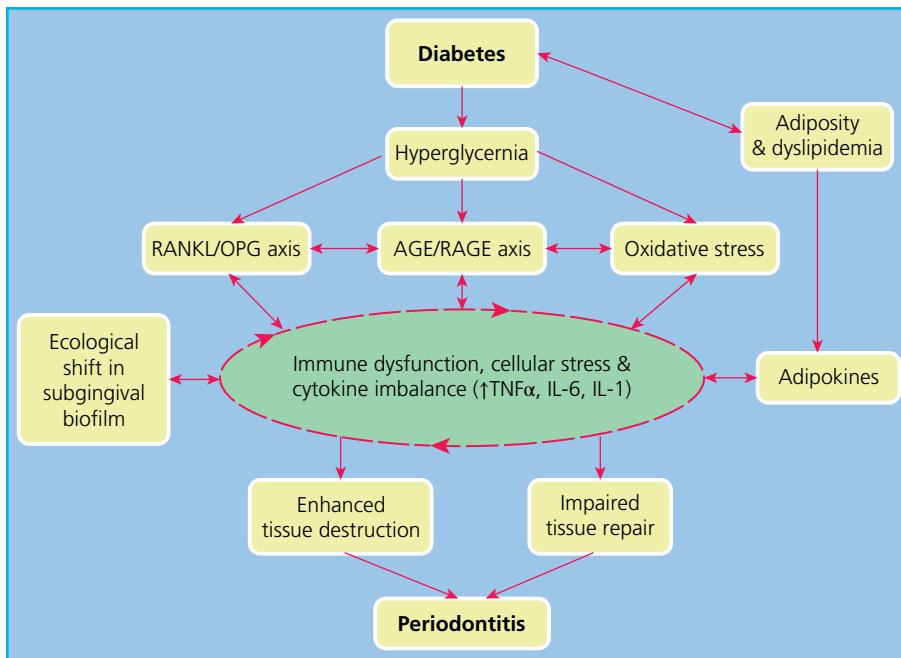

Figure 56.8 The network of potential mechanisms involved in the pathogenesis of periodontitis in diabetes. The hyperglycaemic state that characterizes diabetes has several deleterious effects. It drives the formation of irreversible advanced glycation end-products (AGEs) and the expression of their chief signalling receptor RAGE. This interaction, in turn, leads to immune dysfunction, alters the phenotype and function of other key cells in the periodontium, and contributes to cytokine imbalance with increased generation of certain pro-inflammatory cytokines. Hyperglycaemia also contributes to enhanced levels of reactive oxygen species (ROS) and a state of oxidative stress, both directly and indirectly through the AGE/RAGE axis, promoting quantitative and qualitative shifts in cytokine profiles. Finally, hyperglycaemia modulates the receptor activator of nuclear factor- κ B ligand (RANKL)/osteoprotegerin (OPG) ratio, again directly and indirectly via the AGE/RAGE axis, tipping the balance towards enhanced inflammation and destruction. All of this, complemented by the effects of ecological shifts in the subgingival biofilm and the circulating adipokines generated due to diabetes-associated adiposity and dyslipidaemia, drive this vicious cycle of cellular

Both the release of pro-inflammatory mediators and the presence of bacteria in the periodontal pockets, which, as the result of daily procedures such as chewing, tooth brushing, and flossing, may spread after penetration of the vasculature [69], are possible mediators of systemic consequences [20]. Moreover, as described for *P. gingivalis*, which is closely associated with periodontitis, microorganisms may evade attack from circulating phagocytes via so-called immune adherence by binding to complement receptor 1 at the surface of erythrocytes [70]. This means that *P. gingivalis* exploits erythrocytes as a transport vehicle, rendering it inaccessible to attack by phagocytes, thereby playing a role in the development of systemic diseases, for instance by increasing systemic low-grade inflammation, as previously shown by a higher plasma level of IL-6 [71].

Thus, pro-inflammatory cytokines produced locally in the inflamed periodontal tissues, where they are involved in tissue-destructive processes, may ‘spill over’ to the circulation. This as well as increased cytokine production due to bacteraemia may have a systemic impact and contribute to a state of elevated systemic low-grade inflammation [72–74]. Dysregulation of the cytokine production is also essential for the pathogenesis of diabetes [50]. Thus, both diabetes and periodontitis may be associated with increased systemic low-grade inflammation and pro-inflammatory cytokines, including TNF- α , IL-1- β , IL-6, and IL-18,

dysfunction and inflammation. The end result is a loss of equilibrium where enhanced periodontal tissue destruction and impaired repair ensue, leading to accelerated and severe periodontitis. Importantly, as shown, several of the associations between the different elements in the figure are bidirectional, for example the pro-inflammatory state further feeds the generation of AGEs, ROS, and adipokines, increases the RANKL/OPG ratio, and helps pathogenic subgingival bacteria thrive. It is also important to note that the amount and quality of evidence supporting the various pathways in this figure vary, and that although the goal is to depict the major mechanisms and networks described in the literature, other pathways and links among the various elements shown do exist, but cannot easily be demonstrated in a single schematic. Finally, the processes outlined are potentially modified by several other factors, such as genetics, age, smoking, and stress, all of which may contribute significantly to inter-individual variations in disease experience. IL, interleukin; TNF, tumour necrosis factor. which are increased in both diseases. Increased cytokine levels may contribute to insulin resistance and to diabetes-related complications, as well as to destruction of pancreatic β cells [75–78]. Interestingly, adipose tissue is an important source of cytokine production, and obesity may predispose to both type 2 diabetes and periodontitis [79–83], although the significance of obesity for periodontal tissue degradation is still to be resolved [84].

β cells from individuals with periodontitis produce a pro-inflammatory cytokine profile similar to that of β cells from individuals with type 2 diabetes [85]. Finally, hyperlipidaemia seems to interact with diabetes and periodontitis by increasing the risk of both diseases. The production of pro-inflammatory cytokines is increased by hyperlipidaemia, and this may aggravate both insulin resistance and periodontitis [86].

Periodontitis and late diabetes-related complications

A number of diabetes-related complications have been investigated in relation to periodontitis and a majority of the studies have shown a higher association or risk of severe periodontitis and late diabetes-related complications. After confounder adjustment, retinopathy appears to be significantly associated with periodontitis, and there are indications of a correlation of periodontitis severity with severity of retinopathy [2]. Periodontitis also appears to be significantly

associated with renal complications in both type 1 diabetes and type 2 diabetes. The occurrence of neuropathic foot ulceration has been associated with periodontitis too [2]. Both diabetes and periodontitis are independently associated with cardiovascular diseases. Therefore, it is not surprising that when the two diseases come together there is an increased risk of cardiovascular diseases. Thus, in type 2 diabetes cardiovascular complications appear to be significantly associated with periodontitis, and overall mortality is significantly higher in these individuals also suffering from periodontitis [2].

Significance of periodontal treatment for the course of diabetes

The treatment of gingivitis and periodontitis includes mechanical removal of dental biofilm and calculus. The responding reduction of clinical inflammation is followed by reduced systemic low-grade inflammation, as reflected in reduced inflammatory markers; that is, IL-6, TNF- α , and CRP in serum [87, 88]. The available scientific evidence indicates that individuals with diabetes can successfully receive periodontal treatment provided that effective self-care is conducted. Both clinical periodontal and local inflammatory measures improve after non-surgical treatment even in people with sub-optimally managed diabetes [2].

Many studies have examined the role of periodontal treatment for the course of diabetes, but long-term randomized clinical trials are scarce. The studies are characterized by different inclusion criteria, including various types of diabetes, with few individuals with type 1 diabetes included, and various diagnostic criteria for a case of periodontitis as well as various outcome measures. Moreover, stratification for confounders such as smoking, overweight, and medication is difficult. Meta-analyses of short-duration studies [88–90] indicate a positive effect on metabolic management of non-surgical periodontal treatment. This is particularly evident in individuals with type 2 diabetes. The meta-analyses showed that non-surgical periodontal treatment significantly reduced HbA_{1c} and fasting plasma glucose in people with diabetes. The mean decrease of HbA_{1c} was approximately 0.3–0.6% (3–6 mmol/mol) and the decrease in fasting plasma glucose was 9.0–13.6 mg/dl (0.5–0.8 mmol/l) after 3–6 months. Moreover, markers of systemic inflammation were reduced – that is, TNF- α (-1.33 ng/l) and hs-CRP (-1.28 mg/l) – but there was no positive effect of adjunctive antimicrobials. Interestingly, a recent well-conducted UK study, involving 264 individuals with diabetes and periodontitis followed for one year, showed that intensive periodontal treatment reduced HbA_{1c} by 0.6 percentage points (7 mmol/mol) compared with the control group after correction for background factors [91]. As another British study has shown that a 0.9 percentage point (10 mmol/mol) reduction in HbA_{1c} value can lead to a 10% reduction in mortality, such a reduction may be crucial for the course of diabetes [92].

A model-based cost-effectiveness analysis of periodontal treatment among individuals with type 2 diabetes has shown that providing non-surgical periodontal treatment for people with type 2 diabetes and periodontitis would likely have meaningful public health benefits. Substantial reductions in morbidity would most likely be observed, including reduced tooth loss and less microvascular disease via improved glycaemic management. Expanding periodontal treatment among individuals with type 2 diabetes would thus be cost saving or cost-effective [93, 94].

The reported effect of periodontal treatment has led to new guidelines from the National Health Service (NHS) in England emphasizing the importance of routine periodontal treatment of

individuals with diabetes, as well as the importance of periodontal treatment in all people with periodontitis to prevent development of overt type 2 diabetes [38].

Globally, almost half (46.5%) of all people with type 2 diabetes (192.8 million) are estimated to be unaware of their disease [19, 95], and dentists may help reduce the number with undiagnosed type 2 diabetes. Dentists see their clients regularly, which provides an obvious opportunity for the identification of early signs of undiagnosed type 2 diabetes, such as altered courses of periodontal attachment loss and emerging infection (oral candidiasis). A Danish study showed that 3.1% of 291 examined individuals without diagnosed type 2 diabetes had HbA_{1c} values indicating the presence of type 2 diabetes. In addition, 27.1% had HbA_{1c} values above the limit value for pre-diabetes [42]. Individuals with periodontitis more frequently had elevated HbA_{1c} values than people without periodontitis. Periodontitis may therefore be an indicator of elevated HbA_{1c} and pre-diabetes or overt type 2 diabetes. Contributing to the early diagnosis of type 2 diabetes, in addition to the prevention of diabetes-related complications such as cardiovascular disease, neuropathy, and nephropathy, is important in reducing the increased risk of attachment loss and other diseases of the oral cavity.

Caries

Tooth decay is extremely common worldwide [13]. Among children and adolescents with type 1 diabetes the incidence of caries is very high (67%), and it is related to disease duration and the degree of hyperglycaemia [96]. Caries growth may be higher in children with dysregulated type 1 diabetes than in healthy children, but according to a systematic review [97] the evidence is inconclusive. Increased caries activity and experience might be associated with increased salivary glucose concentration, increased plaque incidence, and changes in the oral microbiota [98–100] as well as decreased salivary secretion rate and lower pH in saliva [100, 101]. Thus, several studies have shown that the incidence of carious teeth appears to be increased in individuals with diabetes [102, 103], including dysregulated type 2 diabetes [104]. A consequence of major destruction due to caries is tooth loss, but another result of deep caries is that the dental pulp tissue may be affected. This may not only result in pain but also in necrosis of the dental pulp tissue. The following leakage of toxins from the apical foramen to the periapical bone, inflammation known as periapical periodontitis (localized osteomyelitis), may occur and sometimes be followed by abscess formation. Individuals with sub-optimally managed diabetes seem to have an increased prevalence of periapical lesions compared to those with better-managed diabetes [105]. Endodontic treatment is necessary, including removal of the necrotic pulp tissue and after mechanical preparation of the root canals; they are filled with a material that closes the apical foramen. However, studies have indicated that diabetes appears to increase the extraction rate of such root-filled teeth [106].

Hyposalivation

Reduced secretion of saliva and xerostomia occurs often in persons with diabetes [107, 108]. An average reduction of 16% has been described in people with type 1 diabetes and as much as 54% in individuals with type 2 diabetes, in both cases after a disease duration of

10 years [109, 110]. The difference may be due to higher age in individuals with type 2 diabetes, with more late diabetes-related complications, a higher degree of comorbidity, and increased intake of xerogenic drugs than in people with type 1 diabetes. Hyposalivation associated with diabetes may be due to changes in the salivary glands due to hyperglycaemia or due to diabetic neuropathy, but probably polyuria may play a role as well. Hyposalivation may be associated with increased salivary glucose and mucin, which again may result in a change in viscosity. A reduced content of salivary antimicrobial substances may in addition to the reduced amount of saliva account for increased susceptibility to oral diseases, including caries and candidal infection. Lubricating and digestive properties are affected as well as speaking, chewing, and swallowing potentially being difficult. Halitosis and coated tongue are other associated characteristics [1]. Several studies have suggested that persons with diabetes also have a reduced taste perception and a higher electrical taste threshold than healthy individuals [111–113].

Candidal infection

In people with type 1 diabetes and type 2 diabetes an increased oral incidence of *Candida* species, especially *C. albicans*, has been related to hyperglycaemia [114], long diabetes duration, late diabetes-related complications (nephropathy and retinopathy), and smoking [115]. Also, in individuals with diabetes an increased susceptibility to manifest candidal infection is seen [114, 115], either manifest as classic oral candidiasis or as candida-associated lesions, including median rhomboid glossitis, denture stomatitis, and angular cheilitis [115]. The associated symptoms may be a burning sensation in the oral mucosa, a metallic taste, and dry mouth.

Oral cancer

Diabetes has been associated with an excess risk of cancer in several sites of the body. In the oral cavity various types of malignancy may occur, with squamous cell carcinoma accounting for the vast majority. A systematic review has summarized existing observational studies and found a 15-fold higher risk of oral cancer and pre-cancerous lesions in individuals with type 2 diabetes [116]. In general, there appears to be a higher excess risk in women compared with men. This also applies to oral cancer, the excess risk among women being 13% greater than among men [117]. The increased prevalence of candidiasis in individuals with diabetes [114, 115] may partly explain why pre-malignant lesions of the oral mucosa also appear to be slightly more common [118, 119].

Guidelines for physicians and other medical health professions for use in practice

Because of the increased risk of developing periodontitis in individuals with diabetes and the negative impact of periodontitis on hyperglycaemia and complications, the IDF and the EFP have established the following set of recommendations, which may be helpful in daily practice. The guidelines also apply to people with pre-diabetes and the metabolic syndrome [2]:

- Oral health education should be provided to all individuals with diabetes as part of their overall educational programme.
- People with all forms of diabetes should be told that periodontal disease risk is increased, and that, if untreated, periodontitis has a negative impact on metabolic management and may also increase the risk of diabetes complications such as cardiovascular and kidney disease.
- Persons with diabetes should be advised that successful periodontal therapy may have a positive impact on their glycaemic management and risk of late diabetes complications.
- For people with diabetes, physicians should ask about a prior diagnosis of periodontal disease. If a positive diagnosis has been made, the physician should seek to ascertain that periodontal care and maintenance are being provided. Investigating the presence of periodontal disease should be an integral part of a diabetes care visit. People with diabetes should be asked about any signs and symptoms of periodontitis, including bleeding gums during brushing or eating, loose teeth, spacing or spreading of the teeth, oral malodour, and/or abscesses in the gums or gingival suppuration.
- If a positive history is elicited, then a prompt periodontal evaluation should be recommended before their scheduled annual check-up. In the case of a negative history, people with diabetes should be advised to check for these symptoms, and if a positive sign appears they should visit their dentist.
- For all people with newly diagnosed diabetes, referral for a periodontal examination should occur as part of their ongoing management of the diabetes. Even if no periodontitis is diagnosed initially, annual periodontal review is recommended.
- For children and adolescents diagnosed with diabetes, annual oral screening is recommended through referral to a dental professional.
- People with diabetes who have extensive tooth loss should be encouraged to pursue dental rehabilitation to restore adequate mastication for proper nutrition.
- People with diabetes should be advised that other oral conditions such as dry mouth and burning mouth may occur, and if so they should seek advice from their dental practitioner. Also, individuals with diabetes are at increased risk of oral fungal infections and experience poorer wound healing than those without diabetes.
- The physician should liaise with the dentist over diabetes management prior to the oral intervention and/or surgery to avoid hypoglycaemia and consider its potential impact on the patient's ability to eat.

Collaboration in healthcare for the benefit for persons with diabetes

Individuals with diabetes may have limited knowledge about the significance of oral health [118] and in some countries individuals with diabetes appear to visit their dentist less frequently than people without diabetes [39, 121, 122]. Therefore, an intensified effort emphasizing the importance of regular oral home care, dental examination, and treatment may be necessary. This is why a new strategy is important, a strategy that can be accomplished only by interprofessional collaboration in healthcare for persons with diabetes [123]. Hopefully, medical and dental professionals will understand the significance and benefit of regular dental care for these patients. A fruitful collaboration is based on knowledge, and there may be a need to intensify exchange of knowledge between medical and dental professionals [124] to facilitate an active role by medical

care professionals in addressing oral health in their patients, as well as a more active role of dental professionals in identifying individuals with undiagnosed diabetes [42, 125]. In a study from the USA, screening for diabetes in the dental setting was effective in identifying pre-diabetes and type 2 diabetes [126] and early detection led to instigation of cost-effective lifestyle change measures, which resulted in a significant proportion of patients moving from pre-diabetes to normoglycaemia. In the UK, the National Institute of Health and Care Excellence has suggested that healthcare professionals other than physicians, including dentists, should be screening for undiagnosed type 2 diabetes [2].

Conclusion

The association between periodontitis and diabetes has been described as bidirectional, and there is substantial evidence that hyperglycaemia in type 1 diabetes and type 2 diabetes adversely affects periodontitis, resulting in increased extension and severity of periodontitis. Due to the global increase in the prevalence of diabetes, the influence of diabetes on the development of periodontitis may be a growing problem. Current evidence also suggests that periodontitis may have a negative impact on the course of diabetes. The mechanisms by which the two diseases interact are uncertain,

but presumably systemic low-grade inflammation enhanced by both diseases play an important part in their interaction, which obviously involves inflammatory cells and their products. In addition, the formation of AGEs results in modified cellular functions, with a possible negative impact on periodontitis.

The existing clinical trials indicate a positive effect on metabolic management and systemic inflammation of non-surgical periodontal treatment, which may result in a clinically relevant decrease of HbA_{1c}. Intensive prevention and treatment of gingivitis and caries in children and adolescents with type 1 diabetes with elevated HbA_{1c} are also essential to prevent further progression of these conditions.

Individuals with diabetes and decreased salivary secretion are recommended to have frequent, regular dental check-ups and cleaning to prevent the development of caries. Early intervention for special-risk individuals, such as children and young people with obesity, including dietary guidelines to reduce sugar intake, may help reduce the risk of developing not only obesity but also caries. It should also be remembered that people with elevated HbA_{1c} may lack oral hygiene, and they may visit the dentist more infrequently than those with better glycaemic management. Regular examination of oral health is important for the identification of candidal infection, oral pre-malignant lesions, and manifest malignancy, which all appear to be more common in persons with diabetes than in healthy individuals.

- Non-alcoholic fatty liver diseases (NAFLD) embraces a spectrum of lipid-associated liver conditions, extending from simple steatosis (or NAFLD) to non-alcoholic steatohepatitis (NASH) (both with and without liver fibrosis), to cirrhosis.
- NAFLD is defined by the presence of macrovesicular steatosis in $\geq 5\%$ of hepatocytes in individuals who consume little or no alcohol, without evidence of hepatocellular injury. NASH is defined by the presence of $\geq 5\%$ macrovesicular steatosis plus inflammation with hepatocyte injury (ballooning), both with and without any liver fibrosis.
- NAFLD is one of the commonest causes of liver disease worldwide, affecting up to 70% of people with type 2 diabetes.
- Age, sex, ethnicity, some genetic variants, and metabolic risk factors (e.g. obesity and type 2 diabetes) can interact to increase the risk of development and progression of NAFLD.
- Individuals with type 2 diabetes are at higher risk of developing the more advanced forms of NAFLD, including NASH, cirrhosis, liver failure, and hepatocellular carcinoma.
- The presence of NAFLD in people with type 2 diabetes is associated with higher glycated haemoglobin (HbA_{1c}) concentration and greater hepatic and peripheral insulin resistance.
- NAFLD is associated not only with liver-related morbidity and mortality, but also with an increased risk of developing type 2 diabetes,

cardiovascular disease (which is the predominant cause of mortality in people with NAFLD), chronic kidney disease, and certain types of extrahepatic cancers (especially colorectal cancer).

- NAFLD exacerbates insulin resistance, predisposes to atherogenic dyslipidaemia, and causes the release of pro-inflammatory, procoagulant, and proatherogenic factors that have a role in the development of chronic vascular complications of diabetes.
- There are no licensed pharmacological treatments specifically for liver disease in NAFLD. Management is based on promoting weight loss by diet and exercise, controlling all coexisting cardiometabolic risk factors, and preventing the development and progression of liver-related and extrahepatic complications.
- Bariatric surgery improves all of the histological features of NAFLD, including liver fibrosis, and is indicated for people with type 2 diabetes and severe obesity.
- Among glucose-lowering agents, pioglitazone and glucagon-like peptide 1 (GLP-1) receptor agonists (e.g. subcutaneous semaglutide) may improve NASH without worsening liver fibrosis. Sodium–glucose transporter 2 (SGLT-2) inhibitors may be a future treatment option for NAFLD.
- Among newer drugs for NASH, obeticholic acid, a synthetic analogue of chenodeoxycholic acid, can improve both NASH and fibrosis, but increases plasma low-density lipoprotein cholesterol concentrations.

Non-alcoholic fatty liver disease (NAFLD) is a metabolic liver disease that includes a spectrum of progressive pathological conditions, ranging from simple steatosis (or non-alcoholic fatty liver, NAFL) to non-alcoholic steatohepatitis (NASH) and cirrhosis [1, 2]. NAFLD has become one of the most common causes of chronic liver disease worldwide, affecting up to $\sim 30\%$ of adults in the general population [3], up to $\sim 70\%$ of individuals with type 2 diabetes [4], and up to $\sim 35\%$ of adults with type 1 diabetes [5].

Although the pathophysiology of this common liver disease is multifaceted, a large body of evidence indicates that NAFLD and type 2 diabetes frequently coexist. When both conditions do coexist, a ‘vicious’ cycle occurs with either condition adversely affecting the other to increase the risk of developing liver-related and extrahepatic complications [5–9]. In addition, it has become

increasingly clear that there is an intimate bidirectional relationship between NAFLD and type 2 diabetes, and that NAFLD may precede and/or promote the development of type 2 diabetes over time [10, 11]. Notably, given the close inter-relationships between NAFLD, obesity, and type 2 diabetes, a change in the terminology of NAFLD has been recently proposed, changing the name for this common liver disease from NAFLD to metabolic dysfunction-associated fatty liver disease (MAFLD) [12, 13]. Within this newly proposed terminology, the diagnosis of MAFLD is primarily based on the presence of hepatic steatosis (assessed by liver biopsy, imaging techniques, or blood biomarkers/scores) and at least one of the following three metabolic abnormalities: overweight/obesity, pre-existing type 2 diabetes, or metabolic dysregulation (i.e. the coexistence of at least two metabolic risk factors among those

typically used for diagnosing the metabolic syndrome: increased waist circumference, increased blood pressure, high triglycerides, low high-density lipoprotein (HDL) cholesterol, impaired fasting glycaemia, *plus* homeostasis model assessment-insulin resistance or increased plasma C-reactive protein (CRP) concentrations [12, 13]. The newly proposed definition of MAFLD emphasizes that overweight/obesity, type 2 diabetes, and other metabolic risk factors are key factors in the development of this common and burdensome liver disease [14–16]. Moreover, given that increasing evidence now suggests that a safe threshold for daily alcohol consumption is close to zero, the use of a term (like non-alcoholic) based on the exclusion of a risk factor might be oversimplified [14–16]. Finally, the definition of MAFLD might also improve the identification of people at higher risk of liver-related and cardiometabolic complications [16, 17]. However, since it is currently still debated which term should be used, and as some experts [18, 19] consider that a change in the terminology of NAFLD may be premature at this time, in this chapter we consider it appropriate to discuss 'NAFLD' and not 'MAFLD'.

Specifically, in this chapter, we will discuss the definition, diagnosis, and epidemiology of NAFLD (in the context of type 2 diabetes); the aetiology and pathogenesis of NAFLD; the main extrahepatic complications of NAFLD; and the treatment for NAFLD in people with type 2 diabetes with or without coexisting cardiovascular disease (CVD). The relationship between NAFLD and type 1 diabetes is not discussed in this chapter, as research on this topic is still limited.

Non-alcoholic fatty liver disease definition, epidemiology, and diagnosis

Definition

Non-alcoholic fatty liver (NAFL) is defined by the presence of macrovesicular steatosis in $\geq 5\%$ of hepatocytes in individuals who consume little or no alcohol, without evidence of hepatocellular injury in the form of hepatocyte ballooning [1, 2]. Non-alcoholic steatohepatitis (NASH) is defined as the presence of $\geq 5\%$ macrovesicular steatosis and inflammation with hepatocyte injury (ballooning), with or without any stage of liver fibrosis [1, 2]. There are five histological stages of liver fibrosis in NAFLD: F0 = no fibrosis; F1 = perisinusoidal fibrosis; F2 = portal fibrosis; F3 = 'bridging' fibrosis; and F4 = cirrhosis [1, 2].

Non-alcoholic fatty liver disease epidemiology in type 2 diabetes

Across the spectrum of hepatic disease in NAFLD, NAFL, NASH, advanced fibrosis, and cirrhosis occur more frequently in people with type 2 diabetes compared with those without diabetes [4, 6]. Indeed, population-based studies and hospital-based ones have reported that the prevalence of NAFLD (as detected by imaging techniques or biopsy) in individuals with type 2 diabetes ranges from 30% to 70% and from 50% to 70%, respectively [20–30]. These wide inter-study differences are largely due to the clinical characteristics of the study populations and the techniques used for the diagnosis of NAFLD.

The high prevalence of NAFLD in people with type 2 diabetes was confirmed in a systematic review and meta-analysis of 80 observational studies showing that the global prevalence of NAFLD (on imaging techniques or histology) in people with type 2 diabetes was approximately 55%, whereas the global prevalence of more

Table 57.1 Global and regional prevalence of non-alcoholic fatty liver disease (NAFLD, as detected by imaging techniques) in people with type 2 diabetes [4].

Regions	NAFLD prevalence	95% confidence intervals
Worldwide	55.5%	47.3 to 63.7%
USA	51.8%	31.3 to 71.6%
Europe	68.0%	62.1 to 73.0%
Latin America	56.8%	34.1 to 77.0%
East Asia	52.0%	45.4 to 58.6%
South Asia	57.9%	52.9 to 62.7%
West Asia	67.3%	60.4 to 73.6%
Africa	30.4%	11.6 to 67.1%

advanced forms of NAFLD, such as NASH and advanced fibrosis (on liver histology), was 37% and 17%, respectively [4]. As shown in Table 57.1, the global prevalence of NAFLD varied between different countries (with the highest prevalence observed in Europe) [4]. Different ethnic groups have also disparate propensities to NAFLD, with Hispanic individuals being more susceptible than people of white Northern European ancestry, whereas the lowest susceptibility is observed in Black individuals [31].

Diagnosis

NAFLD is essentially a diagnosis of 'exclusion' based on the following criteria (Table 57.2):

- Evidence of hepatic steatosis on liver histology, imaging techniques, or blood biomarkers/scores.
- No excessive alcohol consumption (a threshold of 20 g/d for women and 30 g/d for men is conventionally adopted).
- No other competing causes for hepatic steatosis, such as viral hepatitis, drug use, haemochromatosis, autoimmune hepatitis, and others [1, 2, 32].

Table 57.2 also summarizes the main differences in the diagnostic criteria for NAFLD and MAFLD.

Diagnosis of liver fat (steatosis)

The gold-standard method for diagnosing and staging NAFLD is liver biopsy [1, 2, 32]. However, liver biopsy is expensive, invasive, uncomfortable and inconvenient for the person undergoing the procedure, and potentially risky (serious bleeding may occur in 0.6% of cases, and death in 0.1%) [1, 2, 32, 33]. For these reasons, liver biopsy is not widely used for the diagnosis of NAFLD, nor in the monitoring of progression or resolution of the disease in clinical practice. However, it should be remembered that NASH can currently be diagnosed only by liver biopsy. Furthermore, liver biopsy should be considered when there is diagnostic uncertainty and other chronic liver diseases cannot be definitively excluded [1, 2, 32].

As summarized in Table 57.3, liver ultrasonography is the most widely used imaging technique to diagnose hepatic steatosis in clinical practice [1, 2, 32, 34]. A large meta-analysis showed that ultrasonography has good sensitivity (~85%) and specificity (~95%) for detecting moderate to severe hepatic steatosis, when compared to liver histology [35]. However, it is important to underline that the sensitivity of this imaging technique is relatively poor, when hepatic fat infiltration is present in <20% of hepatocytes [1, 2, 32, 34]. A diagnosis of hepatic steatosis on ultrasonography is established when liver echogenicity exceeds that of renal cortex and spleen; there is attenuation of the ultrasound signal; there is loss of

Table 57.2 Differences in the diagnostic criteria for non-alcoholic fatty liver disease (NAFLD) and metabolic dysfunction-associated fatty liver disease (MAFLD).

NAFLD [1, 2]	MAFLD [12, 13]
Hepatic steatosis (assessed by liver biopsy, imaging techniques, or blood biomarkers/scores ^a) No significant alcohol consumption (a threshold of 20 g/d [\sim 140 g/wk] for women and 30 g/d [\sim 210 g/wk] for men is usually adopted)	Hepatic steatosis (assessed by liver biopsy, imaging techniques, or blood biomarkers/scores ^a) One of the following metabolic criteria: <ul style="list-style-type: none">• Overweight or obesity• Type 2 diabetes• Metabolic dysregulation^b Exclusion of significant alcohol consumption and other secondary causes of hepatic steatosis is <i>not</i> a prerequisite for the diagnosis of MAFLD. Individuals with MAFLD who also have one (or more) of these conditions should be defined as having dual (or more) aetiology of fatty liver disease
No other known causes of hepatic steatosis: viral hepatitis B and C, drugs (e.g. chronic use of amiodarone, corticosteroids, methotrexate, oestrogens, valproic acid, tamoxifen, tetracycline, perhexiline maleate, 4,4'-diethylaminoethoxyhexesterol, chloroquine, L-asparaginase), haemochromatosis, autoimmune hepatitis, Wilson's disease, alpha 1 anti-trypsin deficiency, coeliac disease, and others (e.g. malnutrition, total parenteral nutrition, rapid weight loss, surgically altered bowel anatomy, lipodystrophy, hypobetalipoproteinaemia)	

^a Serum biomarker scores for hepatic steatosis are Fatty Liver Index (FLI), an algorithm-derived score using body mass index, waist circumference, fasting serum triglycerides, and γ -glutamyltransferase concentrations) and NAFLD liver fat score (an algorithm-derived score using the presence of metabolic syndrome, type 2 diabetes, fasting serum insulin, serum aspartate transaminase (AST) levels, and the AST/alanine transaminase (ALT) ratio). For more details see Byrne et al. 2018 [32].

^b At least two metabolic risk abnormalities among increased waist circumference (i.e. \geq 102/88 cm in white European men and women or \geq 90/80 cm in Asian men and women), increased blood pressure (i.e. blood pressure \geq 130/85 mmHg or drug treatment), hypertriglyceridaemia (i.e. plasma triglycerides \geq 150 mg/dl or drug treatment), low high-density lipoprotein (HDL) cholesterol (i.e. plasma HDL <40 mg/dl for men and <50 mg/dl for women or drug treatment), pre-diabetes (i.e. fasting plasma glucose levels from 100 to 125 mg/dl or 2 h post-load plasma glucose levels from 140 to 199 mg/dl or glycated haemoglobin (HbA_1c) from 39 to 47 mmol/mol), insulin resistance (i.e. Homeostatic Model Assessment of Insulin Resistance [HOMA-IR] \geq 2.5) and/or increased plasma high sensitivity C-reactive protein concentrations (plasma hs-CRP $>$ 2 mg/l).

definition of the diaphragm; and there is poor delineation of intrahepatic architecture [32, 34].

The controlled attenuation parameter (CAP), assessed by vibration-controlled transient elastography (FibroScan®, Echosens, Paris, France), can also be used in clinical practice for diagnosing hepatic steatosis, but it is currently unclear what CAP thresholds should be used for the diagnosis of steatosis [32, 34]. Moreover, CAP measurement could be unreliable in individuals with severe obesity [32, 34].

Computed tomography has also been used to detect hepatic steatosis [1, 2, 32, 34]. However, this imaging technique has limited sensitivity to detect low levels of liver fat (<20–30%) and it exposes the person to ionizing radiation [32, 34]. For these reasons, computed tomography is not routinely used in clinical practice for diagnosing NAFLD [32].

Magnetic resonance imaging–proton density fat fraction (MRI-PDFF) and proton magnetic resonance spectroscopy (MRS) have excellent diagnostic accuracy for identifying hepatic steatosis and measuring intrahepatic fat content [1, 2, 32, 34]. Specifically, MRS enables accurate quantification of the hepatic triglyceride content. However, these two magnetic resonance–based techniques are expensive and not easily available, and therefore they are not routinely used in clinical practice for diagnosing NAFLD [1, 2, 32, 34].

Although hepatic steatosis may be associated with mild to moderate elevations of serum liver enzymes (mostly serum aminotransferase and/or gamma-glutamyltransferase [GGT] levels), it is important to note that most people with NAFLD (even if NASH or cirrhosis is present) have normal or only mildly abnormal serum liver enzymes. Therefore, measurement of serum liver enzymes alone should not be used for diagnosing or excluding the presence of NAFLD [1, 2, 32]. In the last decade, serum biomarker scores have been developed to identify NAFLD [1, 2, 32]. Fatty liver index (FLI) is one of the most widely used scores for diagnosing hepatic steatosis

that includes in its equation body mass index (BMI), waist circumference, serum triglycerides, and GGT concentrations [1, 2, 32]. A FLI \geq 60 is highly suggestive of hepatic steatosis on ultrasonography [32, 36, 37]. NAFLD liver fat score is another algorithm-derived score using the presence of metabolic syndrome, type 2 diabetes, serum fasting insulin, and aminotransferase levels. A cut-off point \geq –0.64 is highly suggestive of imaging-defined hepatic steatosis [32, 38]. However, it should be noted that neither of these two biomarker scores of hepatic steatosis has been validated against liver biopsy [32].

Diagnosis of liver fibrosis

Growing evidence indicates that individuals with NAFLD and advanced fibrosis are those at highest risk of developing liver-related and extrahepatic complications, as well as having the highest rates of all-cause and cause-specific mortality (mainly due to liver disease, CVD, and cancer) [1, 2, 5, 8, 39]. In a large meta-analysis of 45 observational studies involving more than 8 million people, followed for a period ranging from 4 to 13 years, the pooled all-cause mortality incidence rate among individuals with NAFLD was 15 per 1000 person-years, whereas among those with NASH with varying stages of fibrosis the pooled all-cause mortality incidence rate was 26 per 1000 person-years [3]. Notably, in a population-based cohort study of 12 253 US middle-aged individuals who were followed for a median of 23 years, Alvarez et al. showed that nearly 8% of all-cause mortality and more than 30% of liver disease-specific and diabetes-specific deaths were attributable to NAFLD [40]. In that study, the attributable risk of NAFLD for diabetes mortality was nearly 40%, whereas the population-attributable fraction (which is the contribution conveyed by a risk factor to a disease or a death) of NAFLD for both CVD and cancer mortality was approximately 10% [40]. That said, there is now strong evidence from the recent results of a nationwide matched-cohort study in Sweden showing that all histological

Imaging techniques	Characteristics	Main advantages	Main limitations
Hepatic steatosis			
Ultrasonography	Recommended first-line imaging technique Liver echogenicity caps that of renal cortex and spleen, attenuation of the ultrasound wave, loss of definition of the diaphragm, poor delineation of the intrahepatic architecture	Inexpensive Non-invasive "Patient friendly" Widespread	Unable to detect mild steatosis Steatosis and fibrosis can have similar appearance Operator dependent Unreliable in individuals with severe obesity
Vibration-controlled transient elastography (FibroScan®) with controlled attenuation parameter (CAP)	Optimal CAP threshold ≥ 248 dB/m for diagnosing hepatic steatosis	Inexpensive Non-invasive "Patient friendly" Promising technique	Unable to detect mild steatosis Operator dependent Unreliable in people with severe obesity
Computed tomography	Attenuation of the liver is at least 10 Hounsfield units (HU) less than that of the spleen Attenuation of the liver less than 40 HU	Useful for investigating additional abdominal pathologies	Unable to detect mild steatosis High levels of radiation
Magnetic resonance imaging–proton density fat fraction (MRI-PDFF)	Chemical shift gradient echo imaging with in-phase and opposed-phase acquisitions Able to detect liver fat accumulation $\geq 5.5\%$ (or less)	Non-invasive Sensitive for liver fat	Expensive Limited availability
Magnetic resonance spectroscopy (proton MRS)	Accurate quantification of liver fat accumulation ($\geq 5.5\%$ or less)	Non-invasive Sensitive for liver fat	Expensive Not easily available
Hepatic fibrosis			
Vibration-controlled transient elastography (FibroScan® with the use of M probe or XL probe for severely obese individuals)	Measures a volume of the liver that is ~ 100 times larger than a liver biopsy sample Speed of propagation is in relation to the stiffness of the tissue Specific software Advanced fibrosis threshold (liver stiffness ≥ 9.7 kPa)	Non-invasive "Patient friendly" Immediate results XL probe has been validated for people with severe obesity	Expensive Limited in the setting of congestive hepatopathy or ascites Operator dependent
Acoustic radiation force impulse elastography (ARFI)	Advanced fibrosis threshold (ARFI > 1.4 m/s)	Integrated into a conventional ultrasonography	Cut-off values for advanced fibrosis may vary Unreliable in people with severe obesity
Magnetic resonance elastography (MRE)	Advantages of MR with elastography	Accurate also in people with obesity Assesses the entire liver	Expensive Time consuming Limited availability

stages of liver disease in NAFLD are associated with increased risk of overall mortality, and that this risk increases progressively with worsening NAFLD histology. Most of this excess mortality is primarily from extrahepatic cancers, followed by cirrhosis, CVD, and hepatocellular carcinoma (HCC) [41].

Although liver biopsy is the reference standard for the assessment of liver fibrosis, the inherent limitations of this invasive procedure, and the need for repeat sampling, have led to the development of several non-invasive tests as alternatives to liver biopsy. Some of these non-invasive algorithmically derived scores for the assessment of liver fibrosis can be useful for identifying clinically significant fibrosis in individuals who may require a liver biopsy [32]. The Enhanced Liver Fibrosis (ELF) is a commercial algorithmically derived score using measurement of serum tissue inhibitor of matrix metalloproteinase-1, hyaluronic acid, and the amino-terminal peptide of pro-collagen III [32]. The ELF test has excellent performance for identifying NAFLD with a high probability of advanced fibrosis [32]. A 2014 meta-analysis con-

firmed that the ELF test performs well in the prediction of advanced fibrosis (F3 and F4 fibrosis) in NAFLD [42]. The NAFLD fibrosis score (NFS) is the most widely validated non-invasive test and it is calculated as follows [43]:

$$\text{NFS} = -1.675 + 0.037 \times \text{age} + 0.094 \times \text{BMI} + 1.13 \times \text{impaired fasting glycaemia or diabetes status (yes = 1, no = 0)} + 0.99 \times \text{AST/ALT ratio} - 0.013 \times \text{platelet count} - 0.66 \times \text{serum albumin}$$

AST is aspartate transaminase and ALT is alanine transaminase. The NFS has adequate performance for identifying individuals with any grade of liver fibrosis, but poorer performance for diagnosing advanced fibrosis [32, 43]. A cut-off point > 0.676 is highly suggestive of advanced fibrosis [43]. The Fibrosis (FIB)-4 score is another validated non-invasive test for identifying individuals who are expected to have significant fibrosis. This score is calculated as follows:

$$(\text{age} \times \text{AST}) / (\text{platelet count} \times \sqrt{\text{ALT}})$$

A cut-off point >2.67 is indicative of advanced fibrosis [32]. Notably, all these non-invasive scores of fibrosis have a modest positive predictive value for identifying advanced fibrosis, and a good negative predictive value, such that they are currently recommended for ruling out advanced fibrosis rather than for diagnosing it [32]. Importantly, algorithmically derived biomarker scores are not good for identifying intermediate stages of liver fibrosis (F1–F2 stages) [32] and therefore, as also suggested by the recent guidelines from important scientific hepatology societies (the European Associations for the Study of the Liver, Diabetes, and Obesity [EASL-EASO-EASD] and the American Association for the Study of Liver Diseases [AASLD]) [1, 2], these non-invasive scores of fibrosis should be used only in a staged approach, and liver biopsy may be required if it is necessary to stage the severity of liver fibrosis or if there is diagnostic uncertainty [32].

Vibration-controlled transient elastography (FibroScan^{*} with the use of M or XL probes for individuals with severe obesity) is a widely used technique to non-invasively stage hepatic fibrosis in clinical practice [32, 34]. This imaging technique measures the velocity of a low-frequency elastic shear wave propagating through the liver [32, 34]. This velocity is directly related to tissue stiffness [32]. The stiffer the tissue, the faster the shear wave propagates [32, 34]. Advantages of this technique include a short procedure time, instant results, and the possibility of performing the test in an outpatient clinic [32, 34]. Conversely, an important limitation of this methodology is its poor capacity to obtain reliable liver stiffness measurements in some individuals, especially people with severe obesity or ascites [32, 34]. Liver elasticity-based imaging techniques are being developed, including 2D acoustic radia-

tion force impulse imaging (ARFI), shear-wave elastography, and 3D magnetic resonance elastography, but these techniques are mostly used in research at the present time (Table 57.3) [32, 34].

The EASL-EASO-EASD jointly and the AASLD have produced guidelines for the diagnosis, monitoring, and management of suspected NAFLD and coexisting metabolic risk factors [1, 2]. Ideally, all individuals with type 2 diabetes should undergo assessment with measurement of serum aminotransferase levels, liver ultrasonography, and measurement of non-invasive scores of fibrosis. Presently, however, there is debate regarding the most appropriate algorithm for diagnosis and monitoring of NAFLD in type 2 diabetes [7]. Figure 57.1 shows a pragmatic algorithm for the diagnosis and monitoring of NAFLD in people with type 2 diabetes [7]. Individuals with type 2 diabetes should be assessed (every 2–3 years) for the presence of NAFLD [7]. Since measurement of serum aminotransferase levels is not useful for the diagnosis or monitoring of NAFLD and most individuals with type 2 diabetes and NAFLD have normal serum liver enzyme levels, serum aminotransferase levels should not be used in isolation [7]. As mentioned, ultrasonography is the recommended first-line imaging technique for the diagnosing of hepatic steatosis in NAFLD [7]. Non-invasive assessment of advanced fibrosis by using specific non-invasive biomarkers (e.g. the FIB-4 score, NFS, or ELF test) can be used initially, followed by vibration-controlled transient elastography (FibroScan^{*}) when the biomarker scores are above a certain threshold, in order to identify individuals with NAFLD and significant fibrosis (\geq F2 fibrosis). Where there is diagnostic uncertainty or where it is important to stage liver fibrosis precisely, a liver biopsy should be undertaken.

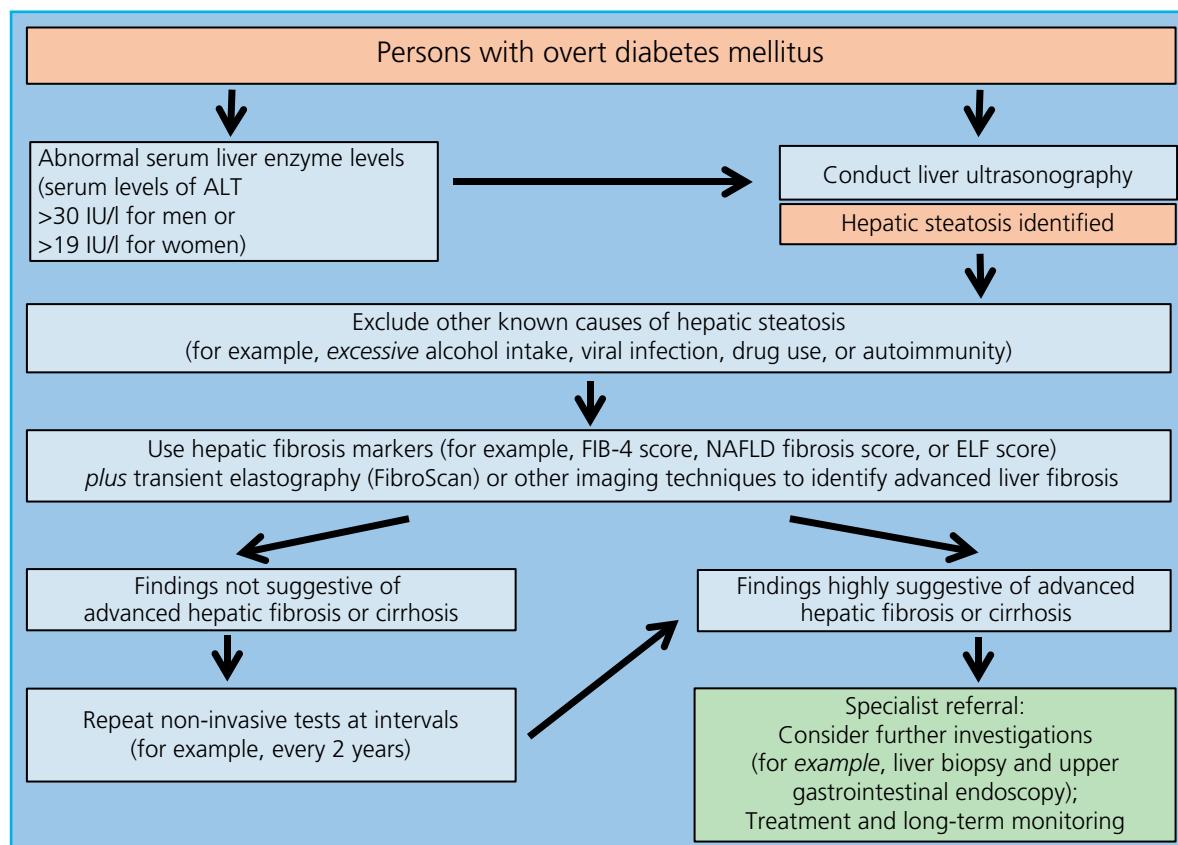

Figure 57.1 Possible pragmatic algorithm for the diagnosis and monitoring of non-alcoholic fatty liver disease (NAFLD) in persons with overt type 2 diabetes. ALT, alanine transaminase; ELF, Enhanced Liver Fibrosis; FIB-4, Fibrosis-4. Source: Modified by permission from Targher et al. [7].

Table 57.4 Typical case presentation of a person with type 2 diabetes and non-alcoholic fatty liver disease (NAFLD).

Case presentation
<p>At a routine health check, a 67-year-old man with established type 2 diabetes was found to have a serum alanine aminotransferase (ALT) level of 66 IU/l (normal 0–40 IU/l), a serum aspartate aminotransferase (AST) level of 72 IU/l (normal 0–40 IU/l; AST/ALT ratio 1.1), and a triglyceride concentration of 2.1 mmol/l (186 mg/dl; normal value <150 mg/dl). Glycated haemoglobin (HbA_{1c}) was of 8% (64 mmol/mol). Other liver function tests, kidney function measures (serum creatinine and albuminuria), as well as other lipid blood tests (including low-density lipoprotein [LDL] cholesterol) were normal. There was no past medical history of viral hepatitis (i.e. hepatitis B or C virus infection) nor pre-existing history of cardiovascular disease or chronic kidney disease. He was treated with metformin (1000 mg twice a day) and ramipril (5 mg/d); he smoked (~10 cigarettes daily) and consumed <4 units of alcohol/wk. Clinical examination revealed moderate hepatomegaly, obesity (body mass index 30 kg/m²; waist circumference 107 cm), and blood pressure 144/90 mmHg.</p> <p>How should this man be investigated?</p>
Investigation and management
<p>The man has established type 2 diabetes and moderately elevated levels of serum transaminases without other secondary causes of chronic liver disease, including excessive alcohol intake, viral hepatitis B or C, or use of potentially hepatotoxic drugs. As suggested by current guidelines, persons with type 2 diabetes should undergo liver assessment by abdominal ultrasonography along with liver enzymes. The liver ultrasonography documented a moderate–severe hepatic steatosis. Hence, a diagnosis of NAFLD should be made. Since the individual has type 2 diabetes, obesity, hypertriglyceridaemia, and hypertension, a liver stiffness measurement (LSM), using vibration-controlled transient elastography (FibroScan®), should also be performed. The FibroScan® documented an LSM value of 8.7 kPa, which is strongly indicative of significant liver fibrosis ($\geq F2$ fibrosis). We would strongly reinforce lifestyle recommendations, such as a programme of regular aerobic exercise (a gradual increase to 30 min of aerobic activity 5 d/wk), weight loss (with a 5–10% weight loss as target), a moderate restriction of sodium intake (e.g. 80–120 mmol/d, corresponding to 4.6–6.9 g of salt), and the substitution of sources of polyunsaturated fats (PUFAs), including oils (mainly olive), nuts, cold-water fish, and shellfish for saturated fats and simple carbohydrates. Given that the man smokes, we should advise and help him to quit. Seeing the presence of significant liver fibrosis on FibroScan®, as well as suboptimal glycaemic levels ($\text{HbA}_{1c} \geq 8\%$, 64 mmol/mol), in addition to lifestyle modifications it is possible to add a second glucose-lowering agent, such as pioglitazone or injectable glucagon-like peptide 1 (GLP-1) receptor agonists (e.g. liraglutide, semaglutide, or dulaglutide). If plasma triglyceride levels remain above 150 mg/dl (>1.8 mmol/l), it would be reasonable to prescribe fenofibrate or omega-3 PUFA supplementation, in addition to lifestyle recommendations. If his blood pressure remains above 140/90 mmHg, it would be reasonable to increase the ramipril dosage to 10 mg/d or add another antihypertensive drug.</p>

Upper gastrointestinal endoscopy (for the purpose of confirming or excluding the presence of oesophageal or gastric varices due to portal hypertension) is necessary in those individuals with established cirrhosis [7]. Long-term surveillance for liver-related complications, including HCC, should be undertaken with liver ultrasonography if cirrhosis is present or in those with advanced fibrosis [7]. The cost-effectiveness of screening for NAFLD in people with type 2 diabetes remains controversial. However, a recent comprehensive cost–utility analysis has shown that the screening for NAFLD in people with type 2 diabetes, based on the use of ultrasonography, serum transaminase levels, and followed by non-invasive testing for advanced fibrosis, is cost-effective compared to not screening [44]. Hence, some authors recommend NAFLD screening for individuals with type 2 diabetes [7, 44]. Table 57.4 shows a typical presentation of a person with coexistent type 2 diabetes and NAFLD.

Aetiology and pathogenesis of non-alcoholic fatty liver disease

The aetiology and pathogenesis of NAFLD are not fully understood. As shown in Table 57.5, several risk factors, including age, sex, ethnicity, lifestyle habits, genetic variants, and multiple acquired metabolic risk factors, can interact additively and potentially synergistically in different ways and contribute to the development and progression of NAFLD [45]. A schematic representation of the putative pathological mechanisms associated with the development and progression of NAFLD is shown in Figure 57.2.

Table 57.5 Main risk factors for non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH).

Overweight or obesity (body mass index [BMI] ≥ 25 kg/m ² in white European individuals; BMI ≥ 23 kg/m ² in Asian individuals)
Abdominal obesity (waist circumference ≥ 94 cm in white European men and ≥ 80 cm in white European women; ≥ 90 cm in Asian men and ≥ 80 cm in Asian women)
Insulin resistance
Pre-diabetes (i.e. impaired fasting glycaemia, impaired glucose tolerance) or established type 2 diabetes
Atherogenic dyslipidaemia
Arterial hypertension
Metabolic syndrome ^a
Family history of type 2 diabetes, NAFLD, or premature cardiovascular disease
NAFLD-related genetic variants, e.g. <i>PNPLA3</i> rs738409 C > G, <i>TM6SF2</i> rs58542926 C > T, <i>GCKR</i> rs1260326 C > T, <i>GCKR</i> rs780094 A > G, <i>MBOAT7</i> rs641738 C > T

^a The National Cholesterol Education Program Adult Treatment Panel III diagnostic criteria for the metabolic syndrome include three or more of the following metabolic risk abnormalities: waist circumference >102 cm (men), >88 cm (women); plasma triglycerides ≥ 150 mg/dl or drug treatment; high-density lipoprotein (HDL) cholesterol <40 mg/dl and <50 mg/dl for men and women, respectively, or drug treatment; blood pressure $\geq 130/85$ mmHg or drug treatment; fasting plasma glucose ≥ 100 mg/dl, previously diagnosed type 2 diabetes, or use of glucose-lowering agents.

Genetic factors predisposing to more severe non-alcoholic fatty liver disease

Numerous genome-wide association studies (GWAS) have clearly identified important genetic contributors to the development and progression of NAFLD [45, 47–49]. Four genetic

variants are noteworthy of mention for several reasons, including their biological plausibility, the relationship with severe NAFLD, and the reproducibility of the findings. Among these four genetic variants, one encodes patatin-like phospholipase domain-containing-3 (*PNPLA3*) [45, 47–49]. The single-nucleotide polymorphism rs738409 C>G (p.I148M) in *PNPLA3* is defined as a non-synonymous cytosine-to-guanine nucleotide transposition mutation, resulting in an isoleucine-to-methionine amino acid change at codon 148 [45, 47–49]. The wild-type *PNPLA3* protein has hydrolase activity on triglycerides and retinyl esters [47–49]. The 148 M substitution determines a loss of function in the enzymatic activity, thereby leading to an entrapment of triglycerides and retinyl esters within lipid droplets in both hepatocytes and hepatic stellate cells [47–49]. Alterations in lipid droplet architecture and in the retinol metabolism of both hepatocytes and hepatic stellate cells play a key role in the development and progression of NAFLD [47–49]. *PNPLA3* rs738409 C>G variant is closely associated with greater susceptibility to NASH, cirrhosis, and HCC [45, 47–49]. Some studies have also reported an association between this genetic variant and liver-related mortality in NAFLD [45, 47–50]. In addition, homozygosity of the *PNPLA3* rs738409 G variant appears to exert its greatest adverse effect on NAFLD severity among individuals in the highest BMI category, while those with a high BMI who are homozygous for the wild-type *PNPLA3* (CC), or who are heterozygous (CG) for this mutation, have a substantially lower risk of NAFLD progression [51].

Another variant that is associated with greater susceptibility to NASH occurs within the transmembrane-6 superfamily member 2 (*TM6SF2*) gene on chromosome 19 [45, 47–49]. The *TM6SF2* rs58542926 C>T (p.E167K) variant is strongly associated with increased hepatic fat content and greater risk of more severe liver disease in NAFLD [45, 47–49, 52]. Mechanistic studies indicate that *TM6SF2* modulates hepatic lipid efflux [45, 47–49]. Deletion (or mutation) of the *TM6SF2* gene results in a reduction in hepatic lipoprotein secretion, as well as an increase in hepatic fat accumulation and hepatocellular lipid droplet size [45, 47–49]. In this context, the *TM6SF2* rs58542926 C>T variant produces a loss of function of the protein [45, 47–49]. Studies have also suggested that *TM6SF2* gene variants may be associated with different disease phenotypes [45, 47–49]. Indeed, evidence now suggests that *TM6SF2* may act as a ‘controller’, with the *TM6SF2* rs58542926 T allele driving hepatic triglyceride retention and the C allele facilitating very low-density lipoprotein (VLDL) excretion (thus protecting the liver), while at the same time increasing the risk of CVD (i.e. the so-called *TM6SF2* Catch-22 paradigm) [53].

Variants in the genes encoding glucokinase regulator (*GCKR*) and membrane bound O-acyl transferase 7 (*MBOAT7*) also play a role in the development of NAFLD [45, 47–49]. *GCKR* modulates hepatic *de novo* lipogenesis by controlling the influx of glucose in hepatocytes [47–49]. Two genetic variants in the *GCKR* gene locus, rs1260326 C>T and rs780094 A>G, have been associated with NAFLD and its more severe histological forms [47–49]. The most common missense loss-of-function *GCKR* mutation is rs1260326 C>T, which encodes the P446L protein variant [47–49]. The P446L variant adversely affects the capacity of *GCKR* to regulate the glucokinase in response to fructose-6-phosphate, thereby activating hepatic glucose uptake [47–49]. This results in increased malonyl-CoA that induces hepatic *de novo* lipogenesis, inhibits fatty acid oxidation, and promotes hepatic steatosis [47–49].

Membrane-bound O-acyltransferase domain containing 7 (*MBOAT7*) is a protein involved in the remodelling of phosphatidylinositol with arachidonic acid [47–49]. The *MBOAT7* rs641738 C>T variant is a common genetic variant linked to the downregulation of *MBOAT7* mRNA and protein [47–49]. The *MBOAT7* rs641738 C>T variant is associated with decreased levels of phosphatidyl-inositol-containing arachidonic acid in hepatocytes [47–49]. Recently, this genetic variant was found to be associated with a higher risk of NAFLD and advanced fibrosis in adults of European descent [54]. However, genetic variants in *GCKR* and *MBOAT7* produce a smaller effect on the risk of progressive NAFLD compared with *PNPLA3* and *TM6SF2* genetic variants [47]. A general concept based on available genetic studies is that the risk of progressive NAFLD is influenced by the effect of these genetic variants on hepatic fat accumulation, thereby emphasizing that accumulation of lipids in hepatic droplets plays a major role in liver damage [47].

Finally, other genes affecting NAFLD progression, identified by candidate gene analyses, have been validated in large studies or using transmission disequilibrium tests [45, 47–49]. Presently, they include *LPIN1* rs13412852 C>T, *SOD2* rs4880 C>T, *UCP2* rs695366 G>A, *ENPP1* K121Q rs1044498 A>C, *IRS1* rs1801278 A>C, *IL28B* rs12979860 C>T, *KLF6* rs3750861 G>A, *MERTK* rs4374383 G>A, and *FNDC5* rs3480 A>G. All these genetic variants have also been implicated in the hepatic regulation of lipid metabolism, insulin signalling, inflammation, oxidative stress, and fibrogenesis [45, 47–49].

Obesity and insulin resistance

A majority of people with NAFLD have obesity (~50%), atherogenic dyslipidaemia (~69%), or type 2 diabetes (~25%) [55]. Individuals with NASH are more likely to be overweight or obese compared to those with simple steatosis (NAFL) or the general population [55]. In individuals with severe obesity, the prevalence of imaging-defined NAFLD is as high as ~90%, although this percentage varies across published studies according to age, ethnicity, degree of obesity, pre-existing type 2 diabetes, and imaging techniques used for diagnosing NAFLD [56, 57]. Notably, more than 30% of individuals with severe obesity have NASH with varying stages of liver fibrosis identified histologically [58]. It has been demonstrated that weight gain is associated with dysfunction of adipocytes that is closely associated with local inflammation and production of a variety of pro-inflammatory cytokines (e.g. tumour necrosis factor- α [TNF- α] and interleukin-6 [IL-6]), thereby promoting systemic chronic inflammation and insulin resistance (IR) (Figure 57.2) [45, 58, 59]. Insulin resistance alters the capacity of adipocytes to accumulate fat and promotes lipolysis [45, 59]. Hepatocytes take up free fatty acids via fatty acid transport protein-5 (FATP5) and the scavenger receptor CD36 [45, 59]. The accumulation of free fatty acids within the hepatocytes drives the synthesis of triglycerides and impairs hepatic insulin signalling by activating protein kinase C ϵ (PKC ϵ) [45, 59]. These mechanisms may also promote hepatic gluconeogenesis and chronic hyperglycaemia [45, 59].

Liver metabolism plays a key role in hepatic steatosis by producing lipid from carbohydrates (hepatic *de novo* lipogenesis) (Figure 57.2) [45, 59]. In a study enrolling individuals with metabolic syndrome and/or elevated serum transaminase levels, it has been clearly reported that hepatic *de novo* lipogenesis was around threefold higher in individuals with NAFLD compared to those without NAFLD, thus further supporting a pathogenetic role of *de*

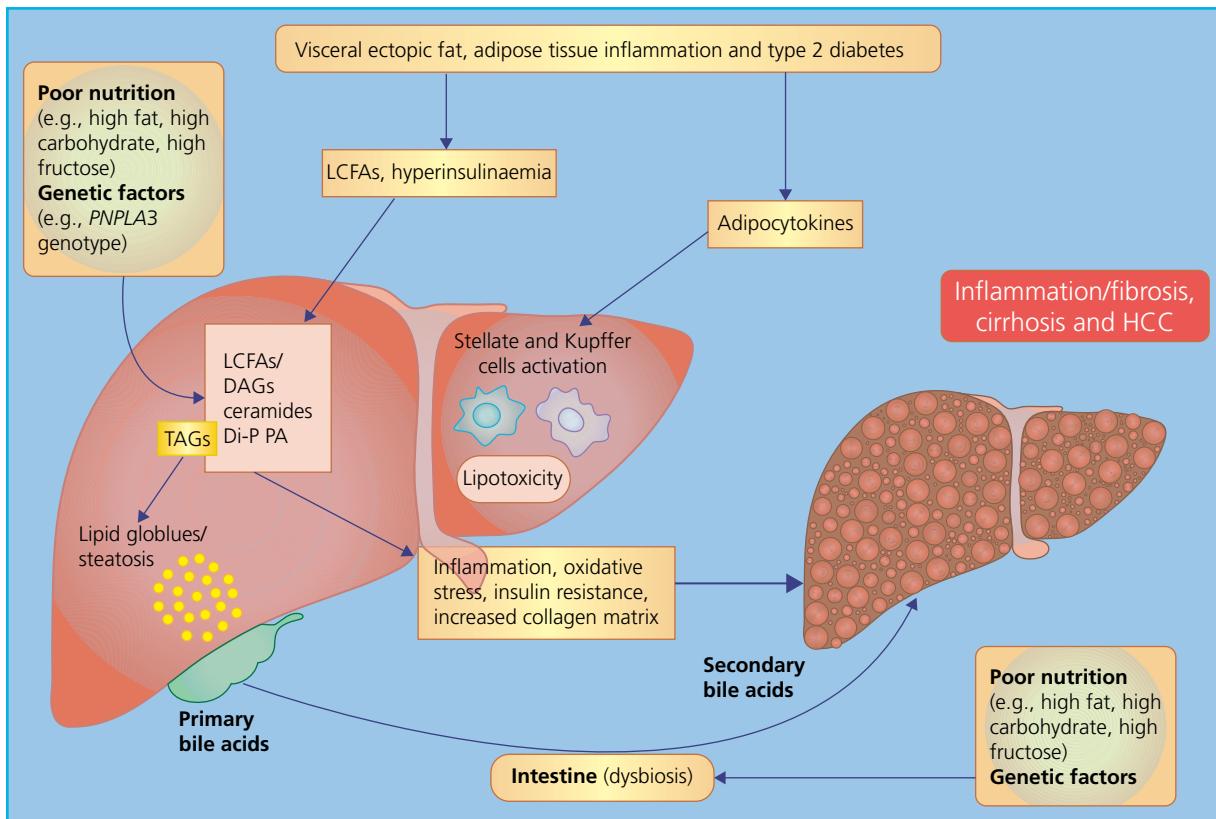

Figure 57.2 Principal pathological mechanisms associated with the development and progression of non-alcoholic fatty liver disease (NAFLD). Visceral ectopic fat accumulation, adipose tissue inflammation, and type 2 diabetes promote the development and progression of NAFLD. Western diet (especially high fat and high fructose intakes), along with some common genetic variants (e.g. *PNPLA3* polymorphism), play a role in NAFLD progression, increasing hepatic lipid accumulation and promoting liver fibrosis. Intestinal dysbiosis (defined by the presence of perturbations to the structure of complex commensal communities in

the intestinal microbiota) alters the production of short-chain fatty acids (from fermentation of dietary carbohydrate) and promotes the production of lipopolysaccharide into the portal circulation. These factors then promote a pro-inflammatory hepatic stimulus, increasing the risk of NAFLD progression. See text for further details. DAG, di-acylglycerol; HCC, hepatocellular carcinoma; LCFAs, long-chain fatty acids; Di-P PA, Di-palmitoyl phosphatidic acid; *PNPLA3*, patatin-like phospholipase domain-containing 3. novo lipogenesis in hepatic steatosis [60]. Through the activity of two main transcription factors, sterol regulatory element-binding protein 1 (SREBP1) and carbohydrate-responsive element-binding protein (ChREBP), both insulin and glucose may upregulate the enzymes implicated in hepatic *de novo* lipogenesis, thereby inducing hepatic fat accumulation [45, 59]. Diets high in fats and carbohydrates also provide substrates for hepatic fat synthesis and contribute to the development of hepatic steatosis via increased *de novo* lipogenesis [45, 59]. Moreover, dietary fructose intake may increase hepatic *de novo* lipogenesis and visceral adiposity, and induce insulin resistance [45, 59].

All forms of NAFLD are closely linked with systemic and hepatic insulin resistance (Figure 57.2) [45, 59]. In the liver, insulin resistance is characterized by impaired insulin-mediated suppression of hepatic glucose production, increased gluconeogenesis, and decreased glycogen synthesis [45, 59]. Insulin activates its receptor, which results in tyrosine phosphorylation of insulin receptor substrate (IRS) and activation of downstream effector pathways, such as the phosphatidylinositol 3-kinase (PI3K)-phosphoinositide-dependent kinase-protein kinase B (Akt) and the RAS-extracellular-signal regulated kinase (ERK) pathways [45, 59]. Several pro-inflammatory pathways can interfere with insulin signalling by inhibiting phosphorylation of IRS [45, 59]. The inhibitor of NF κ B kinase β (IKK β) is an important stimulus for insulin

resistance, along with its role as NF κ B activator [45, 59]. Experimental data suggest that activation of NF κ B and downstream inflammatory signalling pathways play a key role in the development of hepatic insulin resistance [45, 59]. Although there is a link between NAFLD and insulin resistance, observational and GWAS studies have identified some genetic variants (e.g. *PNPLA3* and *TM6SF2* variants) that are associated with greater NAFLD severity, but not with greater insulin resistance [45, 59, 61].

Triglycerides *per se* are not hepatotoxic products [45, 59]. Rather, precursors of triglyceride (i.e. free fatty acids and diacylglycerols) may induce hepatic lipotoxicity [45, 59]. Lipotoxicity drives the release of multiple pro-inflammatory mediators, leading to hepatocyte death [45, 59]. Dying hepatocytes can promote the release of several other factors that, in turn, may activate healing responses in hepatocytes [45, 59]. These healing responses are typically characterized by three elements: recruitment of other cell types (myofibroblasts); remodelling of the vasculature; and recruitment of immune cells that can further release multiple factors able to amplify liver injury [45, 59].

As shown in Figure 57.2, other putative mechanisms implicated in the development and progression of NAFLD include changes in gut microbiota, bile acids and their metabolites, and products of choline metabolism influenced by the intestinal microbiota.

Non-alcoholic fatty liver disease as a multisystem disease

Several studies have consistently documented that NAFLD is associated with an increased risk of extrahepatic complications, such as CVD (which is the leading cause of mortality in people with NAFLD), type 2 diabetes, chronic kidney disease (CKD), and certain types of extrahepatic cancers (especially colorectal cancers) [5–8, 39, 46, 62] (Figure 57.3).

Risk of type 2 diabetes

Type 2 diabetes is associated with increased risk of hospital admission or death for all common chronic liver diseases and the strength of the association may vary by type of chronic liver disease, sex, and socioeconomic status [63]. NAFLD is also associated with an increased risk of CVD, cancer, and mortality among people with type 2 diabetes [64]. Moreover, individuals with NAFLD have an increased risk of developing type 2 diabetes compared to those without NAFLD, even after adjustment for common metabolic risk factors [46, 65–67]. A comprehensive meta-analysis of 33 longitudinal cohort studies (involving 501 022 middle-aged individuals) showed that NAFLD was significantly and independently associated with a 2.2-fold increased risk of incident diabetes over a median follow-up period of five years [68]. Notably, this risk increased further with the severity of NAFLD (especially the severity of liver fibrosis) [68]. In this context, in a small retrospective study of Swedish people with biopsy-proven NAFLD, the authors showed that a significantly higher proportion of individuals with histologic fibrosis stages F3–4 developed incident type 2 diabetes,

when compared to those with fibrosis stages F0–2 (51% vs 31%), over a mean follow-up of 18 years [69].

Some observational studies have also investigated the risk of incident type 2 diabetes in relation to changes in NAFLD status over time. In a retrospective cohort study of ~13 000 Korean individuals who were followed for at least five years, improvement in hepatic steatosis (on ultrasonography) over time was associated with a decreased risk of incident type 2 diabetes, independent of temporal changes in body weight [70], suggesting that liver fat *per se*, or factors associated with a change in liver lipid, may directly influence the risk of incident type 2 diabetes. In line with these findings, another large Korean study reported that improvement of NAFLD (mostly based on FLI scores) could reduce the risk of incident type 2 diabetes, while the development of new NAFLD could increase the risk of type 2 diabetes [71].

The underlying mechanisms by which NAFLD modifies the risk of incident type 2 diabetes are not fully understood [5, 59, 68]. However, NAFLD, especially NASH with varying amounts of liver fibrosis, exacerbates systemic and hepatic insulin resistance and induces the release of many pro-inflammatory cytokines, hepatokines, and other “diabetogenic” mediators that may actively contribute to the development of type 2 diabetes [5, 59, 68, 72]. Conversely, dysfunction of adipose tissue with excessive lipolysis and diets high in fats and carbohydrates supply the liver with chylomicron remnants and free fatty acids [5, 59, 68]. Elevated hepatic lipid availability, along with inadequate adaptation of mitochondrial function, results in the hepatic production of diacylglycerols and various metabolites (e.g. ceramides) that further promote NAFLD development and progression [5, 59, 68].

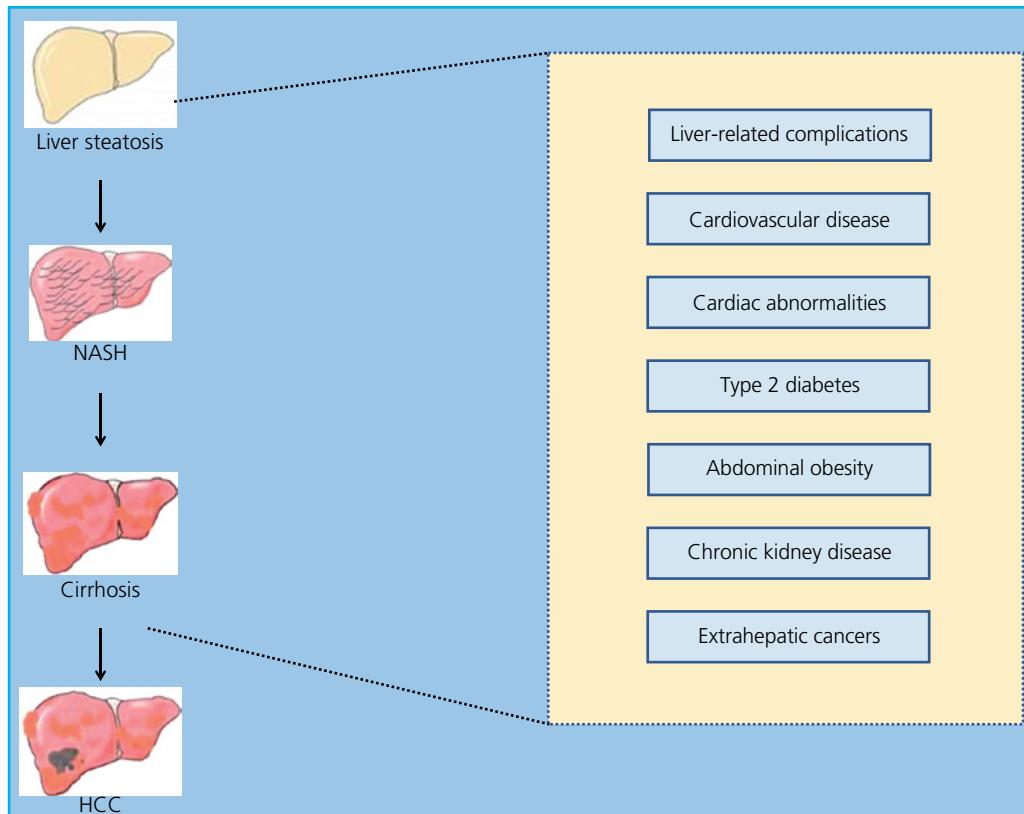

Figure 57.3 Principal liver-related and extrahepatic complications associated with non-alcoholic fatty liver disease. HCC, hepatocellular carcinoma; NASH, non-alcoholic steatohepatitis.

Worsening of glycaemic levels in individuals with type 2 diabetes and non-alcoholic fatty liver disease

Coexistence of NAFLD in people with type 2 diabetes has been associated with higher glycated haemoglobin (HbA_{1c}) and greater hepatic and peripheral insulin resistance [7, 59, 73–76]. The hepatic fat content appears to be the main factor explaining the daily amount of insulin required to achieve optimal glycaemic management in individuals with insulin-treated type 2 diabetes [73]. In an elegant small study of individuals with insulin-treated type 2 diabetes and HbA_{1c} , hepatic fat content (measured by MRS) was strongly associated with the daily insulin dose and the ability of insulin to suppress hepatic glucose production during hyperinsulinaemic-euglycaemic clamp, explaining at least in part the inter-individual variation in insulin requirements [74]. This result was confirmed by another study showing that individuals with NAFLD (assessed by FibroScan® with CAP) were more likely to have features of the metabolic syndrome, elevated HbA_{1c} , and greater requirement for insulin treatment compared to those without NAFLD [76].

Risk of worsening fibrosis and cirrhosis in individuals with type 2 diabetes

Strong evidence shows that individuals with overt type 2 diabetes are at a consistently higher risk of developing NASH and advanced fibrosis, as well as a greater risk of serious liver-related complications, including cirrhosis, liver failure, and HCC [2, 4, 5, 7, 8, 77]. In addition to the findings from the NASH-Clinical Research Network cohort study [27], a large administrative health database (including nearly 2.5 million Canadian individuals) documented that individuals with newly diagnosed type 2 diabetes had a ~2-fold increased risk of developing cirrhosis, liver failure, or liver transplantation compared with matched individuals without type 2 diabetes, during a follow-up of 12 years [78]. Using an electronic administrative database of death certificates in Northern Italy, the authors showed that people with type 2 diabetes had a ~3-fold higher risk of dying of chronic liver diseases, mainly due to NAFLD [79].

Once chronic liver disease progresses to end-stage liver disease, the presence of type 2 diabetes is a strong predictor of worse clinical outcomes [80, 81]. Type 2 diabetes is also closely associated with the severity of liver disease (cirrhosis) based on the Child-Pugh class and the model for end-stage liver disease (MELD) score [80, 81]. In addition, type 2 diabetes is associated with more severe hepatic encephalopathy among individuals with established cirrhosis, regardless of the severity of liver disease and its aetiology [80]. The incidence of HCC and HCC-specific mortality is higher in people with type 2 diabetes than in those without [81]. In a meta-analysis of 28 prospective studies, it has been confirmed that compared to those without type 2 diabetes, individuals with type 2 diabetes had a ~2-fold increased risk of incident HCC and HCC-specific mortality [82]. Furthermore, individuals with type 2 diabetes and HCC also had a ~40% increased risk of all-cause mortality and a ~90% increased risk of decompensated cirrhosis [82].

The effect of type 2 diabetes on the risk of HCC seems to be even more relevant in individuals carrying the *PNPLA3* rs738409 polymorphism [81]. In a case-control study enrolling 257 individuals with HCC and 494 controls, the risk of HCC was higher in individuals with type 2 diabetes carrying the *PNPLA3* rs738409 variant than in people without diabetes with the same genetic variant [83]. In this context, the presence of insulin resistance and

compensatory hyperinsulinaemia plays a key role in HCC development in type 2 diabetes, promoting growth signalling pathways, pro-inflammatory cytokine production, and neoangiogenesis [81, 84].

Collectively, these findings strongly emphasize that clinicians need to be aware of the possible coexistence of NAFLD in individuals with type 2 diabetes, and, when a diagnosis of NAFLD is made, clinicians should determine whether NASH with advanced fibrosis is also present.

Risk of cardiovascular disease, arrhythmias, and cardiac diseases

As previously reported, the leading cause of mortality among NAFLD individuals is CVD [5, 6, 39, 85]. In a meta-analysis of 45 observational studies including >8 million people followed from 4 to 13 years, the pooled CVD-specific mortality rate in individuals with NAFLD (irrespective of type 2 diabetes status) was approximately 5 per 1000 person-years [3]. Using the National Vital Statistics System multiple-cause mortality data (2007–2016), Paik et al. showed that CVD was one of the most important causes of mortality among US individuals with NAFLD [85]. Several hospital-based and population-based cohort studies have shown that people with NAFLD have an increased risk of fatal and non-fatal CVD events, when compared with those without NAFLD, even after adjusting for many traditional CVD risk factors, in individuals both with and without type 2 diabetes [6–8, 39, 73, 86, 87]. A 2016 meta-analysis of 16 observational studies (involving 34 043 individuals) confirmed that individuals with NAFLD had a 64% higher risk of fatal and/or non-fatal CVD events than those without NAFLD over a median period of 6.9 years [86]. Individuals with more 'severe' NAFLD were also more likely to develop fatal and non-fatal CVD events (random-effects odds ratio 2.58, 95% confidence interval [CI] 1.78 to 3.75) [86]. Other studies confirmed that the magnitude of risk of CVD events paralleled the underlying severity of NAFLD [41, 88, 89]. More recently, in a nationwide, matched-cohort study of 10 568 Swedish individuals with biopsy-confirmed NAFLD and 49 925 matched controls (followed up for a median period of 14.2 years), the investigators reported that all NAFLD histological stages were independently associated with increased mortality rates from CVD [41]. In a multinational retrospective cohort study of 619 individuals with biopsy-proven NAFLD (38% with type 2 diabetes), increasing fibrosis stage, but no other histological features of NASH, was strongly associated with long-term overall mortality, liver transplantation, and liver-related complications [88]. Similar findings were also documented in other hospital-based cohorts involving people with type 2 diabetes [6, 8, 26, 39, 73, 87].

To date, increasing clinical evidence substantiates the existence of a strong relationship of NAFLD with subclinical myocardial remodelling and dysfunction, valvular heart diseases (mainly aortic valve sclerosis and mitral annulus calcification), and arrhythmias (mainly permanent atrial fibrillation) in individuals with and without type 2 diabetes [6, 8, 26, 39, 46, 73, 87]. For example, in a cross-sectional study enrolling individuals with type 2 diabetes, Mantovani et al. reported that NAFLD (on ultrasonography) was independently associated with increased risk of early left ventricular diastolic dysfunction [90]. Another cross-sectional study showed that cardiac structure alterations (assessed by cardiac magnetic resonance) were more prevalent in individuals with type 2 diabetes and NAFLD compared to those with NAFLD alone or people without either condition [91]. Some studies using liver biopsy

or FibroScan® reported a graded, positive relationship between cardiac structure abnormalities and the severity of NAFLD in individuals with and without type 2 diabetes [39]. Studies have also reported an association between NAFLD and risk of aortic valve sclerosis and mitral annulus calcification in individuals with and without type 2 diabetes [39, 92].

Accumulating clinical evidence now suggests that NAFLD is associated with an increased risk of permanent AF in individuals with and without type 2 diabetes [39]. AF is the most common sustained arrhythmia in clinical practice, and it is closely related to cardiovascular morbidity and mortality [39]. A large meta-analysis of five observational studies (involving a total of ~240 000 middle-aged and elderly individuals) showed that NAFLD was associated with a higher prevalence and incidence of permanent atrial fibrillation [93]. In a retrospective study of individuals undergoing atrial fibrillation ablation, it has been reported that NAFLD was associated with increased arrhythmia recurrence rates following ablation, during a mean follow-up of ~2.5 years [94]. Other studies documented that imaging-defined NAFLD was associated with an increased risk of prolonged QTc interval, ventricular arrhythmias, or certain cardiac conduction defects in people with type 2 diabetes [39, 95–98], even after adjustment for established CVD risk factors. The aforementioned findings are of clinical importance

because these NAFLD-related cardiac and arrhythmic complications may, at least in part, contribute to the increased risk of CVD events observed among individuals with NAFLD.

There are most likely multiple underlying mechanisms through which NAFLD may directly increase the risk of CVD and cardiac and arrhythmic complications [46]. Although NAFLD might be simply a consequence or a marker of shared cardio-metabolic risk factors and comorbidities, growing evidence supports the notion that NAFLD plays a part in the pathophysiology of CVD and other cardiac and arrhythmic complications (Figure 57.4).

Current evidence indicates that a diagnosis of NAFLD identifies a subgroup of individuals that are at high risk of CVD mortality and morbidity, and the EASL-EASO-EASD and AASLD practice guidelines strongly recommend a CVD risk assessment in all individuals with NAFLD [1, 2].

Risk of microvascular complications

Several studies have reported that NAFLD is associated with an increased risk of CKD in people with and without type 2 diabetes, independent of established cardio-renal risk factors [62]. In 2008, the Valpolicella Heart Diabetes Study showed for the first time that individuals with type 2 diabetes and NAFLD (on ultrasonography) had

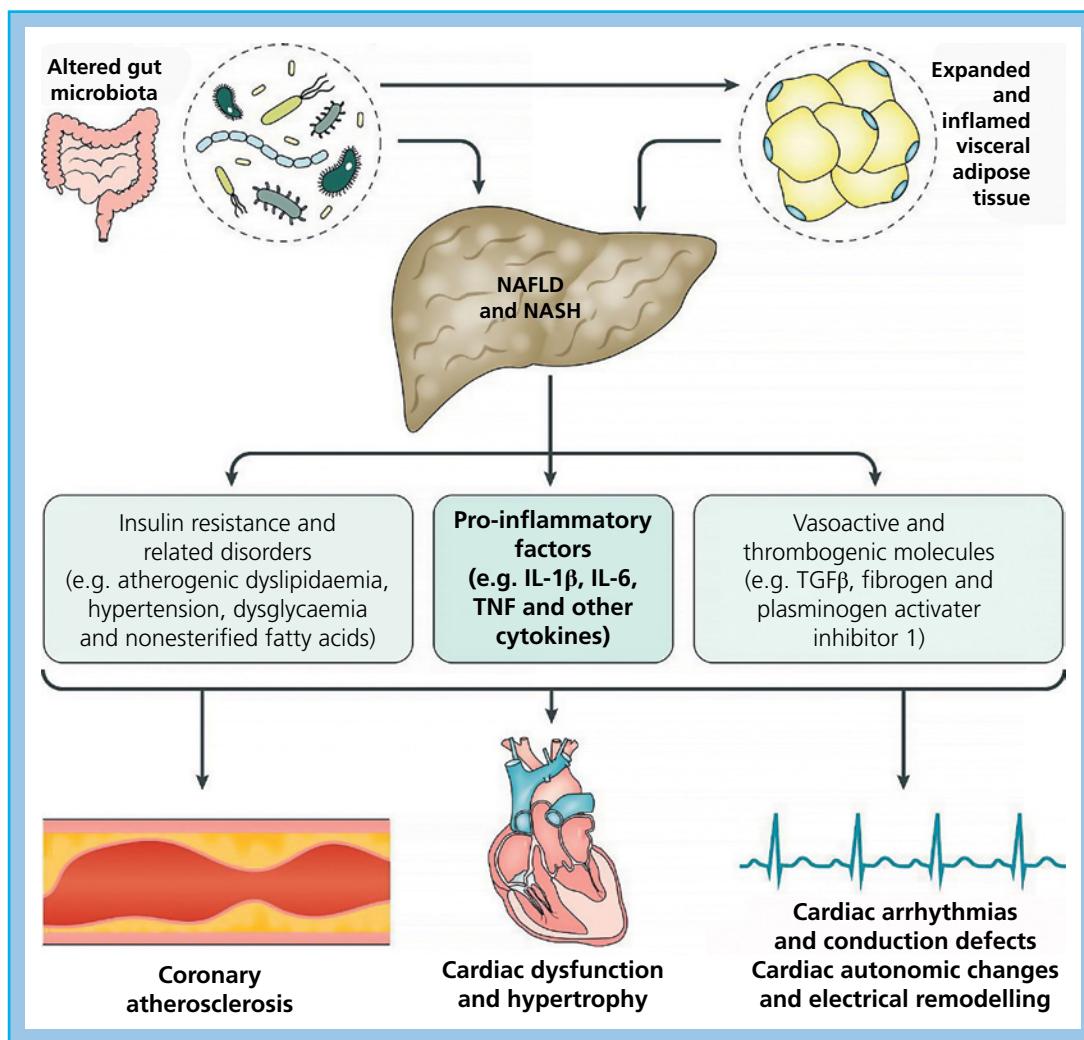

Figure 57.4 Possible biological mechanisms responsible for the association between non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) and the risk of developing cardiovascular disease (CVD) and other structural cardiac complications. NAFLD may directly promote the development and progression of CVD complications, possibly through the hepatic production of lipids and atherogenic lipoproteins; the induction of hepatic/peripheral insulin resistance and dysglycaemia; as well as the release of numerous pro-inflammatory, pro-fibrogenic, and pro-coagulant mediators into the bloodstream. See text for further details. IL, interleukin; TGF, tumour growth factor; TNF, tumour necrosis factor. Source: Reproduced by permission from Anstee QM 2018 [39].

an increased risk of incident CKD stage ≥ 3 , compared to their counterparts without NAFLD, over a mean follow-up of 6.5 years [99].

A large meta-analysis of 13 observational longitudinal studies involving more than 1 million middle-aged individuals from different countries showed that the long-term risk of developing CKD stage ≥ 3 was increased ~ 1.5 -fold in individuals with NAFLD. Furthermore, the risk of incident CKD stage ≥ 3 remained significant in those studies where analysis was adjusted for age, sex, adiposity measures, smoking, pre-existing type 2 diabetes, hypertension, dyslipidaemia, and baseline estimated glomerular filtration rate (eGFR). In addition, this risk seemed to parallel the severity of NAFLD, especially the severity of liver fibrosis [100]. Another meta-analysis showed that this risk could be even greater in individuals with type 2 diabetes [101].

Experimental and clinical data suggest that NAFLD may contribute to the activation of multiple pathways potentially involved in CKD pathophysiology (Figure 57.5) [46, 62, 102]. For example, impaired activation of the renin–angiotensin system may contribute to the reno-vascular injury by inflammation and coagulation pathways. Atherogenic dyslipidaemia, insulin resistance, increased oxidative stress, and pro-inflammatory factors that are promoted by NAFLD may all contribute to the development of vascular and renal damage. Increased production of toxins by intestinal microbiota may induce renal injury or worsen the liver damage. Finally, pre-

liminary evidence suggests an association between the *PNPLA3* rs738409 variant and the presence of kidney dysfunction, independent of common renal risk factors and NAFLD severity [62, 102–108].

Treatment for non-alcoholic fatty liver disease in individuals with type 2 diabetes

The EASL-EASO-EASD guidelines recommend consideration of pharmacological treatment for NAFLD not only in those with NASH with varying stages of liver fibrosis, but also in individuals with less severe liver disease who are at the highest risk for disease progression (e.g. those with type 2 diabetes or metabolic syndrome) [1]. Conversely, the AASLD [2] and the UK National Institute for Health and Care Excellence (NICE) guidelines [109] recommend limiting pharmacological treatment for the liver disease only to those with biopsy-proven NASH and varying stages of fibrosis.

Currently, there are no licensed pharmacological treatments specifically for liver disease in NAFLD [1, 2]. The management of NAFLD is based on the following main principles:

- To promote weight loss by diet and exercise (Table 57.6).
- To control all coexisting cardiometabolic risk factors.
- To prevent the development and progression of both liver-related and extrahepatic complications [1, 2].

Table 57.6 Recommended lifestyle interventions to improve non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) liver histology.

Nutrition
5–10% weight loss as target
Long-term maintenance approach
Prefer Mediterranean diet (i.e. high intake of vegetables, legumes, whole grains, olive oil, fish, seafood, nuts, and fruits, as well as low intake of red meat, processed meats, and sweets)
Avoid alcohol intake
Avoid fructose intake, soft drinks, processed meat, and saturated fatty acids
Low-carbohydrate ketogenic diets
Physical activity
Moderate-intensity aerobic physical activities (~150 min/wk)
Resistance training (alternatively to aerobic physical activities)
3–5 sessions weekly
Other
Avoid cigarette smoking

Western dietary pattern has detrimental effects on NAFLD [110, 113]. Potential mechanisms for the hepatic benefits of the Mediterranean diet include the presence of polyphenols, carotenoids, oleic acid, polyunsaturated fatty acids (PUFAs), and fibre [113]. These components favourably influence multiple pathways involving the liver, adipose tissue, and intestine, thereby mediating long-term beneficial effects on NAFLD [114].

Different forms of exercise (aerobic exercise, resistance exercise, or high-intensity intermittent exercise) seem to have similar effects on liver fat content [110, 115]. In a systematic review, physical exercise, irrespective of weight loss, produced a ~20–30% relative reduction in hepatic fat content, as measured by MRS [116]. However, if individuals do not continue to exercise, the benefits are lost [110]. The mechanisms underpinning the changes in liver fat content mediated by exercise may be due to changes in energy balance and improvements in systemic and hepatic insulin resistance and glycaemic management [110]. Exercise also has positive effects on intra-abdominal visceral accumulation and hepatic fatty acid uptake, with an increase in VLDL clearance, further promoting liver fat reduction [110]. Lastly, given that people with NAFLD are at high CVD risk, it is important to remember that the beneficial effects of exercise extend beyond the liver, with favourable effects on traditional CVD risk factors [110]. Table 57.6 summarizes the main lifestyle interventions that may improve the histology of NAFLD/NASH, as recommended by EASL-EASO-EASD and AASLD practice guidelines [1, 2].

Bariatric surgery

The most widely adopted bariatric surgery procedures are laparoscopic sleeve gastrectomy, laparoscopic Roux-en-Y gastric bypass, laparoscopic adjustable gastric banding, and duodenal switch [117]. Bariatric surgery may substantially improve all of the histological features of NAFLD, including liver fibrosis [1, 2, 117]. In a meta-analysis of 32 cohort studies comprising 3093 biopsy specimens, bariatric surgery resulted in histological resolution of hepatic steatosis in ~70% of cases, hepatic inflammation in ~50%, ballooning degeneration in ~75%, and hepatic fibrosis in ~40% [118]. However, these beneficial hepatic effects seem to be not always consistent, as a subset of these individuals may progress to more severe forms of NAFLD after bariatric surgery, whereas others may develop *de novo* NAFLD. Specifically, in the aforementioned meta-analysis, the authors found that ~10% of individuals had new or worsening features of NAFLD after bariatric surgery [118].

The possible liver-related benefits derived from bariatric surgery may extend beyond weight loss [45, 119]. Bariatric surgery can increase circulating glucagon-like peptide 1 (GLP-1) levels, which, in turn, decrease appetite, slow gastric emptying, and improve insulin sensitivity and glycaemic management [45]. GLP-1 also modulates bile acid signalling via the farnesoid X receptor (FXR) nuclear receptor, which may modify the gut microbiome [120, 121]. The current guidelines indicate that bariatric surgery could be a therapeutic option in people with type 2 diabetes and severe obesity (i.e. BMI >35 kg/m²) [1, 2]. Bariatric surgery should also be considered as an alternative option in individuals with obesity and a BMI between 30 and 35 kg/m² when type 2 diabetes is not adequately managed by optimal medical regimens, or in the presence of multiple CVD risk factors [1, 2]. Although bariatric surgery is effective, there are some important limitations that should be considered, such as peri-/post-procedural complications, patient acceptability, service availability, and cost [117].

Lifestyle modifications

Strong evidence supports the role of lifestyle modifications as primary therapy for management of NAFLD [1, 2, 110]. Weight loss can result in improvement or resolution of NAFLD and decrease in risk of CVD and type 2 diabetes [110]. Weight reduction of ≥10% promotes histological resolution of NASH, as well as fibrosis improvement by at least one stage [110]. Mild to moderate weight loss (5–10%) may improve hepatic steatosis, necro-inflammation, but not liver fibrosis [110]. The EASL-EASO-EASD and AASLD guidelines for NAFLD management indicate that 5–10% weight loss should be the goal of lifestyle interventions in most individuals with overweight or obesity and NAFLD [1, 2]. Some evidence suggests that individuals without obesity can also achieve NAFLD resolution or improvement with modest weight loss of 3–10%, and that they are more likely to maintain weight reduction and normal serum liver enzyme levels over time than individuals with obesity and NAFLD [111].

The effect of weight loss on the histological improvement or resolution of NASH largely reflects the amount of weight reduction, rather than the methods used to achieve it [110]. Different lifestyle interventions (hypocaloric diet, physical exercise) and weight loss induced by drugs or bariatric surgery produced similar favourable effects on NASH resolution and fibrosis regression [110]. All individuals with NAFLD should avoid alcohol consumption [1, 2, 112] and, when possible, the use of hepatotoxic drugs [1, 2]. Healthcare professionals should also recommend avoidance of cigarette smoking, as well as fructose-containing beverages and foods [1, 2].

Different diets have been tested in individuals with NAFLD [110, 113]. Observational studies and small randomized controlled trials (RCTs) have documented that the Mediterranean diet may exert favourable hepatic effects, as this style of food consumption reduces liver fat content and improves the histological severity of NAFLD, regardless of weight loss. Hence, the Mediterranean diet is the most frequently recommended style of eating in people with NAFLD [1, 2, 113]. Importantly, it is well documented that Mediterranean diet also reduces the risk of CVD and type 2 diabetes [113]. Conversely, the consumption of components characterizing a

Metformin

Metformin is recommended as the initial drug of choice for people with type 2 diabetes [122, 123]. This drug reduces blood glucose levels mainly through mechanisms involving the AMP-activated protein kinase-dependent reduction in hepatic glucose production and improvement in skeletal muscle glucose uptake [122]. Metformin may also reduce the risk of CVD events and mortality in people with type 2 diabetes, especially in those who have overweight or obesity [122, 123]. In published RCTs involving individuals with biopsy-proven NASH, despite its beneficial effects on serum liver enzyme levels and glycaemic management, metformin showed little or no effects on the resolution of NASH and individual histological scores of NASH (Table 57.7) [124, 125]. Presently, the EASL-EASO-EASD and AASLD practice guidelines for NAFLD management do not recommend metformin for treatment of NAFLD or NASH [1, 2]. As suggested by some observational studies, metformin use is associated with reduced risk of cirrhosis and HCC [126–130]. However, future large RCTs are needed to confirm these findings.

Peroxisome proliferator-activated receptor- γ agonists

Pioglitazone is a selective ligand of the peroxisome proliferator-activated receptor (PPAR)- γ [122, 123]. PPARs are nuclear receptors capable of modulating key elements of glucose and lipid metabolism and also regulate inflammatory and fibrotic processes [131]. By binding PPAR- γ , pioglitazone modulates insulin action, glucose, and lipid metabolism, as well as inflammation and adipose tissue biology [122, 123, 131]. The PPAR- γ 2 receptor (one of the three isoforms of PPAR- γ) is highly expressed in adipose tissue, playing a key role in the redistribution of intra-abdominal

and subcutaneous adipose tissue by promoting accumulation of triglycerides in peripheral adipose tissue depots [122, 123]. The PPAR- γ receptor is also expressed in Kupffer cells, which are involved in hepatic fibrogenesis [122, 123]. A systematic review showed that the long-term use of pioglitazone in individuals with biopsy-confirmed NASH has significant benefits on serum liver enzyme levels, liver fat content, and resolution of NASH in individuals both with and without type 2 diabetes (Table 57.7) [124].

The effect of pioglitazone on liver fibrosis is rather modest [124]. However, in a placebo-controlled RCT of 101 individuals with biopsy-proven NASH and pre-diabetes or overt type 2 diabetes, who were randomly assigned to pioglitazone (45 mg/d) or placebo for 18 months, Cusi et al. showed that treatment with pioglitazone was associated with greater resolution of NASH and improvement in individual histological scores, including the fibrosis score, compared with placebo [132]. In a meta-analysis of eight RCTs enrolling nearly 500 individuals with biopsy-confirmed NASH who were followed up to 24 months, pioglitazone treatment improved advanced fibrosis in individuals with NASH, irrespective of type 2 diabetes status [133]. Currently, the EASL-EASO-EASD and AASLD practice guidelines for NAFLD management strongly recommend the use of pioglitazone in individuals with biopsy-proven NASH, regardless of the presence or absence of type 2 diabetes [1, 2]. However, it is important to note that pioglitazone is not licensed by most national medicines agencies specifically for treatment of NASH and, for these reasons, its off-label use for NAFLD/NASH treatment requires the patient's informed consent [123]. Concerns regarding weight gain (most trials reported a weight gain of ~2–3 kg after 6–36 months of treatment), peripheral oedema, and risk of distal bone fractures (mostly in postmenopausal women) restrict the use of pioglitazone in many individuals with NASH (Table 57.7).

Table 57.7 Efficacy and safety of main glucose-lowering agents to non-alcoholic fatty liver disease (NAFLD)/non-alcoholic steatohepatitis (NASH) treatment.

	Serum liver enzymes	Liver fat content ^a	Liver inflammation ^b	Liver fibrosis ^b	NASH resolution ^b	Common adverse effects
Metformin	↑	↑	=	=	=	Lactic acidosis, diarrhoea, nausea, vomiting, flatulence
Pioglitazone	↑	↑	↑	↑	↑	Moderate weight gain (2–4% of body weight, especially subcutaneous fat), fluid retention, distal bone fractures (mostly in women), bladder cancer (uncertain)
Glucagon-like peptide 1 (GLP-1) receptor agonists (liraglutide, exenatide, dulaglutide, semaglutide)	↑	↑	↑	=	↑ ^d	Loss of appetite, nausea, constipation, diarrhoea
Sodium–glucose cotransporter 2 (SGLT-2) inhibitors (empagliflozin, dapagliflozin, canagliflozin)	↑	↑	Unknown ^c	Unknown ^c	Unknown ^c	Genitourinary infections (mainly mycotic infections), diabetic ketoacidosis, hypotension

↑ improved; = no effect; ↓ worse.

NB: Presently, no robust data exist with histological endpoints as a primary outcome to examine the effectiveness of the use of dipeptidyl peptidase 4 (DPP-4) inhibitors for treatment of NAFLD. In addition, DPP-4 inhibitors have a neutral effect on cardiovascular disease outcomes in persons with type 2 diabetes, making this class of glucose-lowering agents less attractive for treatment of NAFLD or NASH [124].

^a Data derived from randomized controlled trials (RCTs) where liver fat was assessed by imaging techniques.

^b Data derived from RCTs where liver inflammation, fibrosis, and resolution of NASH were assessed by liver biopsy.

^c No RCTs with paired liver biopsy data.

^d RCTs with paired liver biopsy data available only for liraglutide or semaglutide.

Lastly, pioglitazone can exert significant cardiovascular benefits, decreasing the risk of myocardial infarction and stroke in individuals with type 2 diabetes or pre-diabetes [134–136].

New drugs able to promote the safe disposal of various metabolic substrates are under study, especially PPAR α/δ and PPAR α/γ agonists [131, 137]. Furthermore, a recent phase 2b RCT of 247 people with biopsy-proven NASH (42% with type 2 diabetes) showed that a 24-week treatment with lanifibranor (a pan PPAR agonist) induced significant improvements in resolution of NASH and regression of liver fibrosis compared with placebo [138].

Glucagon-like peptide 1 receptor agonists

GLP-1 receptor agonists (GLP-1 RAs) are a class of glucose-lowering drugs that are able to induce significant weight loss (on average 3–5 kg) and improve insulin resistance [122, 123]. GLP-1 receptors have been documented in human hepatocytes and the activation of such receptors may promote the reduction of hepatic steatosis by improving insulin-signalling pathways [124]. For these reasons, GLP-1 RAs have also been investigated as a therapeutic option for NASH. A recent systematic review supports the use of GLP-1 RAs (mainly liraglutide) to reduce serum aminotransferase levels and improve hepatic steatosis, as detected by imaging techniques or histology (Table 57.7) [124]. Liraglutide was evaluated in individuals with either biochemistry-based or imaging-defined NAFLD by the Liraglutide Effect and Action in Diabetes (LEAD) programme and LEAD-2 study [139], as well as in individuals with biopsy-proven NASH by the Liraglutide Efficacy and Action in NASH (LEAN) trial [140]. Evidence from these and other RCTs documented that liraglutide improved serum liver enzyme levels and induced significant improvements in histological resolution of NASH, hepatic steatosis, and hepatocyte ballooning (Table 57.7). In these RCTs, liraglutide was generally well tolerated and had a similar adverse event profile to placebo (or reference therapy), with the exception of an increased frequency of gastrointestinal symptoms (Table 57.7) [124].

Recent phase 2 RCTs using semaglutide or dulaglutide, two long-acting injectable GLP-1 RAs, have documented possible benefits of these agents on hepatic fat content (assessed by MRI techniques) and histological resolution of NASH in people with NAFLD or NASH [141–143]. Given that liraglutide and other long-acting GLP-1 RAs have been also reported to substantially reduce the risk of major CVD events in people with type 2 diabetes [144, 145], it is reasonable to speculate that these glucose-lowering agents will become a valid treatment option in individuals with NAFLD, especially if they have obesity or type 2 diabetes.

Sodium–glucose cotransporter 2 inhibitors

Sodium–glucose cotransporter-2 (SGLT-2) inhibitors are a new class of glucose-lowering agents that increase the glucose reabsorption by the kidneys and also by the bowel and heart [122, 123]. SGLT-2 is particularly expressed on the renal epithelial cells edging the S1 segment of the proximal convoluted tubule and promotes glycosuria [122, 123]. Experimental evidence supports a favourable effect of SGLT-2 inhibitors on liver steatosis, necro-inflammation, and also fibrosis, owing to a combination of negative energy balance by increased glycosuria and substrate switching towards lipids as a source of energy expenditure [146, 147]. In 2020, the results of some systematic reviews and meta-analyses supported the role of SGLT-2 inhibitors (empagliflozin, dapagliflozin, or canagliflozin) in improving serum liver enzyme levels and liver fat content, as assessed by MRI-based techniques (Table 57.7) [124, 148]. However, most of the RCTs available so far are small with a short duration and

did not test the efficacy of SGLT-2 inhibitors on liver histology of NAFLD.

Recently, in a single-arm, open-label, pilot trial enrolling Asian individuals with type 2 diabetes and biopsy-confirmed NASH, the authors showed that a 24-week treatment with empagliflozin (25 mg/d) was associated with some improvement in histological scores of NASH [149]. In the published RCTs, SGLT-2 inhibitors had a similar adverse event profile to placebo (or reference therapy), with the exception of increased risk of genitourinary infections (Table 57.7) [124]. Given that SGLT-2 inhibitors also have relevant cardio-renal benefits in large RCTs enrolling individuals with and without type 2 diabetes [150, 151], they are attractive drugs in individuals with NAFLD. Currently, there are ongoing RCTs testing the hepatic effects of different SGLT-2 inhibitors in individuals with biopsy-confirmed NASH.

Lipid-lowering drugs

Statins decrease low-density lipoprotein (LDL) cholesterol by inhibiting 3-hydroxy-3-methylglutaryl-coenzyme-A reductase, which is a key enzyme implicated in cholesterol synthesis [152]. Along with their lipid-lowering effects, statins exert multiple pleiotropic properties, including anti-oxidative and anti-inflammatory effects, reduction of neo-angiogenesis, and improvement of circulatory endothelial function [152]. Although statins may moderately increase serum aminotransferase levels, liver damage due to statins is uncommon [152, 153]. Indeed, it is estimated that an increase of serum liver enzymes >3 times the upper limit of normal is observed in <1% of individuals treated with statins [152, 154]. For this reason, the monitoring of serum transaminase levels is not recommended for individuals treated with statins [152]. *Post hoc* analyses of some published RCTs have documented that statin treatment is safe and can improve liver tests and reduce cardiovascular morbidity in people with mild to moderately abnormal liver tests that are potentially attributable to NAFLD [155]. Preliminary evidence from some non-randomized interventional studies also suggested that in individuals with NAFLD, statin treatment is associated with some improvement in liver steatosis, necro-inflammation, and even fibrosis [156–158], but future *ad hoc* RCTs are needed to confirm the possible hepatic benefits of statins in people with NASH.

Ezetimibe is another lipid-lowering drug that inhibits the small intestinal enterocyte uptake and absorption of cholesterol by binding to Niemann-Pick C1-like 1 (NPC1L1), which keeps cholesterol in the intestinal lumen for excretion. A meta-analysis of six studies (two RCTs and four single-arm trials), involving 273 individuals with NAFLD with and without type 2 diabetes, reported that ezetimibe reduced serum liver enzyme levels and improved hepatic steatosis and hepatocyte ballooning, but not liver fibrosis [159].

Omega-3 (n-3) PUFAs contain several long-chain fatty acids, such as α -linolenic acid, stearidonic acid, eicosapentaenoic acid, docosapentaenoic acid, and docosahexaenoic acid [160]. In a recent meta-analysis of 22 RCTs including 1366 participants with and without type 2 diabetes, the investigators reported that n-3 PUFA supplementation reduced liver fat content (on imaging techniques) when compared with placebo [160]. Similar findings were also observed in another meta-analysis [161]. However, it is important to point out that the size of the effect is relatively small, and that the optimal dose, type of n-3 PUFA, and duration of treatment with n-3 PUFAs are not established [161]. One phase 2 RCT testing the effects of high-dose n-3 PUFAs in people with and without type 2 diabetes with NAFLD suggested that docosahexaenoic acid may be more effective than eicosapentaenoic acid in reducing liver fat

content [162]. Hence, well-designed RCTs are still required to address the question of whether a specific type of n-3 PUFA supplementation is beneficial for the treatment of NAFLD in people with or without type 2 diabetes.

Antihypertensive drugs

Some experimental studies in animals showed that angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers exert antifibrotic effects on the liver [163]. However, clinical studies testing the potential antifibrotic effects of these drugs in individuals with NAFLD have produced inconsistent results [164–167]. Future RCTs are required to better clarify this issue.

New drugs for non-alcoholic fatty liver disease

Several other potential drugs have been tested for NAFLD or NASH [137]. However, in most of the published RCTs available so far only a subset of NASH individuals had established type 2 diabetes.

Synthetic ligands activating the FXR improve insulin resistance, regulate glucose and lipid metabolism, and have anti-inflammatory and antifibrotic hepatic effects in animal NASH models [137]. Obeticholic acid (OCA), a synthetically modified analogue of chenodeoxycholic acid, is the prototype for this new class of agents [137]. A phase 2 RCT of 283 individuals with non-cirrhotic NASH (~50% with type 2 diabetes) showed that OCA treatment improved histological features of NASH, including fibrosis [168]. In an 18-month interim analysis of a multicentre phase 3 RCT that included 931 individuals (57% with type 2 diabetes) with biopsy-proven NASH and fibrosis, the investigators reported that OCA (25 mg/d) significantly improved liver fibrosis compared to placebo [169]. However, OCA had some important side effects, including pruritus and elevated plasma LDL cholesterol levels [169]. In this trial, plasma LDL cholesterol levels increased by ~20% from baseline, although it was suggested that the increase tended to be transient and was controlled by statin treatment [169]. The adverse effect of OCA on plasma lipid profile is of clinical importance, as individuals with NAFLD are at high CVD risk.

Conclusion

NAFLD and type 2 diabetes frequently coexist and act synergistically to increase the risk of adverse liver-related and extra-hepatic clinical outcomes. Type 2 diabetes is also one of the strongest clinical risk factors for faster progression of NAFLD to NASH, cirrhosis, and HCC. Strong evidence now indicates that NAFLD is also associated with an increased risk of developing incident type 2 diabetes and contributes to the development of CVD and other chronic vascular complications of diabetes. CVD is the predominant cause of death in people with NAFLD and, therefore, aggressive CVD risk reduction measures and CVD treatments may be required in people with NAFLD, regardless of whether these individuals have coexisting type 2 diabetes.

Since NAFLD is very common in people with type 2 diabetes (affecting up to nearly 70% of these individuals), healthcare professionals need to be aware of how to diagnose NAFLD and the different stages of the liver disease. When NAFLD is diagnosed, lifestyle modifications focused on weight loss and increased physical activity are effective in promoting histological resolution of NASH, particularly in the early stages of the disease. When advanced fibrosis or cirrhosis is present, specialist referral is required, because of the potential risk of portal hypertension, liver failure, and HCC. Randomized controlled trials of existing licensed drugs for the treatment of type 2 diabetes, such as pioglitazone and GLP-1 RAs (e.g. subcutaneous liraglutide and semaglutide), showed that these glucose-lowering agents may be effective in inducing NASH resolution in up to ~50% of individuals with biopsy-proven NASH compared to placebo. It is an exciting time for NAFLD research and, considering the multiple pathways implicated in the pathogenesis of NASH, and the many novel treatments that are being tested in ongoing randomized trials, it is possible that combination therapy might prove to be the most effective strategy for ameliorating NASH in people with type 2 diabetes.

The Skin in Diabetes

Paul Devakar Yesudian

Department of Dermatology, Wrexham Maelor Hospital, Betsi Cadwaladr University Health Board, Wrexham, UK

Key points

- Some of the skin manifestations associated with diabetes may be relatively specific, while others are more common among individuals with diabetes than those without diabetes.
- The skin changes associated with diabetes can be roughly divided into metabolic, vascular, infections, and iatrogenic, though there is considerable overlap between them.
- Acanthosis nigricans, pigmented papillomatous overgrowth of the epidermis seen in flexures, is associated with hyperinsulinaemia.
- Many of the metabolic changes in the skin are related to glycation of structural proteins that occurs more extensively in diabetes.
- Necrobiosis lipoidica is most frequently seen in type 1 diabetes, often on the shins in women. It remains problematic to treat.
- Thickening, loss of elasticity, and yellowing of the skin are related to glycation of collagen and elastin in the skin.
- There are numerous vascular changes in cutaneous vessels with reddening and telangiectasia of the skin similar to premature degenerative ageing of the skin.
- Skin infections, including bacterial, fungal, and yeast, occur more commonly in people with diabetes compared to people without diabetes and tend to be more severe.
- Some skin conditions occur more commonly in people with diabetes compared to the general population, including psoriasis, generalized granuloma annulare, pruritus, perforating disorders, vitiligo, and lichen planus.
- Reactions to recombinant human and analogue insulin preparations and newer classes of anti-diabetes agents are unusual.
- Glues used in newer medical devices in the management of diabetes can cause contact sensitivities.

Many skin conditions are associated with diabetes and occur in about one-third of those affected [1]. Some are relatively specific, usually caused by the metabolic changes in diabetes or side effects of treatment, while others are non-specific but occur more frequently than in individuals without diabetes. Cutaneous changes may be the first sign of diabetes or develop at any time during the course of the disease [2]. As suggested by the aetiopathogenesis, autoimmune skin conditions occur more commonly in people with type 1 diabetes, while infections tend to predominate in type 2 diabetes [3]. The classification used in this chapter, including associated conditions and infections, is shown in Table 58.1.

The flexural areas, particularly the axillae, groins, inframammary region, and neck, are most frequently symmetrically affected and may become macerated or malodorous if severe [4] (Figure 58.1). The condition occurs at a higher frequency in skin of colour compared to people of white European ancestry [5]. Rarely, more generalized changes involve the knuckles, other extensor surfaces, palms, and soles. Histological features include extensive hyperkeratosis, papillomatosis, and acanthosis with retained keratotic material (which accounts for the dark colour).

Acanthosis nigricans is associated with various endocrine disorders that share the common features of insulin resistance and hyperinsulinaemia; these include diabetes, acromegaly, Cushing's disease, polycystic ovarian disease, obesity, metabolic syndrome, and genetic and autoimmune insulin receptor defects [6]. The presence of acanthosis nigricans is an independent prognostic indicator for the development of type 2 diabetes [7]. A severe malignant form is associated with gastric adenocarcinoma. Hyperinsulinaemia induced by insulin resistance activates insulin-like growth factor type 1 receptors on various tissues, including epidermal cells and fibroblasts [8]. Stimulation of keratinocyte proliferation gives rise to hyperkeratosis and acanthosis (Figure 58.2).

Acanthosis nigricans, which can be disfiguring and upsetting, is most frequently seen in people with type 2 diabetes and obesity. Management is by dietary alterations, weight reduction in obesity, and increasing physical activity, which can reverse changes to a

Metabolic manifestations

This group includes several conditions that appear relatively specific to diabetes (e.g. diabetic thick skin) or are more common than in the general population (e.g. necrobiosis lipoidica) [4]. The aetiology of these conditions is largely related to the process of non-enzymatic glycation of cutaneous structural proteins or hyperinsulinaemia.

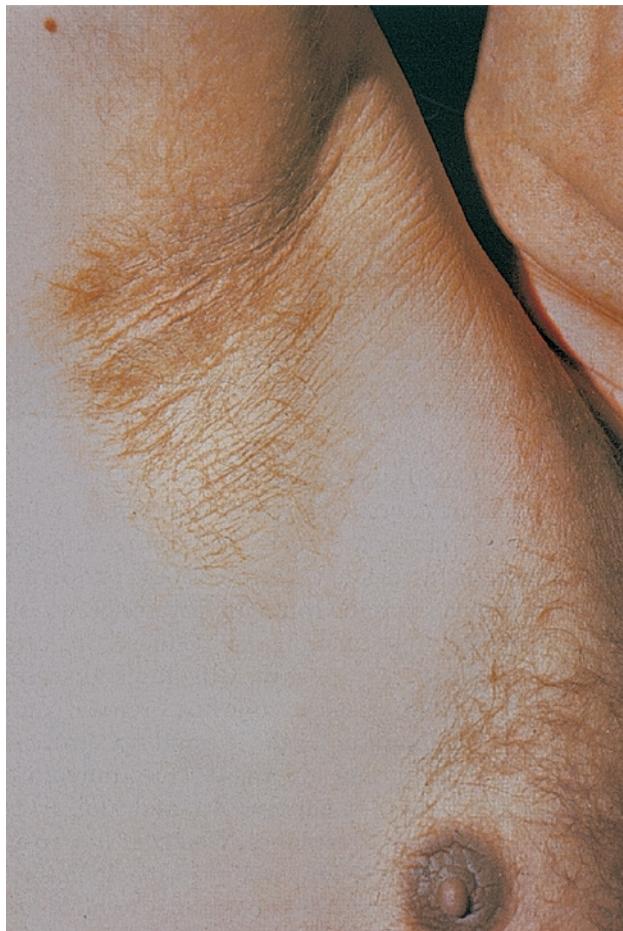

Acanthosis nigricans

Acanthosis nigricans is characterized by velvety papillomatous overgrowths of the epidermis, which are usually hyperpigmented.

Table 58.1 Cutaneous manifestations of diabetes.

Metabolic manifestations		Acanthosis nigricans Diabetic bullae Diabetic thick skin Yellow skin and nails	Achrochordons Eruptive xanthomas Diabetic scleroderma
Vascular changes		Diabetic dermopathy Facial erythema Lower-limb vascular changes	Necrobiosis lipoidica Periungual telangiectasia Calciphylaxis
Infections	Bacterial	Staphylococcus Erythrasma Malignant otitis externa	Streptococcus Necrotizing fasciitis
	Fungal/yeast	Dermatophytosis Mucormycosis	Candida
Associated conditions		Pruritus Lichen planus Clear cell syringomas Disseminated granuloma annulare	Perforating disorders Vitiligo Glucagonoma Psoriasis
Iatrogenic		Insulin induced Immediate: localized/generalized Delayed: lipodystrophy Reactions to oral anti-diabetes drugs Reactions to medical devices

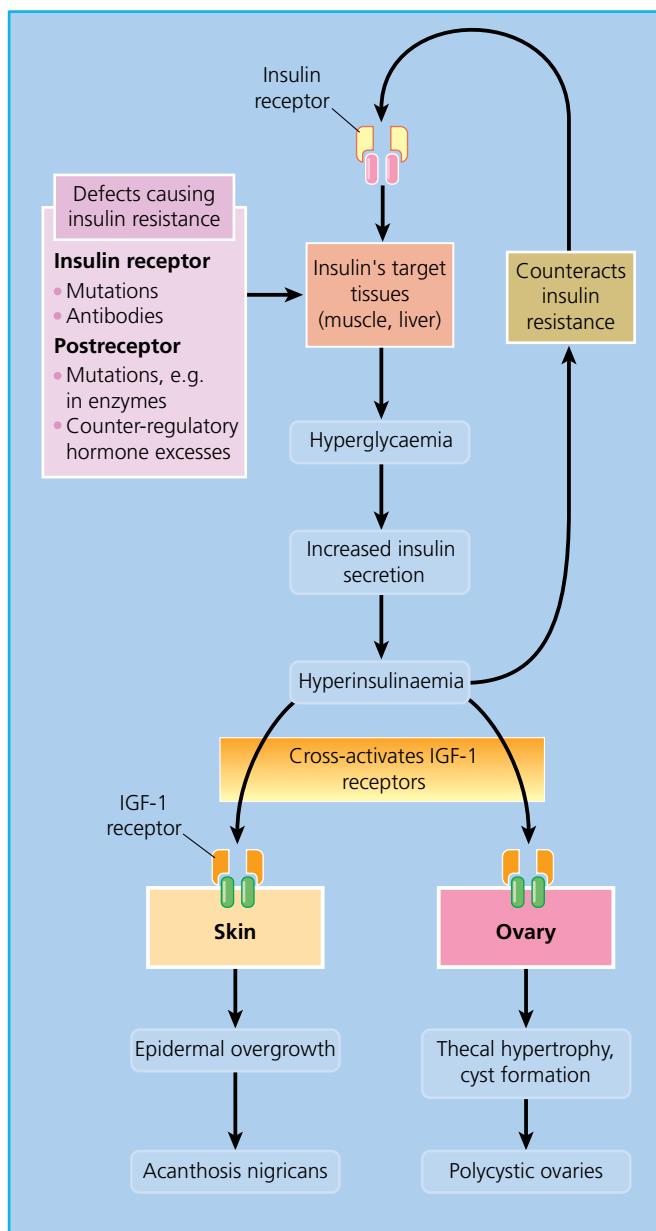

Figure 58.2 Suggested relationship of insulin resistance and hyperinsulinaemia to acanthosis nigricans. Raised insulin levels may act on insulin-like growth factor I (IGF-I) receptors in the skin to cause epidermal overgrowth. Similar events in the ovary could lead to polycystic ovary disease, which is also associated with insulin-resistant states.

certain extent [9]. Topical retinoids, calcipotriol, and mild peeling agents, such as salicylic acid or lactic acid, may be helpful for limited involvement. Systemically, metformin and rosiglitazone reduce insulin levels and give modest improvement in the condition [10].

Achrochordons (skin tags)

Skin tags are benign, soft, fleshy, polypoid skin-coloured fibromas, which occur with increasing age and are particularly common in people with diabetes [11]. They may occur in about 66% of individuals with diabetes and are probably related to the proliferative effect of hyperinsulinaemia on keratinocytes and fibroblasts, as in acanthosis nigricans [12]. Large numbers may be a marker of impaired glucose tolerance [13]. Individuals with more than 30 skin tags and women with lesions under their breasts are particularly prone to diabetes [14]. Skin tags occur predominantly in flexural regions around the eyes, neck, axillae, and in women in the inframammary area. Treatment is usually not required, although snip excision, cryotherapy, or electrodesiccation is effective if they cause discomfort through irritation or give cosmetic concern.

Diabetic bullae (bullosis diabetorum)

Diabetic bullae affect men more than women and are more common in older people and those with peripheral neuropathy [15]. The condition usually presents as tense, sterile, asymmetrical blisters, from a few millimetres up to several centimetres in size, on a non-inflammatory base, appearing rapidly and healing over a few weeks without scarring (Figure 58.3). The feet and lower legs are the commonest sites, followed by the hands. The condition is most commonly seen in long-standing type 1 diabetes with late complications. Risk factors include sudden blood glucose changes, magnesium and calcium alterations, microangiopathy, and renal failure [16]. Electron microscopy studies demonstrate a subepithelial split at the level of the lamina lucida and immunofluorescence studies are negative [17]; however, the aetiology of bullae is unclear. Other causes of subepithelial blisters, including the autoimmune blistering diseases porphyria cutanea tarda, pseudoporphyria, and infections such as bullous impetigo, need to be excluded. Treatment is normally supportive to prevent secondary infection, although surgical debridement and negative-pressure dressings have been proposed [18]. Aspirating tense blisters to prevent rupture may be required and most heal within a few weeks.

Diabetic thick skin

The skin of individuals with diabetes is measurably thicker by ultrasound than in people without diabetes [19] and shows loss of elasticity [20]. Thickening is most often seen on the hands and feet and may progress to finger pebbles, groups of indurated papules on the extensor aspect of the fingers and knuckles. Milder changes are

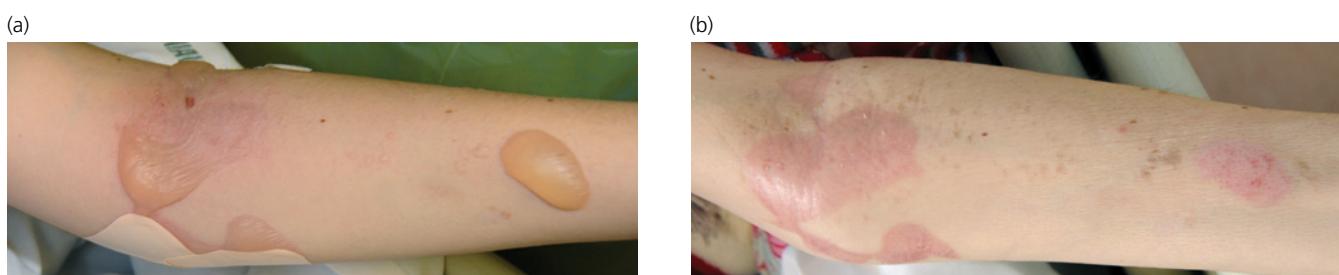

Figure 58.3 Diabetic bullae. (a) Acute bullae on an arm. (b) Resolving lesions 14 days later.

seen in a minority of older people without diabetes. Skin thickness is largely attributable to the filamentous proteins of the dermis, of which collagen is by far the most abundant. In people with diabetes, the collagen bundles are thickened and disorganized, as a result of irreversible non-enzymatic glycation and cross-linking of protein. The formation of advanced glycation end-products (AGEs) damages the protein, thereby reducing the ability of enzymes such as collagenase to remodel the fibres [21]. Gradual and irreversible modification of collagen, elastin, and other structural dermal proteins is part of the physiological ageing process, but is accelerated in diabetes, especially if there is persistent hyperglycaemia.

Skin thickness shows some correlation with the duration of diabetes [22] and the presence of complications such as neuropathy and microangiopathy [23, 24]. Topical emollients help with the associated skin dryness, but there is no effective treatment. Rigorous glycaemic management may slow the development of skin thickening. While skin thickness is often clinically insignificant, when advanced it may lead to the specific complications of *diabetic hand syndrome* and diabetic scleroedema [25]. The combination of thick, tight waxy skin and limited joint mobility has been called cheiroarthropathy and is present in up to a fifth of people with type 1 diabetes [26].

Diabetic hand syndrome usually occurs in those over 60 years of age (Chapter 59) [27]. The early changes include thickening of the skin over the dorsa of the hands and digits, especially the proximal interphalangeal joints (sclerodactyly). More extreme cases present with a tight, waxy appearance together with pebbly pads over the knuckles and distal fingers. The interphalangeal joints are particularly susceptible and involvement of periarticular connective tissue contributes to painful stiff fingers [28]. In a minority, the condition progresses to cause a fixed flexion deformity of the fingers and Dupuytren contracture, while soft tissue thickening of the wrist may cause carpal tunnel syndrome by compression of the median nerve.

Scleroedema of diabetes

This is marked dermal thickening, commonly involving the posterior aspect of the neck and upper parts of the back, and extending to the face, arms, and abdomen with more severe involvement, but sparing acral areas. It has a prevalence of 2.5–14% in diabetes and is found particularly in men with type 2 diabetes and those with overweight and persistent hyperglycaemia [29]. The onset is insidious and asymptomatic, but can lead to neck and back pain in severe cases [30]. The skin is hard, thick, and may be indurated and erythematous. Histology reveals dermal thickening that contains large collagen bundles and an increased number of mast cells [25]. The pathogenesis is linked to non-enzymatic glycation of collagen, leading to increased collagen crosslinking and therefore reduced degradation, resulting in increased thickness of the skin [7]. No therapy is particularly effective for scleroedema, although response to ultraviolet light or psoralens with ultraviolet A (PUVA) [31] has been reported. Strict glycaemic management is recommended as this may slow the progression.

Yellow skin

Individuals with diabetes develop yellowish skin and nails more frequently than the general population. This is most noticeable on the palms and soles. It has been referred to as carotenaemia, but there is little evidence to support the theory that carotenoids are the cause [32]. The most probable explanation is that the discolouration is due to non-enzymatic glycation of dermal collagen. The end

product 2-(2-furoyl)-4(5)-(2-furanyl)-1H-imidazole has a yellowish colour. This occurs to a much greater extent with the hyperglycaemia of diabetes compared to individuals without diabetes.

Eruptive xanthomas

Eruptive xanthomas are rare and pathognomonic of extreme hypertriglyceridaemia [33]. This can occur at the initial presentation of type 1 diabetes when there is insulinopaenia [11]. Insulin is a stimulatory factor for lipoprotein lipase, which if not activated leads to impaired clearance of very low-density lipoproteins and chylomicrons. Xanthomas present as clusters of yellowish papules of triglyceride up to 5 mm on extensor surfaces of the limbs and buttocks (Figure 58.4). The onset is usually rapid and lesions frequently occur in groups or crops with surrounding erythema. Men are more commonly affected. Although xanthomas may itch initially, they are typically asymptomatic. Rarely, acute presentations can be painful and the Koebner phenomenon, whereby lesions occur at the site of trauma, has also been reported with eruptive xanthomas [34]. Lesions regress slowly within months after hypertriglyceridaemia has been corrected by lipid-lowering drugs, dietary modification, or improved glycaemic levels.

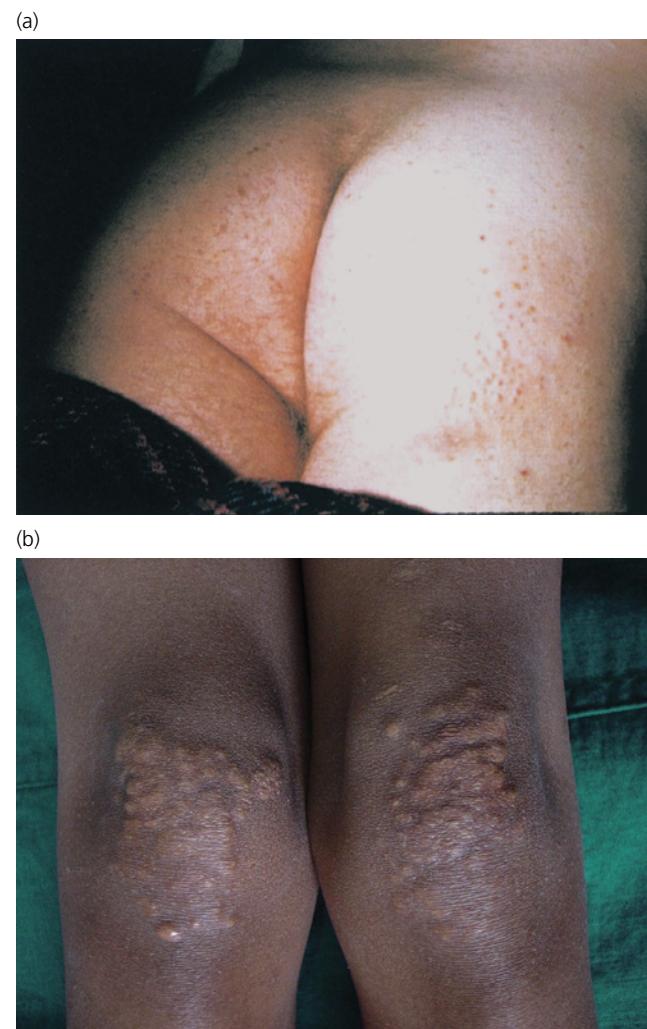

Figure 58.4 Eruptive xanthoma: (a) buttocks; (b) knees.

Vascular changes

Diabetic dermopathy (shin spots)

Diabetic dermopathy is the commonest dermatological condition associated with diabetes, occurring in up to 50% of people with diabetes and nearly 3% of the adult general population, who usually have only one or two lesions. By contrast, most individuals with diabetes have four or more [35]. Men are more frequently affected. It is commoner in those over 50 years of age and in long-standing diabetes. The condition is associated with the microangiopathic complications of diabetes such as neuropathy, nephropathy, and retinopathy, and also coronary artery disease [36, 37]. The presence of diabetic dermopathy is a subtle sign that suggests more serious complications [38]. Diabetic dermopathy does not correlate with obesity or hypertension in individuals with diabetes [39]. The presence of microvascular changes, notably thickening of arterioles and capillaries, led to the term *diabetic dermopathy* [40]. It has been hypothesized that diabetic dermopathy arises from local abnormal blood flow. This was confirmed with laser Doppler technology, which revealed a functional abnormality in blood flow in 25 people with diabetes compared to 67 people without diabetes [41].

The lesions are well-circumscribed, atrophic, brownish scars often on the shins, giving the alternative name *diabetic shin spots* [35] (Figure 58.5). The forearms, thighs, and bony prominences may also be affected [39]. The lesions are usually bilateral and may appear in crops. Early lesions are oval, red papules measuring up to 1 cm in diameter, which slowly develop scaling and a brown colour due to the presence of haemosiderin-laden histiocytes and extravasated erythrocytes in the superficial dermis. There is no recommended treatment, as they are usually asymptomatic and tend to resolve over 1–2 years. Variable improvement has been observed with better glycaemic levels [36]. However, it is worthwhile screening for other microangiopathic complications of diabetes [42].

Necrobiosis lipoidica diabetorum

Necrobiosis lipoidica is a chronic granulomatous skin condition that most frequently affects the shins of those with type 1 diabetes. This is a rare condition with a 1% prevalence in people with diabetes [23, 43]. Although it is much commoner in individuals with diabetes, the relationship to diabetes and the aetiology of necrobiosis lipoidica remain unclear. In a retrospective study, only 22% of 65 participants with necrobiosis lipoidica had or developed diabetes in a 15-year follow-up. Necrobiosis lipoidica may precede the onset of diabetes by years, develop concurrently, or arise years later. The presence of necrobiosis lipoidica is thus an indication for investigation of possible diabetes and future monitoring. Necrobiosis lipoidica usually develops in young adults or early middle life, but has also been reported in children with type 1 diabetes [44]. Women are three times more commonly affected than men. There is no proven association with glycaemic levels, but those with diabetes and necrobiosis lipoidica appear to have a higher incidence of chronic diabetes complications such as retinopathy, neuropathy, and microalbuminuria [45]. Though the exact cause of necrobiosis is unknown, it is proposed that microangiopathy, metabolic changes, and trauma could play a role [2].

Necrobiosis lipoidica has a distinctive appearance (Figure 58.6). Early lesions may be rounded, dull red, symptomless papules or plaques that slowly progress to the typical chronic lesion – an oval or irregularly shaped indurated plaque with central atrophy.

Figure 58.5 Diabetic dermopathy, 'shin spots'. Source: Courtesy of Professor Julian Verbov, Royal Liverpool University Hospital, UK.

Necrobiosis lipoidica often has a shiny surface, with prominent telangiectatic vessels crossing over a waxy yellowish central area due to lipid deposition. The margin of lesions may be brownish or red and sometimes with comedo-like plugs, where necrotic material is extruded through the surface. The shin is the most commonly affected site, but the thighs, ankles, and feet may also be affected; lesions rarely occur on the trunk, upper limbs, or scalp [45]. Ulceration occurs in up to 35% of cases and may be very slow to heal. Necrobiosis lipoidica lesions may be partially or completely anaesthetic and alopecia is frequently present. Lesions are variable in number but usually few, and most extend slowly over several years, sometimes coalescing with adjacent areas. Long periods of quiescence may occur or occasionally lesions may heal with scarring. The condition can lead to significant morbidity and can be cosmetically distressing to individuals with diabetes [2]. The diagnosis is usually clinical; a diagnostic skin biopsy is not normally required and may risk ulceration in atrophic lesions. The differential diagnosis of early lesions includes granuloma annulare, cutaneous sarcoid, necrobiotic xanthogranuloma, and diabetic dermopathy.

Histologically, necrobiosis lipoidica lesions comprise foci of degenerate collagen bundles with a hyalinized appearance (necrobiosis), surrounded by fibrosis, with diffuse or perivascular

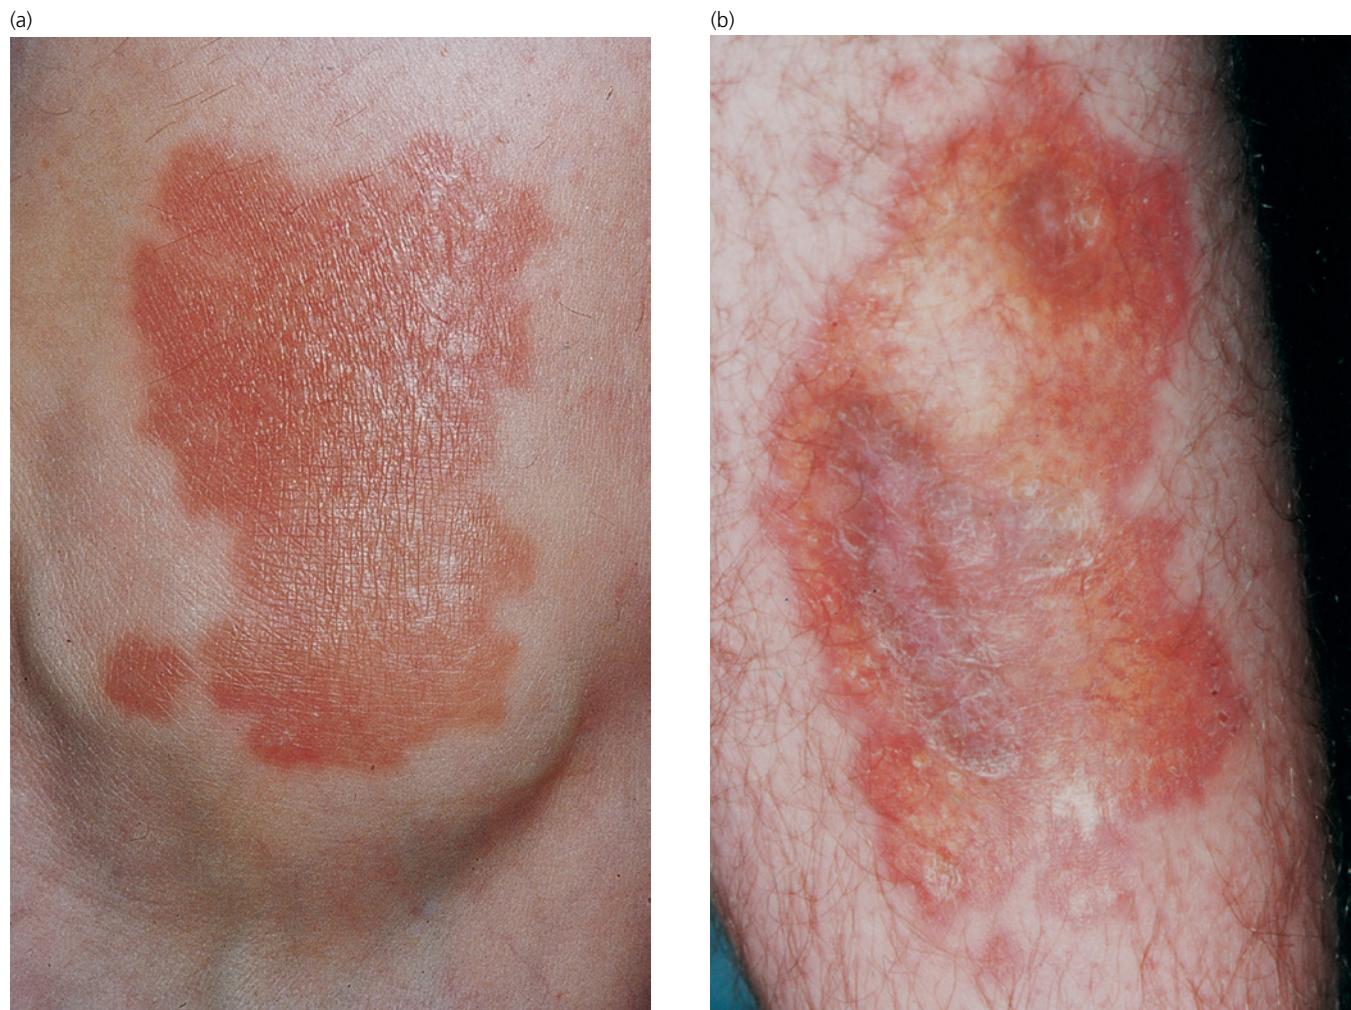

Figure 58.6 Necrobiosis lipoidica diabetorum. (a) An early lesion on an ankle showing the erythematous stage. (b) A long-standing area of necrobiosis lipoidica; note the typical yellow atrophic appearance with telangiectasia.

infiltrate of histiocytes, lymphocytes, and plasma cells. Frequently a palisading granulomatous reaction with giant cells is seen (Figure 58.7). These abnormalities occur throughout the dermis with telangiectasia and epidermal thinning [46]. There is considerable overlap between these features and those of granuloma annulare. The similarity contributed to the suggestion that localized granuloma annulare is associated with diabetes. Despite histological similarities in the earlier stages of the two conditions, they run different clinical courses and only the generalized form of granuloma annulare is linked to diabetes [46].

No treatment for necrobiosis lipoidica has proved effective in double-blind placebo controlled trials and treatment remains unsatisfactory. Spontaneous remission is unusual and optimal glycaemic management does not usually have a significant effect on the course of the condition. People with diabetes should be encouraged not to smoke and to avoid trauma to the area, which may result in a painful and recalcitrant ulcer. The multitude of case reports of diverse treatments suggests that there is no established benefit for most [4]. In many cases, cosmetic camouflage may be the preferred option. Topical steroids, calcineurin inhibitors, and PUVA are the most-used therapies [47]. For early lesions corticosteroids either applied topically (perhaps under occlusion) or by intralesional injection may be beneficial [48] (Figure 58.8). The

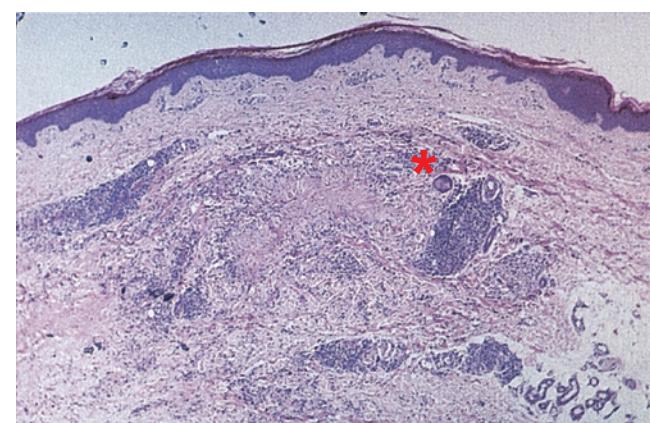

Figure 58.7 Histological feature of necrobiosis lipoidica diabetorum showing degeneration of the collagen (necrobiosis), associated with fibrosis and a granulomatous histiocytic infiltrate. A giant cell is indicated by the asterisk. Haematoxylin and eosin stain $\times 40$.

inflammatory process extends beyond the clinical margins and topical steroids may halt or slow progression if applied to the periphery of lesions. Once atrophy has developed, it is irreversible and topical steroids should be cautiously used in chronic lesions

Figure 58.8 Necrobiosis lipoidica diabetorum treated with intralesional triamcinolone (before and after images). Source: Courtesy of Dr P. Balasubramaniam, Wrexham Maelor Hospital, Wrexham, UK.

because they may worsen skin atrophy. An alternative to topical steroids is the calcineurin inhibitor tacrolimus, which does not cause cutaneous atrophy. Several small open studies report an approximately 50% response rate to topical PUVA [49] while topical retinoids have been beneficial in atrophic cases [50]. Pentoxyphyllin, hydroxychloroquine, and low-dose aspirin are other options [48]. Pulsed dye laser treatment may improve telangiectasia and erythema, but there is a risk of skin breakdown. There are reports of good results following excision and grafting, although the disease may recur locally. The tumour necrosis factor α (TNF- α) antagonists infliximab and etanercept are beneficial for ulcerative necrobiosis lipoidica [51]. Topical application of platelet-rich plasma has shown encouraging results in ulcerated lesions. In an open study, all 15 participants showed marked reduction in ulcer size after 10 weekly applications [52]. Tofacitinib, a Janus kinase inhibitor, has shown promise in treating recalcitrant and ulcerated necrobiosis lipoidica [53, 54].

Rubeosis faciei

Rubeosis faciei (also called rubeosis facie diabetorum) is the chronic flushed appearance in the face and neck of people with diabetes [55]. The intensity of coloration is dependent on the vascular engorgement in the superficial venous plexus [56]. The changes occur due to altered vascular tone or diabetic microangiopathy. It appears more obvious in fair-skinned individuals and can be difficult to distinguish from normal facial redness in the general population. Rubeosis can be exaggerated by hypertension [57]. The

condition may improve with optimal glycaemic management and avoidance of vasodilators (caffeine and alcohol) [42].

Periungual telangiectasia

Erythema of the skin surrounding the nail bed resulting from the dilatation of proximal nailfold capillaries is an excellent marker of functional microangiopathy [58]. It can occur in up to 49% of individuals with diabetes. Even though connective tissue diseases can exhibit similar periungual telangiectases, the lesions are morphologically different. In those with diabetes, isolated homogenous engorgement of venular limbs is seen, whereas mega-capillaries or irregularly enlarged loops are observed in connective tissue disease [59].

Lower-limb vascular changes

An erysipelas-like erythema is described with well-demarcated patches of cutaneous reddening, occurring in the legs and feet of people with diabetes. It can be mistaken for erysipelas, but is differentiated by the lack of associated fever, leucocytosis, or elevated erythrocyte sedimentation rate [60]. Cutaneous signs of ischaemia in the lower limbs include cold or cyanosed feet, erythema, hair loss, and atrophy. A sign of large-vessel disease is dependent rubor with delayed return of colour (>15 s) after pressure has been applied to the skin. Individuals with diabetes who have both venous insufficiency of the lower legs and arterial disease are particularly prone to developing non-healing ulcers; these frequently become superinfected and can be very troublesome to manage. Neuropathy, with lack of pain sensation, also contributes to lower-leg injury and ulceration. Repeated trauma and increased shear forces affect the skin without the usual protective mechanisms that are impaired by peripheral neuropathy, leading to further skin breakdown [59]. The term diabetic foot syndrome encompasses these vascular and neuropathic changes and has a prevalence of between 4% and 10% of those with diabetes [61]. Compared to people without diabetes, the risk for gangrene and amputation is higher in those with diabetes [62]. More detail of the diabetic foot is found in Chapter 53.

Calcific uremic arteriolopathy (calciphylaxis)

Calcific uremic arteriolopathy is a small-vessel vasculopathy occurring in renal failure and sometimes in those with diabetes. It is characterized by mural calcification, intimal proliferation, fibrosis, and thrombosis [63]. The lesions start as localized areas of erythema and tenderness of the skin that become ischaemic, forming a livedo-reticularis pattern. This leads to the development of subcutaneous nodules and poorly healing, necrotizing skin ulcers that demonstrate black eschars [64]. They can serve as a portal of entry for infectious agents. It typically affects the extremities, but can involve the abdomen and buttocks as well. The prognosis in those with calciphylaxis is poor due to impaired wound healing and infection leading to sepsis. Treatment is usually unsatisfactory. Aggressive analgesic therapy may be required for ischaemic pain, along with optimal blood glucose management and weight reduction [65, 66]. Newer treatments in the setting of renal failure include sodium thiosulphate [67] and cinacalcet hydrochloride [68].

Infections

The relationship between skin infections and diabetes is controversial [69]. Previous studies suggested that there was no significant increase in the prevalence of infections in most people with diabetes

and questioned the strength of assumed associations (Chapter 61) [70]. Hyperglycaemia can increase the risk of infection by causing abnormal microcirculation, decreased phagocytosis, impaired leucocyte adherence, and delayed chemotaxis [71]. Recent literature associates skin infection in diabetes with an immunocompromised state from hyperglycaemia. It is a cause for morbidity and occasionally mortality. Although it can occur in all anatomical sites, the foot is the most commonly affected [72]. Infectious skin diseases, particularly fungal infections, were more common in men compared to women [57]. In a national cohort study in South Korea, the adjusted incidence rate ratio of skin and soft tissue infections was 3.52 times higher in those with diabetes compared to the general population. People with diabetes also had a higher incidence of infection-related hospitalizations [73].

Bacterial infections

Furuncles, carbuncles, folliculitis, and erythrasma were particularly frequent before the introduction of insulin and antibiotics, and skin infections due to *Staphylococcus aureus* are probably commoner in those with diabetes.

Foot infections are the commonest soft tissue infection in diabetes. The area between the web spaces tends to be the portal of entry and staphylococcal infections are the most frequent.

Severe (*malignant*) otitis externa is an uncommon but potentially lethal infection caused by invasive *Pseudomonas* spp. It occurs in older people with diabetes and manifests as purulent discharge with severe pain in the external ear. It progresses from cellulitis to osteomyelitis, meningitis, and cerebritis. Subsequent cranial nerve damage can also occur and carries a high mortality [74]. Treatment involves ear canal irrigation, skin debridement, and systemic antibiotics, particularly quinolones [75].

Erythrasma, caused by *Corynebacterium minutissimum*, is rare and occurs with increased frequency in people with diabetes and obesity. It presents as a red, shiny, or scaly patch in the intertriginous areas and with UV light exhibits a characteristic coral-red fluorescence. Topical or systemic erythromycin is curative. A recent series confirmed the effectiveness of topical mupirocin 2% ointment in this condition [76].

Unusual infections with coliforms or anaerobes occur in those with diabetes, as can *Pseudomonas* infections of the toe web spaces or nailfold (paronychia) and secondary infection of venous ulcers [77]. Anaerobic cellulitis with *Clostridium* spp. can occur in people with diabetic ketoacidosis, requiring aggressive debridement of devitalized tissue, and intravenous antimicrobial therapy [63].

Necrotizing fasciitis is a potentially lethal skin and soft tissue infection that is commoner in people with diabetes [12]. The infection is polymicrobial, including *Streptococcus pyogenes*, anaerobic *Streptococci*, *Bacteroids*, and *Staphylococcus aureus*, and may arise from trivial wounds like injection sites or begin from decubitus ulcers. It presents initially with the triad of pain, swelling, and erythema [78] and can be misdiagnosed as cellulitis (Figure 58.9). An initial clue to necrotizing fasciitis is pain out of proportion to the swelling or erythema with tenderness beyond the apparent involved area (Figure 58.10). Rapid progression ensues, with extensive tissue destruction and severe systemic toxicity, leading to death. Necrotizing fasciitis should be treated with extensive surgical debridement of necrotic tissue and high-dose antibiotics, with blood and tissue culture. The mortality remains high in spite of optimal treatment [79]. This condition should be considered in those with cellulitis who have associated systemic features like tachycardia, leucocytosis, marked hyperglycaemia, or acidosis.

Fungal/yeast infections

Candida

Infection with *Candida albicans* may be a presenting feature of diabetes or manifest as a complication of suboptimally managed diabetes. The infection appears as erythematous papules, coalescing to form glazed plaques, with satellite pustules affecting the flexural areas in the body, the vulva, and penis (Figure 58.11a). In women, vulvovaginitis is the commonest manifestation and presents with pruritus vulvae that can be intense and distressing. The vulva appears erythematous and fissured, with peripheral pustulation in severe cases, and may be particularly troublesome in

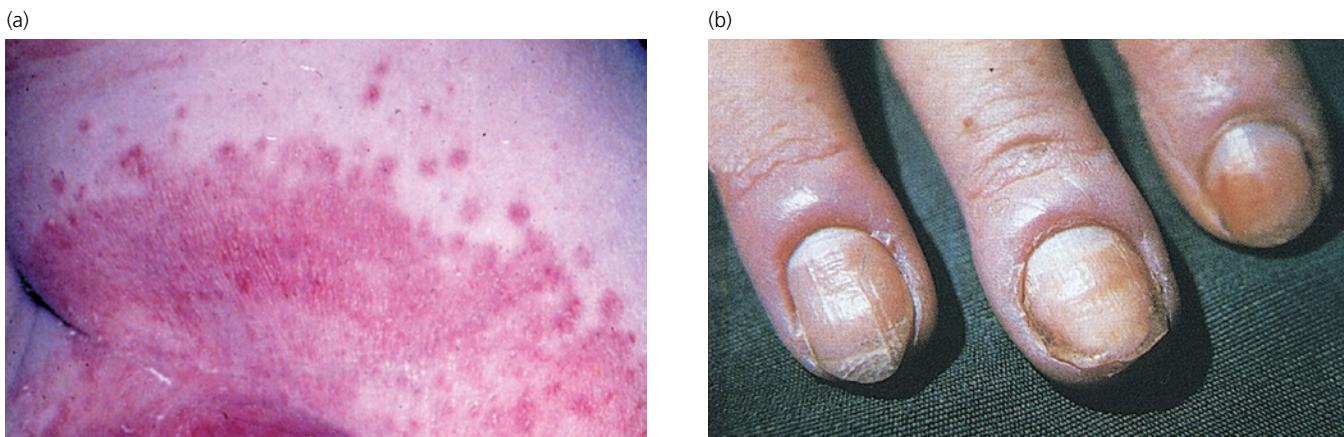

Figure 58.11 Candida infections in people with diabetes. (a) Flexural infection showing satellite lesions. (b) Chronic paronychia caused by *Candida albicans*. Note the swollen and erythematous nailfolds.

hyperglycaemia with glycosuria [12]. Candida balanitis, balanoposthitis, and phimosis occur less commonly in men, but may be a presenting feature [80]. Candida angular stomatitis and an atrophic tongue resembling median rhomboid glossitis are oral manifestations of diabetes. Oral candidiasis occurs more commonly in people with diabetes who smoke or wear dentures [81]. Candida intertrigo occurs on opposing surfaces under the breast, in the groins and axillae, or in the folds of the abdominal skin.

Candida infection of the hands and feet is probably equally seen in people with diabetes as those without, but tends to be more severe in the former. Chronic paronychia presents as swelling and erythema around the lateral nailfold, with more severe involvement leading to onycholysis (Figure 58.11b). Microscopic examination and culture of the extruded material will confirm the infection. Less common than paronychia is infection of the web space between the middle and fourth fingers (*erosion interdigitale blastomycetica*) [82]. Exclusion of moisture is an essential aspect to the treatment, and systemic antifungal drugs (e.g. oral fluconazole or itraconazole) rather than topical preparations may be required.

Dermatophytosis

Epidemiological studies have shown a higher incidence of onychomycosis in individuals with diabetes; the severity of the nail disease correlates with the duration of diabetes [83]. Fungal skin infection can serve as a portal of entry for other infectious agents, particularly in those with neurovascular complications. *Trichophyton rubrum* is the commonest pathogen, causing erythematous lesions that are often annular with scaly edges. Intertrigo or interdigital infection presents as maceration and superficial scaling. The diagnosis is confirmed by finding fungal hyphae in the superficial scale, ideally taken from the edge of the lesion. Treatment is with a topical imidazole antifungal or terbinafine, although extensive systemic itraconazole or terbinafine may be required. Severe onychomycosis can contribute to foot ulcers and hence require treatment with topical and systemic antifungal therapy, proper nail maintenance, and aggressive debridement [84].

Phycomycoses infections

Suboptimal metabolic management, resulting in hyperglycaemia and ketoacidosis, may permit organisms that are normally non-pathogenic to establish infections in traumatized skin [72, 85]. Leg ulcers or non-healing surgical wounds may have super-added

phycomycete infections. Deep phycomycetes infection like rhinocerebral mucormycosis is a rare but life-threatening complication of diabetes. Early manifestations include facial or ocular pain and nasal stuffiness, which progresses to fever, facial cellulitis, periorbital oedema, proptosis, and rarely blindness [86]. The infection spreads along the turbinates, septum, palate, maxillary and ethmoid sinuses, and can extend into the frontal lobe, cavernous sinus, or carotid artery. It should be suspected in anyone with diabetes presenting with sinusitis, purulent nasal discharge, altered mentation, and infarcted tissue in the nose or palate. Treatment involves correction of acid-base imbalance, aggressive debridement of devitalized tissue, and intravenous antifungal therapy.

Associated conditions

These are a group of dermatoses that are reported more commonly in individuals with diabetes.

Vitiligo

Vitiligo is a common autoimmune condition characterized by complete loss of pigment in the skin. The exact pathogenesis is unknown. It is seen more frequently in type 1 diabetes, but can occur in type 2 diabetes as well. Polyglandular autoimmune syndrome type 2 is characterized by adrenal failure, autoimmune thyroid disease, and type 1 diabetes, and can be associated with vitiligo [87]. It manifests as patchy, symmetrical depigmented areas of skin and, although asymptomatic, can cause significant emotional distress. Treatment is unsatisfactory, although topical steroids and calcineurin inhibitors can be used. People with diabetes should be advised on photoprotection.

Lichen planus

Lichen planus is an inflammatory disorder of the skin recognized by the presence of violaceous flat-topped polygonal papules, distributed in the flexural aspects of the limbs. An increased incidence of diabetes has been reported in people with lichen planus, particularly the erosive oral lichen planus variant [88, 89]. Impaired glucose metabolism is present in half of the individuals and 25% will have overt diabetes [90]. However, most studies have examined the presence of diabetes in those with lichen planus rather than the reverse. The link between diabetes and lichen planus is therefore still unproven, especially since both are relatively common conditions.

Pruritus

Even though there is a common assumption that itching is a symptom of diabetes, this is questionable. Studies have failed to link the presence of generalized pruritus with diabetes [91, 92]. Localized itching, particularly in the genital area, can be associated with candidal infections. The presence of xerotic skin, a feature present in individuals with and without diabetes, can also predispose to pruritus. People with diabetes who are smokers are more likely to experience generalized pruritus compared to smokers without diabetes [93]. It has been hypothesized that sympathetic nerve dysfunction leading to hypohidrosis and dry skin and peripheral sensory neuropathy can contribute to pruritus [94]. Higher post-prandial glucose levels are associated with an increased probability of having generalized pruritus in type 2 diabetes [93]. The regular use of emollients ameliorates the itch to a certain extent [95].

Perforating dermatoses

Acquired perforating dermatoses are a group of perforating conditions associated with systemic disease. Reactive perforating collagenosis (folliculitis) is one such condition characterized by transepidermal elimination of degenerative collagen, and is seen in end-stage renal disease caused not only by diabetes but other conditions as well [96]. It presents with pruritic hyperkeratotic papules on the extensor surfaces of the lower limbs, but can occur on the trunk and face. The papules can be pinpoint to about 6 mm in diameter, with central keratotic plugs (Figure 58.12). They sometimes resolve spontaneously, leaving atrophic scars [97]. Histology reveals an atrophic epidermis surrounding a plug of degenerate material comprising elastin and collagen [59]. It is a disorder of keratinization that engenders a proliferation of epidermis to eliminate abnormal tissue. Although it appears to be an inflammatory condition, microvasculopathy has been noted in the underlying dermis of biopsy specimens [98]. The lesions can be exacerbated by injury or excoriation. It is notoriously difficult to treat, but may be helped by topical steroids and retinoids, failing which phototherapy is an option. Intralesional steroid injections and cryotherapy can also be considered. Management of the underlying renal insufficiency or diabetes may be beneficial. The effectiveness of doxycycline and allopurinol has also been documented [99, 100].

Clear-cell syringomas

Syringomas are adnexal non-neoplastic lesions that are derived from the intra-epidermal part of the sweat duct. They present as yellowish papules distributed around the eyes and are asymptomatic. Clear-cell syringoma is an unusual variant that has two features of note: the histological preponderance of clear cells and the frequent coexistence with diabetes [101, 102]. There may be a phosphorylase deficiency secondary to hyperglycaemia that in turn results in the formation of clear cells. Generalized eruptive clear-cell syringomas have also been associated with diabetes [103].

Glucagonoma

The glucagonoma syndrome is caused by tumours of the α cells of the pancreas that secrete glucagon (Chapter 22). Even though the syndrome is rare, it needs to be considered in people with diabetes who present with diffuse atypical rashes. It comprises four major components: increased glucagon levels, diabetes (usually mild), weight loss, and necrolytic migratory erythema. Necrolytic migratory erythema occurs in 70% of cases, manifesting as an annular erythematous and figurate erythema with peripheral

Figure 58.12 Erythematous papules of reactive perforating folliculitis affecting the lower limbs, with some scarring from previous lesions evident. Source: Courtesy of Dr A. Nott, Adayar Cancer Institute, Adayar, Chennai, India.

vesicles, pustules, and erosions (Figure 58.13). It involves the intertriginous areas and face, but can affect acral sites as well. The dermatosis can be a presenting clue, occurring 1–6 years before the diagnosis of glucagonoma [104]. It can be associated with other physical findings, including glossitis, stomatitis, dystrophic nails, and alopecia. A skin biopsy shows suprabasal acantholysis and psoriasiform hyperplasia with pallor, ballooning, and necrosis of the upper spinous layer of the epidermis [105]. The role of hyperglucagonaemia in the cause of the skin eruption is unclear. Deficiency of essential fatty acids, zinc, and amino acids may be important in the pathogenesis. Resection of the pancreatic islet cell tumour clears the rash, sometimes within 48 hours. Management may also involve chemotherapy, essential amino acid and fatty acid supplementation, and the use of somatostatin or its analogue octreotide, which suppresses glucagon levels and improves skin lesions.

Disseminated granuloma annulare

Granuloma annulare is an inflammatory condition in the skin characterized by annular erythematous plaques with central normal skin, usually distributed in the extensor aspect of the limbs, particularly in the dorsal hands. The uncommon disseminated form of granuloma annulare has been reported with diabetes [106, 107]. The lesions in the disseminated form are usually asymptomatic and may lack the typical annular morphology. Histology reveals granulomatous infiltration with lymphocytes and histiocytes with central areas of degenerated collagen associated with giant cells. Lesions can resolve

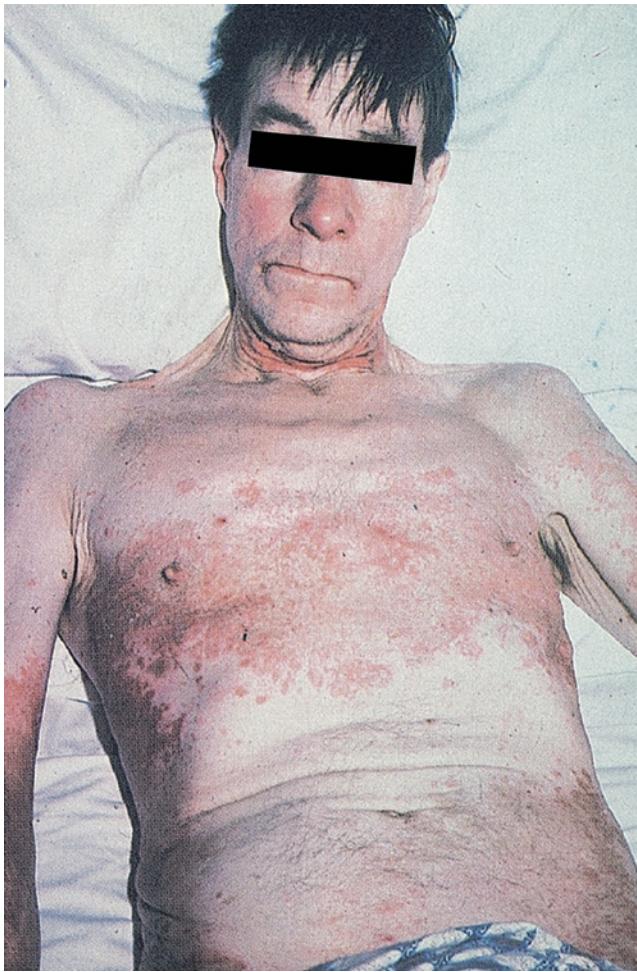

Figure 58.13 Necrolytic migratory erythema in a person with the glucagonoma syndrome. Courtesy of S. Bloom, Royal Postgraduate Medical School, London, UK.

spontaneously or persist for prolonged periods. Treatments include topical steroids, phototherapy, systemic retinoids, antimalarials, dapsone, and topical calcineurin inhibitors [108]. The link between diabetes and generalized granuloma annulare is controversial, with some authors questioning the association [109].

Psoriasis

Psoriasis is a common inflammatory dermatosis affecting about 2% of the world population, characterized by erythematous, scaly plaques predominantly in the extensor surfaces of the limbs. Younger individuals have a higher risk of developing diabetes. There is robust evidence for an association between psoriasis and diabetes [110]. In individuals with psoriasis, diabetes occurs at a twofold increased risk compared to the general population. The strong association with the metabolic syndrome explains the high incidence of diabetes in those with significant cutaneous psoriasis [111]. A recent systematic review and meta-analysis suggests an estimated odds ratio of 1.69 for diabetes in individuals with psoriasis compared to those without [112].

Nail changes in diabetes

The nail manifestations of diabetes can be variable and grouped according to the possible aetiological factors [58]. They are classified as infections, vascular lesions, neuropathic changes, and miscellaneous, although overlap between these factors is common.

Infections

Fungal and bacterial infections occur more commonly in the nails of people with diabetes compared to the general population. Fungal nail infection affects mainly toenails [113]. Studies have shown subclinical onychomycosis in 7.5% of persons with type 2 diabetes [114]. Nails become thick, brittle, and discoloured (whitish or yellowish), with the infection entering beneath the free distal edge of the nail plate. Prompt treatment is recommended and prolonged courses may be required [58]. Drug interactions need to be considered, as azole antifungals like fluconazole and itraconazole can interact with oral anti-diabetes agents.

Bacterial infections with *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Proteus vulgaris* and *Escherichia coli* cause an acute paronychia involving the proximal and lateral nailfolds. It manifests as painful swellings of the margins of the nails that can exude pus on pressure.

Candida infection of the nail and surrounding skin may be more prevalent in persons with diabetes [115].

Vascular

Nailfold redness has been observed in diabetes. Nailfold capillaroscopy, a non-invasive method of observing the microvasculature, demonstrates possible characteristic patterns including tortuous, cross-linked capillaries, avascular zones, and ectasias [116]. Thickening of nails with surface irregularities (onychauxis) may be due to vascular insufficiency. Pterygium (scarring of the proximal nailfold to the nail plate) can result from arterial spasm. Reduced circulation to the nail matrix contributes to thin, brittle nails that separate from the nail bed (onycholysis).

Yellow nails have frequently been noted in persons with diabetes, particularly the distal hallux [117]. An early sign of diabetes may be the presence of a yellowish or brownish discoloration in the distal part of the hallux nail plate. The canary yellowish hue that can affect the toe and fingernails is distinct from the yellowish discoloration seen in association with onychomycosis. Yellowish discoloration of the nails could occur from vascular impairment and biochemical changes [118]. While this appearance may give cosmetic concerns, it is benign and there is no effective treatment.

Neuropathy

Diabetic peripheral neuropathy can predispose to thickened nails, abnormal curvature and hypertrophy of the nail plate (onychogryphosis), and increased fragility. Lack of sensation also predisposes to increased infection, ulceration, and changes in the underlying bone.

Miscellaneous

Small, pitted craters on the surface of the nail plate, mostly seen on the middle and ring fingers, are called Rosenu's depressions and can be seen in diabetes [58]. Ingrowing toenails are also seen in type 2 diabetes. The main predictable variables for developing ingrowing nails include increased body mass index, previous trauma, weak dorsalis pedis, onychogryphosis, and subungual hyperkeratosis [119]. Separation of the proximal plate from the nail bed (onychomadesis) may be due to metabolic derangements of diabetes. The appearance of white areas on the nail plate, leuconychia, has been linked to vascular disease seen in diabetes. The glucagonoma syndrome, which predisposes to diabetes, is associated with soft and flexible fingernails [120].

A recent review [121] summarizes the techniques used to detect and monitor diabetes in the nail unit. These include:

- Estimating glycated nail protein (fructosamine) as a reflection of average blood glucose levels. A study of fingernails has shown that people with diabetes have high levels of furosine-lysine, another marker of non-enzymatic glycation [122].
- Analysing the molecular structure of human fingernail proteins (α -helical structure), as people without diabetes do not have α -amide structures.
- Laser-induced breakdown spectroscopy, which can be a screening tool for diabetes in large populations.

Iatrogenic

Reactions to insulin

Insulin allergy

Reactions to insulin were previously common due to the presence of impurities of cow or pig proteins, and preservatives or additives. The use of human and analogue recombinant insulin has decreased the incidence of insulin allergy and it is now less than 1% of people with insulin-treated diabetes [63]. Allergic reactions to insulin can be classified as immediate-local, general, delayed, or biphasic. Immediate-local reactions occur within a few minutes of injection and subside within an hour. Erythema with urtication can occur and is possibly immunoglobulin (Ig)E mediated. Treatment of the immediate local reaction is to change the insulin to a more purified product. Systemic reactions include generalized urticaria and, rarely, anaphylaxis. Generalized urticarial reactions to purified insulins are uncommon [123], but a few people sensitized to animal insulins have suffered anaphylaxis with human insulin [124]. Delayed hypersensitivity reactions are the commonest, appearing about two weeks after the start of insulin therapy. Itchy nodules are evident at the sites of injections, 4–24 hours after injection. Biphasic responses have been reported in some individuals, with immediate urticaria followed by a delayed reaction several hours later. They are considered Arthus-immune complex reactions. The hypersensitivity may be to insulin itself, or to preservatives, such as aminobenzoic acid or zinc [125]. Allergic reactions can be managed by antihistamines, addition of glucocorticoids, discontinuation of therapy, or a change in the insulin delivery system.

Lipoatrophy

Lipoatrophy occurs at sites of insulin injections and is particularly prominent with the longer-acting preparations [126]. It is characterized by a loss of subcutaneous fat and can be a cosmetic concern. This complication is less common with the advent of purer insulins. It is more common in young women with diabetes. The pathogenesis is secondary to an immunological reaction, as biopsies from affected sites show immunoglobulin M and complement. Repeated injections to the same site may predispose to this problem [127].

Lipohypertrophy

Lipohypertrophy presents as soft, subcutaneous nodules or thickening at sites of repeated injections [128]. It occurs due to the lipogenic action of insulin, with repeated local stimulation of adipocytes being causative. As lipohypertrophic areas are relatively painless, young people with diabetes tend to inject the same site repeatedly, worsening the hypertrophy [43]. Insulin absorption may be delayed at such sites, potentially resulting in disruption of glycaemic levels [129]. It resolves spontaneously, usually over a few months, by changing the site of insulin injections. Hyperkeratotic verrucous variants of lipohypertrophy have also been described [130].

Other complications of insulin

Granulomatous lesions that have a furuncular or pustular appearance can occur following insulin injections [131]. Keloids, hyperkeratotic papules, purpura, and localized pigmentation are also reported. Postinflammatory pigmentation following insulin injection is commoner in Asian skin and may take 6–12 months to fade. Epidermal inflammation around an injection site gives hyperpigmentation [43] and contributory factors include intradermal or intraepidermal injections, reuse of needles, non-rotation of injection sites, and occasional injections through clothing. People using insulin pumps for subcutaneous insulin delivery can experience local infections at the site of needle insertion, contact allergy to the associated tape and tubing material, and rarely subcutaneous nodules [132]. Acanthosis nigricans can occur as a local cutaneous side effect to insulin injections; the proliferation of the type 1 insulin-like growth factor (IGF) receptor, epidermal growth factor receptor, and fibroblast growth factor receptor may be causative [43].

Reaction to oral anti-diabetes agents

Sulfonylureas

Sulfonylureas are the most common oral anti-diabetes agents that cause skin reactions. About 1–5% of those taking first-generation sulfonylureas develop cutaneous reactions within two months of treatment [63]. Maculopapular, morbilliform, urticarial, or generalized erythematous reactions are common and resolve with discontinuation of the medication (Figure 58.14). Photosensitive

Figure 58.14 Drug rash with chlorpropamide.

(a)

Figure 58.15 Erythema multiforme. (a) The varied appearance of the condition: annular, arcuate, and blistering lesions and confluent erythema on the right side of the face. (b) Mouth ulceration in Stevens–Johnson syndrome, the severe form of erythema multiforme.

reactions, usually of the photoallergic type, as well as lichenoid eruptions have also been reported. Erythema multiforme, characterized by erythematous and haemorrhagic skin lesions associated with *target* lesions, can be a severe manifestation of drug reactions (Figure 58.15). Extensive blistering that includes the mucosal surfaces can occur and if the conjunctiva are involved, urgent ophthalmological opinion is mandatory. The chlorpropamide alcohol flush is a disulfiram-like effect occurring in 10–30% of those taking this drug. Individuals experience facial erythema, headache, and palpitations about 15 minutes after drinking alcohol and it subsides in about an hour. Endogenous opioids may be important, as the flush is blocked by naloxone [133].

Second-generation sulfonylureas like glipizide and glimepiride are less likely to cause cutaneous side effects. Glipizide has rarely been associated with photosensitivity, rash, urticarial, and pruritus. Glimepiride can similarly cause lichenoid skin reactions [134]. Pemphigus and psoriasisform eruptions can be precipitated by glibenclamide [135, 136].

Other oral anti-diabetes agents

Rashes with other oral anti-diabetes agents are much less common than with sulfonylureas. Transient erythema or urticaria may occur with metformin. It is also reported to cause a psoriasisform drug eruption, erythema multiforme [137], photosensitivity, and leucocytoclastic vasculitis [138]. Acarbose can cause a generalized erythema multiforme. As it is minimally absorbed from the gut, it may be the degradation products of acarbose that cause the allergic reaction [139]. Acute generalized exanthematous pustulosis, a dermatosis characterized by generalized pustules all over the body, has been reported to be induced by acarbose [140]. Thiazolidinediones are not commonly

Bone and Rheumatic Disorders in Diabetes

Andrew Grey¹ and Nicola Dalbeth²

¹Department of Medicine, University of Auckland, Auckland, New Zealand

²Department of Primary Care Health Sciences, University of Oxford, Oxford, UK

Key points

- Musculoskeletal disorders may cause pain and disability, and adversely affect management of diabetes.
- Fibroproliferative disorders of soft tissue such as limited joint mobility, frozen shoulder, Dupuytren's contracture, trigger finger, and carpal tunnel syndrome occur more commonly in diabetes and may lead to upper-limb disability.
- Charcot joint is an infrequent but serious complication of diabetic peripheral neuropathy and is characterized by disordered osteoclastogenesis. Bisphosphonate therapy may be a useful adjunct to standard treatment.
- Individuals with diabetes are at high risk of developing gout, particularly in the presence of renal impairment and diuretic use. Treatment with sodium–glucose cotransporter 2 inhibitors may reduce episodes of gout by up to 30%.
- Osteoarthritis is an important cause of poor health-related quality of life in people with diabetes.
- The prevalence of diffuse idiopathic skeletal hyperostosis (DISH) is increased in people with type 2 diabetes.
- Fracture risk is increased in both type 1 diabetes and type 2 diabetes and fracture healing may be impaired in diabetes.
- Bone mineral density is decreased in type 1 diabetes and increased in type 2 diabetes.
- Disease complications increase fracture risk by increasing the risk of falls and causing regional osteopenia.
- Thiazolidinediones decrease bone formation and bone mineral density and increase fracture risk in type 2 diabetes.
- Other anti-diabetes agents do not affect the skeleton.

Musculoskeletal disease in diabetes

A variety of musculoskeletal disorders are associated with diabetes. These disorders may cause pain and disability, and influence the ability of people with diabetes to follow other aspects of diabetes treatment, particularly exercise and weight management. Therapies commonly used in the treatment of rheumatic disease, particularly corticosteroids and non-steroidal anti-inflammatory drugs (NSAIDs), may be particularly problematic in people with diabetes. The important bone and joint disorders associated with diabetes are discussed in this chapter and are outlined in Table 59.1.

Fibroproliferative disorders of soft tissue

Cheiroarthropathy: limited joint mobility

Limited joint mobility refers to a syndrome of joint contractures resulting in decreased passive mobility of the joints in people with diabetes [1]. Flexion contractures of the proximal interphalangeal joints and metacarpophalangeal joints of the hands are characteristic, with the fifth proximal interphalangeal joint affected first (Figure 59.1). The skin on the dorsum of the hands typically appears tight and waxy [2]. Large joints such as the wrists, elbows, ankle, and cervical spine may also be affected, and reduced lung volumes have been reported in severe cases [3, 4]. Pain is usually mild or absent early in disease, and features of synovitis such as joint swelling, effusion, warmth, and tenderness are typically absent. The disorder can be readily differentiated from systemic sclerosis by lack of

Raynaud's phenomenon and other systemic features, normal nailfold capillary examination, and negative autoantibodies [5, 6].

The presence of limited joint mobility of the hands is detected clinically by assessing for the prayer sign or the table-top sign. The prayer sign is positive if the person is unable to oppose the palmar surfaces at any interphalangeal or metacarpophalangeal joints when the hands are placed in the prayer position. For assessment of the table-top sign, the person places both hands on a table top with the palms down and the fingers fanned out. The fingers are then viewed at table level. In stage 0, the entire palmar surface of the fingers makes contact with the table. In stage 1, one finger is affected (usually the fifth proximal interphalangeal joint of one or both hands). In stage 2, two or more fingers of both hands are affected, usually the fourth and fifth proximal interphalangeal joints. In stage 3, there is involvement of all the fingers and restricted movement in a larger joint, usually the wrist or elbow [7]. Passive joint movement should also be assessed to confirm limitation of joint mobility [8].

Prevalence estimates for limited joint mobility in type 1 diabetes range from 9% to 66%, and from 25% to 75% in type 2 diabetes [1, 9–12]. The prevalence rates have declined in individuals with type 1 diabetes in the last 20 years, due to improvements in glycaemic management [13].

Limited joint mobility is an important entity, primarily because of its clinical associations. It is one of the earliest complications of diabetes and is strongly associated with the presence of microvascular complications such as retinopathy and nephropathy in type 1

Table 59.1 Bone and joint disorders in people with diabetes.

Fibroproliferative disorders of soft tissue
Cheiroarthropathy

Figure 59.1 Limited joint mobility with flexion contractures affecting the finger proximal interphalangeal joints. Source: Courtesy of Dr Tim Cundy.

limited joint mobility does not severely affect hand function, but combinations of these upper-limb disorders may cause upper-limb disability [20–22]. In addition to microvascular complications, risk factors for the development of limited joint mobility in people with diabetes include older age, puberty (in type 1 diabetes), disease duration, and cigarette smoking [10, 23–25].

Advanced imaging techniques have demonstrated thickening of skin, tendons, and tendon sheaths in those with limited joint mobility [26, 27]. Histological examination of the skin shows altered mucopolysaccharide distribution, elastin, and collagen, and reduced vascular lumen [28]. Non-enzymatic glycation and accumulation of collagen have been implicated in the pathogenesis [29]. Disordered glycosaminoglycan metabolism is also a feature; skin biopsies from individuals with severe limited joint mobility show pronounced hyaluronan expression in the epidermis and diminished expression in the dermis and basement membrane, compared with skin from people without diabetes and people with diabetes but without limited joint mobility [30]. In addition, increased urinary glycosaminoglycan excretion has been reported in individuals with limited joint mobility [31]. Reduced circulating insulin-like growth factor I (IGF-I) is associated with limited joint mobility, implicating the growth hormone (GH)-IGF axis in the pathogenesis of this complication [32]. Microvascular abnormalities also contribute to disease, with reports of disordered palmar microvascular flow in response to thermal challenge [33].

The mainstay of therapy remains optimization of glycaemic management, and a reduced prevalence of this disorder has been reported with such interventions [13, 34]. Physiotherapy, particularly hand therapy, may be of benefit to improve joint contractures and function. Corticosteroid injection of flexor tendon sheaths has been reported to lead to resolution of finger contractures in almost two-thirds of cases related to limited joint mobility [35].

Frozen shoulder

This disorder is characterized by shoulder pain, stiffness, and severely restricted range of motion in all planes [36]. Three phases of the disorder are well recognized: first the painful freezing stage with associated nocturnal pain (lasting 4–8 months), followed by the adhesive phase with improvement in pain but severely restricted range of motion (lasting 8–24 months), and finally the resolution phase [37]. The mean time to resolution is 30 months [37]. Plain radiographs of the shoulder are typically normal. Although the condition is usually self-limiting, some people have persistent shoulder pain and restricted range of motion many years after assessment [38, 39].

Imaging and histological studies have demonstrated that the pathological features of frozen shoulder are thickening of the capsule and synovium with contracted joint volume. Affected tissue is characterized by dense type I and type III collagen deposition with proliferating fibroblasts and a chronic inflammatory infiltrate comprising T cells, macrophages, and mast cells [40, 41]. Disordered collagen synthesis and vascular endothelial growth factor 1 (VEGF-1)-mediated angiogenesis have also been implicated [42, 43].

Treatment is tailored to the stage of the disorder [36]. In the painful freezing stage, analgesics, including NSAIDs if tolerated, are indicated. Early use of intra-articular corticosteroids is associated with improved outcomes [44], and physiotherapy with exercise within the limits of pain is of greater benefit than more intensive physiotherapy such as stretching and mobilization [45, 46]. NSAIDs and intra-articular steroids may have similar outcomes over six months [47]. Although oral corticosteroids provide

diabetes [1, 13–16] and macrovascular complications in type 2 diabetes [10]. It is also associated with other fibroproliferative disorders affecting the upper limb, such as frozen shoulder, Dupuytren's contracture, and carpal tunnel syndrome [12, 16–19]. In general,

short-term relief in the painful freezing stage, they are not routinely recommended due to lack of long-term benefit and risk of adverse events [48]. In the adhesive phase, more intensive physiotherapy is indicated. For those who fail to respond to physiotherapy and have persistent shoulder restriction, interventions such as radiographic-guided hydrodilatation, manipulation under anaesthesia, or arthroscopic release should be considered [49, 50].

Diabetes is a major risk factor for frozen shoulder. The prevalence of frozen shoulder is 11–19% of people with diabetes, compared with 2–3% age-matched people without diabetes [17, 20, 51, 52]. Individuals with diabetes are also more likely to have bilateral disease. Key risk factors for frozen shoulder in people with diabetes are older age, duration of diabetes, previous myocardial infarction, retinopathy, and peripheral neuropathy [53]. The presence of other fibroproliferative musculoskeletal disorders such as limited joint mobility and Dupuytren's contracture is strongly associated with frozen shoulder in people with diabetes [53]. Furthermore, frozen shoulder in individuals with diabetes is more difficult to treat due to persistent disease and worse outcomes following surgical interventions [50, 54, 55].

Dupuytren's contracture

Dupuytren's contracture is a fibroproliferative disorder of the palmar fascia leading to the formation of palmar nodules, development of a palmar aponeurosis cord with tethering of the overlying skin, and eventually flexion contractures particularly affecting the ring and little fingers [56]. Older men of Northern European ancestry are most frequently affected. Disordered fibroblast and myofibroblast function has been described, with deposition of type III collagen, potentially mediated by growth factors such as transforming growth factor β (TGF- β) and basic fibroblast growth factor (bFGF) [57–59].

Surgical treatment is the mainstay of therapy, although non-surgical options, particularly local injection of collagenase, are promising [60]. People with diabetes have similar responses to collagenase injections to individuals without diabetes [61]. Splinting and intralesional corticosteroids are frequently ineffective [62]. Surgical referral should be considered in the presence of contracture. Various surgical approaches are available, including fasciotomy (division of the affected palmar fascia) or fasciectomy (excision of the affected palmar fascia). Percutaneous needle fasciotomy is a minimally invasive technique with good short-term outcomes, although recurrence is a frequent problem [63, 64].

Risk factors for Dupuytren's contracture include advanced age, male sex, cigarette smoking, manual labour, and alcohol consumption. Diabetes is also an important risk factor for Dupuytren's contracture, which is present in up to 26% of people with diabetes [20, 21, 65]. Age and disease duration are the major risk factors for development of Dupuytren's contracture in those with diabetes [66]. Dupuytren's contracture is also associated with microvascular complications in type 1 diabetes and macroalbuminuria in type 2 diabetes [67, 68]. Rapidly progressive contractures are less frequently seen in people with diabetes [66]. Coexistent fibroproliferative disease is frequent in individuals with diabetes-associated Dupuytren's contracture, with higher rates of limited joint mobility [68].

Stenosing tenosynovitis (trigger finger)

Trigger finger is a condition in which the flexor tendon is prohibited from gliding through the tendon sheath because of thickening of the synovial sheath over the tendon [69]. This disorder most

frequently affects the ring finger, but may also affect the other fingers and the thumb. The person may report a clicking sensation when moving the finger, discomfort over the palm, or overt triggering when the finger is locked in flexion [70]. Nodular or diffuse flexor tendon swelling may be palpable.

The syndrome occurs due to a discrepancy between the flexor tendon and its sheath in the pulley at the level of the metacarpal head [70]. The pulley becomes thickened with increased extracellular matrix and fibrocartilage metaplasia [71]. These pathological changes may be induced by repetitive trauma.

Corticosteroid injection into the tendon sheath is an effective therapy for most individuals, particularly in the presence of nodular disease. For people with nodular disease for less than six months, local injection has a reported success rate of 90% [72]. Splinting and hand therapy are useful adjuncts to local injection. If conservative therapy fails, release using a percutaneous needle approach or open surgery is indicated [73].

People with diabetes are at higher risk of trigger finger, with a lifetime risk of 10% compared with 2.6% of the general population [70]. Multiple finger involvement is also more common in people with diabetes and is associated with the presence of limited joint mobility and carpal tunnel syndrome [74]. A person's age, diabetes duration, and presence of microvascular complications are all associated with increased risk of trigger finger in diabetes [66, 75]. Outcomes are typically worse when trigger finger is associated with diabetes, with lower responses to corticosteroid injection and greater need for surgery [76–78]. Furthermore, type 1 diabetes is associated with a higher prevalence of disease, more affected digits, greater need for surgery, and higher risk of recurrence [66, 76, 78].

Carpal tunnel syndrome

Carpal tunnel syndrome is a common compressive neuropathy affecting the median nerve as it traverses with the flexor tendons through the carpal tunnel, an anatomical space comprising the carpal bones and the transverse carpal ligament [79]. The most common histological appearance is non-inflammatory tenosynovial fibrosis, with increased fibroblast number and type III collagen deposition, most likely mediated by TGF- β [80]. Compression within the carpal tunnel leads to disordered microvascular supply of the nerve, causing demyelination and axonal degeneration. The typical presentation is hand paraesthesia, particularly affecting the thumb, index finger, and middle finger. Paraesthesia is often more frequent at night and may wake the individual from sleep. Wrist and hand pain may also occur, and these individuals frequently report hand clumsiness.

Clinical examination may be normal, but in the presence of severe and prolonged disease there may be features of median nerve denervation, including thenar wasting, weakness of thumb abduction, and sensory loss over the median nerve distribution. Provocative tests including Phalen's test and Tinel's test may be positive, and if present have relatively high specificity for carpal tunnel syndrome. Phalen's test is positive if paraesthesia in the median nerve distribution is reported following flexion of the wrist at 90° for 60 seconds. Tinel's test is positive if paraesthesia is reported after tapping the volar wrist over the carpal tunnel. The diagnosis is confirmed by nerve conduction testing, with the typical findings of prolonged latencies and delayed conduction velocities affecting the median nerve across the wrist [81].

Treatment comprises maintaining the wrist in a neutral position using a removable wrist splint. Splinting is particularly useful for nocturnal symptoms and may be sufficient to treat mild disease [82].

Although oral corticosteroids have short-term efficacy, side effects are usually unacceptable [83]. Local corticosteroid injection provides good short-term relief [84]. Surgical release under local anaesthesia is a well-tolerated and effective therapy, which should be considered when conservative therapy has failed, or in those who have severe symptoms and signs of nerve compression [85]. Open-release and endoscopic approaches have similar clinical outcomes [86].

Carpal tunnel syndrome may be caused by several factors, including non-specific flexor tenosynovitis affecting the wrist, rheumatoid arthritis and other inflammatory synovial arthropathies, obesity, pregnancy, and disordered wrist anatomy [79]. Diabetes is one of the most common metabolic disorders associated with carpal tunnel syndrome, being present in 16% of affected individuals [87]. Most studies have shown increased risk of carpal tunnel syndrome in people with type 1 diabetes or type 2 diabetes [66, 88, 89]. A survey using clinical and neurophysiological assessment reported a prevalence of carpal tunnel syndrome of 2% in a reference population without diabetes, 14% in people with diabetes but no diabetic polyneuropathy, and 30% in people with diabetic polyneuropathy [90]. Carpal tunnel syndrome is associated with duration of diabetes and is more frequently present in those people with microvascular complications such as retinopathy, nephropathy, and polyneuropathy [66, 91]. Carpal tunnel syndrome is also more common in individuals with limited joint mobility, and this disorder may occur at higher frequency in diabetes due to accelerated thickening and fibrosis of the flexor tendon sheaths within the carpal tunnel [19]. Glycation of collagen may also reduce compliance of connective tissue within the carpal tunnel [89]. In addition, the presence of existing microvascular disease may further increase the risk of endoneurial ischaemia as the median nerve travels through the carpal tunnel. Carpal tunnel syndrome may be more difficult to assess in people with coexistent diabetic neuropathy, due to atypical presentation and neurophysiological assessment [90, 92]. Treatment options for those with diabetes and carpal tunnel syndrome are similar to those without diabetes, and responses to surgery are usually good [93, 94].

Disorders of joints

Charcot joint

Charcot joint is a destructive arthropathy, most commonly affecting people with diabetes in the presence of severe peripheral neuropathy. This disorder affects 0.1–0.4% of people with diabetes and may lead to severe foot deformity and disability, ulceration, and limb amputation (Chapter 53) [95]. Several stages of disease are described [96, 97]. The developmental stage presents as acute inflammation with swelling, warmth, and erythema of the foot. Pain may be a feature, despite the presence of peripheral sensory neuropathy. Peripheral pulses are usually easily palpable. Gradually worsening deformity occurs, with bone resorption, fracture, and dislocation, leading to instability of the foot and the classic rocker-bottom dislocation of the midfoot (Figure 59.2). Plain radiographs may appear normal early in the acute phase of disease (stage 0), but magnetic resonance imaging (MRI) scans show florid bone marrow oedema, subchondral cysts, and microfractures, and bone scintiscan shows increased uptake in the bony phase [97]. As deformity develops, radiographs show severe osteolysis, bone fragmentation, and disordered architecture (stage 1). In the coalescence phase (stage 2), hyperaemia resolves, swelling reduces, and skin temperature normalizes. Bone debris is resorbed and bone sclerosis

may occur. The reconstructive phase (stage 3) is characterized by remodelling of bone, ankylosis and proliferation of bone, and formation of a stable foot. The acute phase (stages 0 and 1) typically lasts 2–6 months, and the reparative phase (Stages 2 and 3) lasts up to 24 months. During both the acute and the reparative phases of disease, bony deformity may lead to abnormal load bearing, with ulceration of overlying skin and secondary osteomyelitis.

Five separate patterns of foot involvement are identified in people with diabetes [98]:

1. Affecting the forefoot with osteolysis of the metatarsophalangeal and interphalangeal joints of the feet, leading to a *sucked candy* appearance on plain radiography.
2. Affecting the tarsometatarsal (Lisfranc's) joint, leading to instability, subluxation, and fracture (Figure 59.2).
3. Dislocation and fracture affecting the midtarsal and naviculocuneiform joints.
4. Affecting the ankle and subtalar joints, often with severe osteolysis.
5. Affecting the calcaneus.

The most common patterns are (2) and (3), and combinations of patterns may be present. Bilateral disease is present in one-quarter of individuals. Rarely, other joints such as the knees, elbows, and shoulders are affected.

The aetiology of the disease remains controversial [99]. Minor trauma frequently precipitates onset of disease and may lead to sub-clinical bone injury that triggers an aberrant inflammatory response [100]. It is likely that disordered weight bearing in joints affected by peripheral neuropathy leads to repetitive injury and instability (the neurotraumatic hypothesis). Additionally, autonomic dysfunction causing vasodilatation, arteriovenous shunting, and hyperaemic bone resorption has been implicated (the neurovascular hypothesis). Development of osteopaenia and osteolysis increases the risk of fractures in the presence of abnormal load bearing with a cycle of joint instability and fracture development, causing further abnormal load bearing [101]. Advanced imaging and histological analysis have demonstrated local inflammation of synovium and bone in Charcot joints, which is characterized by increased expression of the pro-inflammatory cytokines, tumour necrosis factor α (TNF- α) and interleukin-1 (IL-1) [102–105]. Large numbers of osteoclasts are present within affected bone, and

people with Charcot joint have greater circulating pre-osteoclast cells with increased ability to form peripheral blood-derived osteoclasts *in vitro*, compared with people with diabetes but without Charcot arthropathy and those without diabetes [105–107]. Markers of bone resorption are increased in people with acute Charcot joint [108]. Interestingly, acute-phase markers are not significantly elevated, indicating an apparent dissociation between local and systemic inflammatory disease [109]. These data implicate receptor activator of nuclear factor- κ B (RANKL)-mediated osteoclastogenesis, driven locally by pro-inflammatory cytokines, and provide a rationale for the use of agents that target the osteoclast in treatment of the disease.

Management of Charcot joint depends on the stage of disease. Treatment during the acute phase involves immobilization, which reduces inflammation, prevents abnormal load bearing, and stabilizes the foot in a position of least deformity. The standard immobilization method during the acute phase is a non-weight-bearing total-contact cast. This treatment requires close monitoring and regular adjustment, and should be maintained until swelling and temperature normalize and radiographs show no further bony destruction [110]. The use of a weight-bearing total-contact cast may be an acceptable alternative to the non-weight-bearing option, but controlled trials are not yet available [111, 112].

The recognition that the acute phase of Charcot joint is associated with excessive osteoclast activity has led to the testing of agents targeting bone turnover for this condition. Clinical trials of bisphosphonate treatment have shown varying results, with improvement in skin temperature and bone turnover markers, but no clear benefit in immobilization rates [113]. One randomized placebo-controlled trial reported increased immobilization times following zoledronate (3×4 mg infusions) [114]. A randomized trial of intranasal calcitonin demonstrated efficacy with respect to bone turnover markers, but no differences in clinical measures were reported [115]. The efficacy of TNF inhibitors and other anti-resorptive agents such as the RANKL inhibitor denosumab has not yet been studied in Charcot joint.

Surgery is generally not considered first-line therapy, although one study has reported good surgical outcomes following debridement,

open reduction, and internal fixation with autologous bone grafting in the acute phase of disease [116]. In general, surgical management is currently recommended for those in the reparative (rather than the acute) phase of disease, and particularly for deformities associated with chronic foot ulcers and joint instability. Many different surgical approaches to arthrodesis have been described, including open reduction with both internal and external fixation, depending on the presence of local infection and other anatomical variables [117]. Other surgery includes exostotomy, osteotomy, intramedullary rodding, and amputation. Infection, non-union, and triggering of an acute Charcot reaction are important postoperative complications, and careful postoperative management is essential.

Outcomes in people with Charcot foot are frequently poor. An analysis of 115 individuals reported that non-operative management was associated with a 2.7% annual rate of amputation, a 23% risk of requiring bracing for >18 months, and a 49% risk of recurrent ulceration [118]. The presence of open ulcers at initial presentation or chronically recurrent ulcers is associated with an increased risk for amputation.

Gout

Gout is an inflammatory arthritis caused by intra-articular deposition of monosodium urate crystals [119]. This disorder is the commonest form of inflammatory arthritis in men and affects 1–2% of the white European adult population [120]. In early disease, gout presents as recurrent episodes of self-limiting acute inflammatory attacks (*flares*) of arthritis. These attacks most often affect the first metatarsophalangeal joint, midfoot, and ankle. In the presence of prolonged hyperuricaemia, some individuals develop recurrent polyarticular attacks, tophaceous disease, and erosive arthritis (Figure 59.3).

The key risk factors for gout are hyperuricaemia, male sex, chronic renal impairment, hypertension, obesity, diuretic use, coronary heart disease, and seafood, meat, and alcohol intake [121–123]. The relationship between gout and metabolic syndrome is well recognized. Serum urate concentrations and gout are strongly associated with abdominal adiposity and predict the development of type 2 diabetes [124–126]. The metabolic syndrome and type 2 diabetes

Figure 59.3 Tophaceous gout of the hands in a person with type 2 diabetes.

are more common in people with gout [127]. Promotion of renal tubular reabsorption of uric acid by insulin may mediate this relationship [128]. Recent identification of the glucose and fructose transporter SLC2A9 as a key regulator of serum urate concentrations suggests a further aetiological link between hyperuricaemia and hyperglycaemia [129]. The prevalence of gout is up to 22% in people with type 2 diabetes treated in secondary care [130]. Key risk factors for gout in this population were male sex, renal impairment, and diuretic use. Interestingly, severe hyperglycaemia may reduce urate concentrations, as glycosuria has a uricosuric effect. Thus, as glycaemic levels improve in individuals initiating treatment for diabetes, there is a potential risk of increasing serum urate concentrations and worsening gout attacks [131, 132].

Long-term urate-lowering therapy is indicated for individuals with gout who have recurrent flares, tophi, chronic kidney disease, or urolithiasis [133]. Serum urate lowering to below 0.36 mmol/l (6 mg/dl) is needed to dissolve monosodium urate crystals, prevent flares, and achieve tophus regression. Allopurinol is the mainstay of urate-lowering therapy, but may be ineffective at recommended doses. If the serum urate target is not achieved with allopurinol alone, further options include dose escalation of allopurinol, addition of a uricosuric agent such as probenecid or benzbromarone, or consideration of the xanthine oxidase inhibitor febuxostat, which provides effective urate lowering in people with diabetes and gout [134]. Treatment options for acute gout flares include NSAIDs, corticosteroids, and/or colchicine [135]. Initiation of urate-lowering therapy is frequently associated with exacerbation of gout flares; this side effect can be avoided by commencement of urate-lowering therapy once the acute flare has resolved, gradual introduction of the urate-lowering drug, and co-prescription of low-dose colchicine.

The presence of coexistent gout has several implications for individuals with type 2 diabetes. Poorly controlled gout may hinder attempts at exercise and weight loss. For those with morbid obesity and diabetes, bariatric surgery may have beneficial effects not only on glycaemia and blood pressure, but also on control of serum urate [136]. Diuretic therapy may exacerbate hyperuricaemia and should be avoided in individuals with gout unless absolutely required. Drugs such as losartan and fenofibrate have weak urate-lowering effects and may be of particular benefit in people with diabetes and gout if antihypertensive or lipid-lowering therapy is required [137, 138]. Treatment of type 2 diabetes with sodium-glucose co-transporter 2 (SGLT-2) inhibitors, in contrast to glucagon-like peptide 1 (GLP-1) receptor agonists, may reduce episodes of gout by up to 30% [139, 140].

Osteoarthritis

Osteoarthritis is the most common form of arthritis and is a major cause of pain and disability worldwide. In people with diabetes, the presence of osteoarthritis leads to substantially lower health-related quality of life [141]. Increased load bearing of articular cartilage is a key risk factor for the development of osteoarthritis, and a strong positive relationship has been reported between obesity and the risk of developing osteoarthritis [142–145]. There has been substantial uncertainty about whether type 2 diabetes is an independent risk factor for the development of osteoarthritis [142, 144, 146, 147], or whether the association between type 2 diabetes and osteoarthritis is primarily mediated through increased body mass index (BMI). However, MRI studies of knee cartilage have shown that diabetes is associated with higher T2 relaxation times (indicating increased cartilage degeneration), even after adjusting for other metabolic features including abdominal circumference [148].

Diabetes is also an independent risk factor for severe osteoarthritis requiring arthroplasty, even after adjusting for BMI [149]. Furthermore, the presence of metabolic syndrome and diabetes increases the risk of knee osteoarthritis in women with obesity, even after adjusting for age and joint asymmetry [150]. Chondrocytes express glucose transporters and hyperglycaemia has several direct and indirect deleterious effects on articular cartilage [151]. Inadequately controlled osteoarthritis pain is more frequently observed in people with diabetes at both the knee and the hand [152, 153].

A holistic approach to osteoarthritis management is recommended, with education, exercise, and weight loss if overweight within the core management recommendations for all people with osteoarthritis [154]. Analgesic approaches include topical NSAIDs, which are generally well tolerated in people with diabetes [155]. Intra-articular steroids may provide short-term analgesia in symptomatic knee osteoarthritis, but can lead to short-lived elevations in blood glucose among people with diabetes [156]. For those undergoing hip and knee arthroplasty, diabetes is associated with higher risk of prosthetic infection, postoperative activity limitation, and need for early revision [157–159].

Rheumatoid arthritis

Rheumatoid arthritis and type 1 diabetes share several genetic associations such as *PTPN22*, *HLA-DR9*, the chromosome 4q27 region, the *IDDM5* region, and the *IDDM8* region [160–164]. There is evidence of familial clustering of these disorders: 2.8% of first-degree relatives of probands with rheumatoid arthritis have type 1 diabetes, compared with 0.35% of the general population [165]. The presence of type 1 diabetes is a risk factor for a particular subset of rheumatoid arthritis: anti-cyclic citrullinated peptide (CCP)-positive disease [166]. Anti-CCP antibodies are associated with an increased risk of persistent arthritis in individuals presenting with early inflammatory arthritis [167] and the development of erosive disease in those with established rheumatoid arthritis [168]. The association between type 1 diabetes and anti-CCP-positive rheumatoid arthritis is in part related to the effects of *PTNP22* variants on the risk of both conditions [166].

Skeletal disease in diabetes

Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a disorder characterized by increased bone formation, particularly at the entheses (the insertions of ligaments and tendons into bone) [169]. Ossification of the anterior longitudinal ligament of the spine occurs, most commonly in the thoracic spine (Figure 59.4). Extraspinous ossification may also be identified. The prevalence is as high as 15% in women and 25% in men over the age of 50 years [170]. These individuals may present with back pain and stiffness, although it remains controversial whether DISH is associated with increased back pain, and the disorder is frequently detected as an incidental finding on chest radiographs [171, 172]. Rare complications such as dysphagia, vocal cord paralysis, compression of the inferior vena cava, and neurological compression syndromes have been described in those with florid hyperostosis [173]. Spinal fracture may occur after relatively minor injury and cause significant neurological compromise [174]. The diagnosis is made radiographically, according to the Resnick criteria [175]:

- Presence of flowing calcification and ossification along the anterolateral aspects of at least four contiguous vertebral bodies.

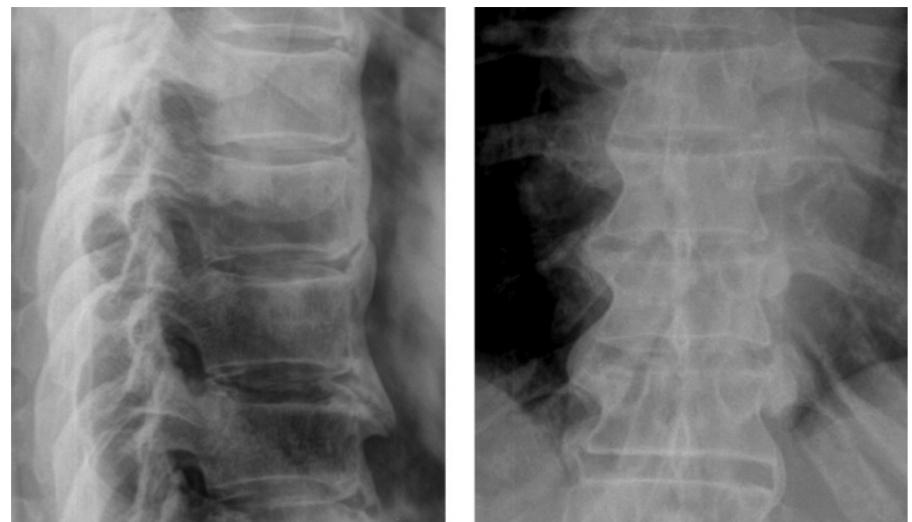

Figure 59.4 Plain radiographs of diffuse idiopathic skeletal hyperostosis (DISH) affecting the thoracic spine. Source: Courtesy of Dr Anthony Doyle.

- Relative preservation of intervertebral disc height and the absence of extensive degenerative disc disease.
- Absence of features of spondyloarthropathy.

There have been no controlled trials of therapies for DISH. For symptomatic individuals, analgesics and physiotherapy are standard therapy. A small uncontrolled study reported that a physiotherapy programme focusing on spinal mobility, stretching, and strengthening had some benefits in improving lumbar spinal mobility after 24 weeks, with no significant benefits in pain or functional outcomes [176]. Surgery is rarely required, but may be indicated for compressive syndromes caused by florid hyperostosis.

Obesity and type 2 diabetes are key risk factors for DISH [177–180]. The presence of additional metabolic disorders such as dyslipidaemia or hyperuricaemia further increases the risk of DISH associated with diabetes [181]. People with DISH have higher rates of hyperglycaemia and higher circulating insulin levels, particularly after a glucose load [178, 182]. Obesity has direct biomechanical effects, due to increased load at the entheses. Additionally, systemic factors may contribute to the development of DISH, as people with this disorder have increased bone mineral density (BMD) elsewhere in the skeleton [183, 184]. Insulin, growth hormone, and IGF-I have been implicated in the pathogenesis of DISH, and high circulating concentrations of these hormones may contribute to the development of hyperostosis [182, 185, 186]. High expression of NF- κ B, platelet-derived growth factor BB (PDGF BB), and TGF- β 1 has also been reported in affected tissue in people with DISH, implicating these factors in osteoblast activation and new bone formation [187].

Osteoporosis and fractures

Fragility fractures are a major cause of morbidity and public health expenditure. The most devastating fracture, that of the proximal femur, is associated with a 20% risk of dying within six months of the event, and a substantial risk of loss of independence [188]. Individual fractures are associated with considerable periods of disability and loss of productivity [189]. Important risk factors for fragility fracture include older age, low BMD, female sex, light body weight, previous fracture during adulthood, cigarette smoking, falls, and glucocorticoid use [188]. Dual-energy X-ray absorptiometry (DEXA) is the preferred modality for

measurement of BMD. Recently, absolute fracture risk algorithms have been developed, using these risk factors, to provide 5–10-year estimates of the risk of major osteoporotic fracture, or specifically of hip fracture [190, 191].

Insight into the mechanisms by which bone loss occurs can be gained by measurement of biochemical markers of bone turnover, which reflect either osteoblast function/bone formation or osteoclast function/bone resorption. At present, bone markers are important tools in evaluating the pathogenesis and treatment of osteoporosis in clinical studies, but their utility in the management of individual patients is limited by assay variability, low predictive value for skeletal events, and high cost [192].

The risk of fragility fractures is increased in both types of diabetes, albeit perhaps by different mechanisms. In addition, attention has focused recently on the skeletal effects of treatments for type 2 diabetes, in particular thiazolidinediones.

Fracture epidemiology in diabetes

Type 1 diabetes

Meta-analyses of observational studies have examined the relationship between type 1 diabetes and risk of fracture [193, 194]. Hip fracture is the only fracture type evaluable in these analyses, because of the paucity of studies of other fracture types. Both meta-analyses demonstrated a substantially increased (6–9-fold) relative risk of hip fracture in type 1 diabetes [193, 194] (Figure 59.5). Studies of other fracture types in type 1 diabetes generally support the notion that non-vertebral fracture risk is increased, with relative risk estimates of 1.3–3 for any fracture [195, 196] and of 2.4 for foot fractures [197]. The only study to date to assess vertebral fractures found no increase in risk in type 1 diabetes [198].

Type 2 diabetes

Epidemiological studies have also suggested that fracture risk is increased in type 2 diabetes. Meta-analyses of observational studies report increased risk of all fractures, and also those of the hip, forearm, and foot [193, 194] (Figure 59.5). Relative risk estimates for hip fracture are lower in type 2 diabetes (1.4–1.7) than in type 1 diabetes, and estimates of fracture risk at other sites in type 2 diabetes range from 1.2 to 1.4. Since the meta-analyses were published, the Women's Health Initiative (WHI) Observational Study, which included >5000 postmenopausal women with type 2 diabetes,

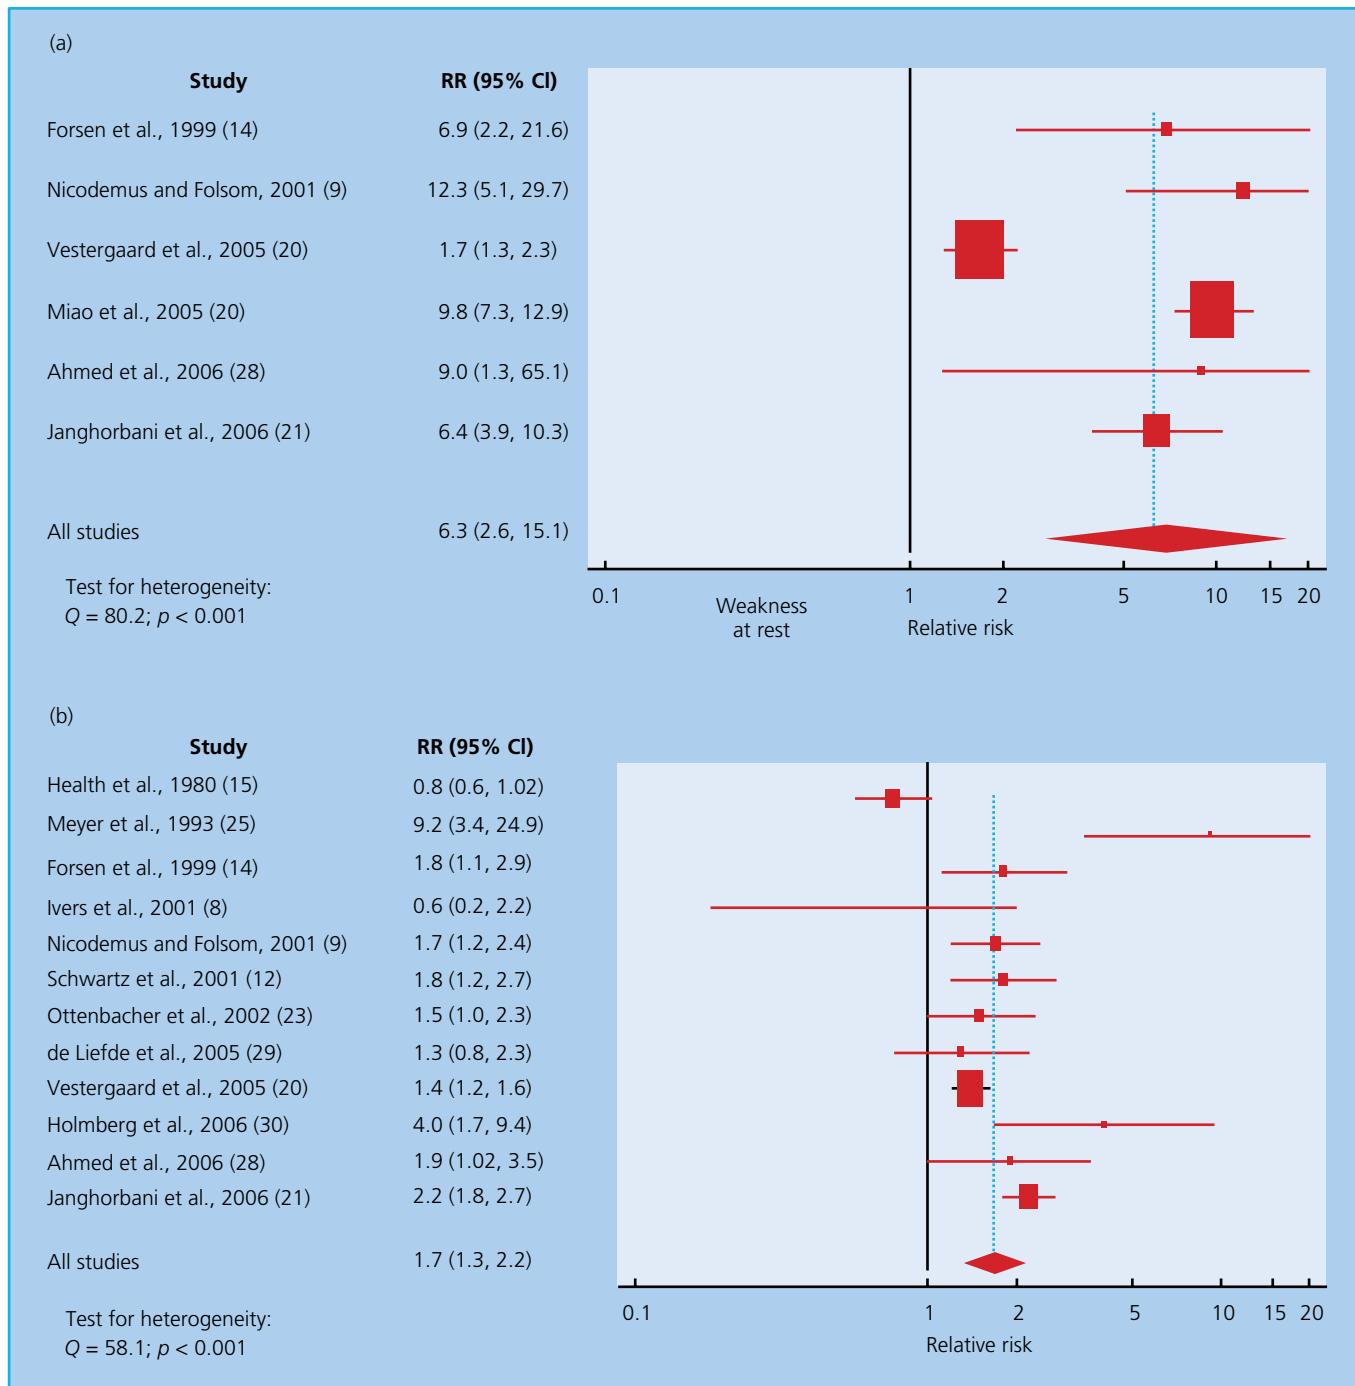

Figure 59.5 Association of (a) type 1 diabetes and (b) type 2 diabetes with hip fracture risk in meta-analyses of case-control and cohort studies. Each square shows the study-specific relative risk (RR) estimate (the size of the square reflects the study-specific statistical weight; that is, the inverse of the variance) and the horizontal line shows the related 95% confidence interval (CI). The diamond shows the summary RR estimate and its width represents the corresponding 95% CI. For details of the studies referred to, see [194]. Source: Janghorbani et al. 2007 [194]. Reproduced by permission of Oxford University Press.

reported increased risks of any fracture and of fractures at several specific sites, including the hip, spine, foot, and upper arm [199]. Risk estimates ranged from 1.2 to 1.5 across the skeletal sites. The WHI study was one of the few with the capacity to evaluate vertebral fractures. Although there was an increased risk of spine fractures in the WHI study, it remains uncertain whether risk of this fracture type is higher in type 2 diabetes, as other studies have not found an association [200].

Mechanisms of skeletal fragility in diabetes

Although fracture risk appears to be increased in both type 1 diabetes and type 2 diabetes, important differences may exist in the pathogenesis of skeletal fragility in the two conditions (Table 59.2). At least two mechanisms underlie the increased skeletal fragility in type 1 diabetes. Most cross-sectional studies of people with type 1 diabetes report decreased BMD throughout the skeleton, although there is no consistent association between age of participants, dura-

Table 59.2 Mechanisms of increased skeletal fragility in diabetes.

Type 1 diabetes	Type 2 diabetes
Decreased BMD	Regional osteopenia

tion of disease, and magnitude of BMD deficit [201, 202]. Interestingly, studies performed in children and young adults demonstrate lower than normal BMD at hip and spine at the time of diagnosis [203, 204]. Taken together with the observations from longitudinal studies that BMD does not progressively decline in type 1 diabetes [205–208], and cross-sectional studies of middle-aged people with type 1 diabetes that report normal levels of bone turnover markers [209–211], the observed deficit in BMD in type 1 diabetes occurs early in the course of the disease, and perhaps prior to clinical presentation. It is possible that deficiency of insulin and other pancreatic β -cell hormones such as amylin and prepitin, each of which has been implicated in skeletal homeostasis [212–215], contributes to the decreased BMD in type 1 diabetes. Low IGF-I levels have been implicated in the pathogenesis of cortical bone loss in type 1 diabetes [216]. Insulin deficiency alone is probably not sufficient to explain the lower BMD, since insulin therapy does not normalize BMD. Lower body weight may also be a factor, as there is a strong positive relationship between weight and BMD [217, 218].

The magnitude of the reduction in BMD (3–8%) is probably insufficient to explain the higher rates of fracture in type 1 diabetes [202]. A second mechanism by which skeletal fragility is likely to be increased is via an increased propensity to falls as a result of disease complications. Neuropathy, visual impairment, cerebrovascular disease, and hypoglycaemia are likely to increase falls risk. In the one study that has evaluated this possibility, substantially higher risks of hip fracture were seen in individuals with type 1 diabetes with a range of diabetes-related complications than in those without complications [219]. Neuropathy may also have an adverse impact on BMD in the distal limbs, as people with type 1 diabetes and neuropathy have lower cortical bone mass in the distal limbs than those without neuropathy [220]. Animal studies suggest that interruption of nerve supply to bone decreases regional bone mass independent of changes in mechanical loading [221]. The presence of regional osteopenia may contribute to the increased risk of distal limb and foot fractures in type 1 diabetes.

The mechanisms by which skeletal fragility is increased in type 2 diabetes are uncertain (Table 59.2). The observation that fracture risk is increased is surprising, because the higher body weight that commonly accompanies type 2 diabetes might be expected to preserve bone mass and protect against adverse skeletal outcomes. In fact, BMD in the axial skeleton is higher in people with type 2

diabetes than in those without diabetes [193, 199, 200]. However, BMD remains an important risk factor for fracture in type 2 diabetes, since incident fractures occur more frequently in people with type 2 diabetes and decreased BMD than in those with normal BMD [222]. The limited available evidence suggests that people with type 2 diabetes who have neuropathy and nephropathy have lower BMD than those free of these complications [193, 223].

As in type 1 diabetes, it is likely that complications of type 2 diabetes, such as neuropathy, vascular disease, and impaired vision, increase the risk of falling, and thereby of fracture. In the Study of Osteoporotic Fractures, a prospective study of fracture epidemiology in older American women, participants with type 2 diabetes had a 22% higher risk of non-spine fractures than participants without diabetes [200]. Participants with type 2 diabetes who were treated with insulin had both a higher prevalence of disease complications and a higher risk of fracture than those with type 2 diabetes who were not treated with insulin. In the Health, Aging and Body Composition (Health ABC) study, a prospective study of older (>70 yr) American men and women, there were strikingly higher prevalences of neuropathy, cerebrovascular disease, and falls in participants with type 2 diabetes who suffered a fracture, compared to those with type 2 diabetes who did not fracture [222]. Many risk factors for falls, including use of medications associated with increased falls risk, are more commonly present in populations with type 2 diabetes than in those without diabetes [224]. Low-impact falls are more frequent in individuals treated with insulin [225]. Curiously, however, adjusting for diabetes complications and/or falls risk does not necessarily attenuate the increased fracture risks seen in type 2 diabetes [200, 222].

It is possible that aspects of bone strength and/or quality that are not captured by DEXA assessment are abnormal in people with either type of diabetes and contribute to increased bone fragility. At present, there are no validated methodologies for assessing these aspects of bone quality. Several cross-sectional studies have evaluated bone microarchitecture in small numbers of people with type 2 diabetes using high-resolution computed tomography [226–230]. Four of five studies found similar bone structural variables between participants with and without type 2 diabetes, while one reported increased porosity of cortical bone at the radius but not the tibia in those with type 2 diabetes. In one study, microindentation analysis suggested a lower bone mechanical strength in the group with type 2 diabetes [228]. It therefore remains unclear whether abnormality of bone structure or quality exists in diabetes.

Potentially relevant to the notion that bone quality is impaired in diabetes is evidence that advanced glycation end-products (AGEs), products of non-enzymatic glycation, are present in greater amounts in the skeletons of diabetic animals than those of control animals [231]. The glycation of matrix proteins in bone may alter biomechanical properties in such a way as to decrease bone strength [232, 233]. *In vitro* studies suggest that AGEs inhibit differentiation of osteoblasts [231, 234] and increase differentiation of osteoclasts [235], thereby potentially altering bone remodelling and/or strength in a detrimental fashion. There may be AGE-specific effects on bone remodelling, as pentosidine decreases osteoclast development *in vitro* [236]. Mice deficient in the receptor for AGE exhibit increased bone mass and decreased osteoclast function, suggesting that the overall effect of increased AGE signalling in bone is likely to be detrimental [237]. A pivotal role for AGEs in the increased risk of fractures in diabetes implies that improved

glycaemia should ameliorate the risk. However, a secondary analysis of a randomized trial of intensive glycaemic management in type 2 diabetes did not find such an effect [238].

Finally, in type 2 diabetes there is clear evidence that treatment with either of the currently available thiazolidinediones, rosiglitazone and pioglitazone, increases fracture risk, at least in the appendicular skeleton in women [239, 240]. Data collected as adverse events during randomized controlled trials of each thiazolidinedione in middle-aged populations with type 2 diabetes demonstrated a twofold increase in risk of distal limb fractures in women, although not in men [241–243] (Figure 59.6). However, observational data from an older cohort of individuals with type 2 diabetes suggest that fracture risk is also increased in men exposed to thiazolidinediones, and that the incidence of *classic* osteoporotic fractures (hip, forearm, humerus) is also higher in thiazolidinedione users [244].

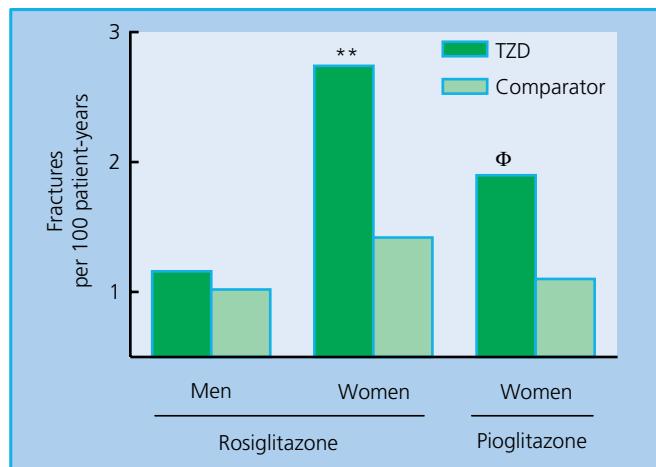

Figure 59.6 Fracture rates, captured as adverse events, in randomized controlled trials of thiazolidinedione (TZDs). **, $p<0.01$ vs comparator; *, significantly higher than comparators. Source: Courtesy of A. Grey.

The mechanisms underlying the adverse skeletal effects of thiazolidinediones are complex and may involve both direct and indirect pathways (Figure 59.7). Of primary importance is the effect of the thiazolidinediones to directly inhibit bone formation, by diverting mesenchymal stem cell precursors from the osteoblast to the adipocyte lineage [239]. In addition, thiazolidinediones increase or maintain bone resorption at inappropriately elevated levels, via direct actions on osteoclast development [239, 245]. Indirect actions of thiazolidinediones that potentially contribute to their detrimental skeletal effects include decreasing systemic and skeletal production of IGF-1, modulating production of skeletally active adipokines, and decreasing levels of pancreatic β -cell hormones with known skeletal activity [240]. A substantial body of pre-clinical studies in rodents demonstrates that thiazolidinediones decrease bone formation and BMD *in vivo* [239]. In humans, randomized controlled trials have reported that thiazolidinediones reduce BMD over 12–18 months, although not markedly [246–249]. There was not a consistent pattern of changes in markers of bone turnover.

The skeletal toxicity of thiazolidinediones has prompted interest in the effects of other oral anti-diabetes agents on bone health. At present, the available data suggest that metformin, sulfonylureas, agents that modulate GLP-1 signalling, and SGLT-2 inhibitors are neutral in regard to the skeleton [250–253].

Investigation and management of osteoporosis in diabetes
Diabetes of either type should be regarded as a risk factor for fragility fracture, and included in clinical fracture risk assessment, along with recognized risk factors such as age, sex, body weight, previous fracture, cigarette smoking, glucocorticoid use, and BMD. Fracture risk algorithms assist in determination of an individual's short- to medium-term absolute fracture risk [190, 191], although they may underestimate risk in populations with diabetes [230]. Although BMD is on average increased in type 2 diabetes, measurement of BMD in people with type 2 diabetes is still helpful in defining that person's fracture risk. Prescription of thiazolidinediones to people with type 2 diabetes who are found to be at high risk of fracture should be avoided unless there are compelling reasons to do so.

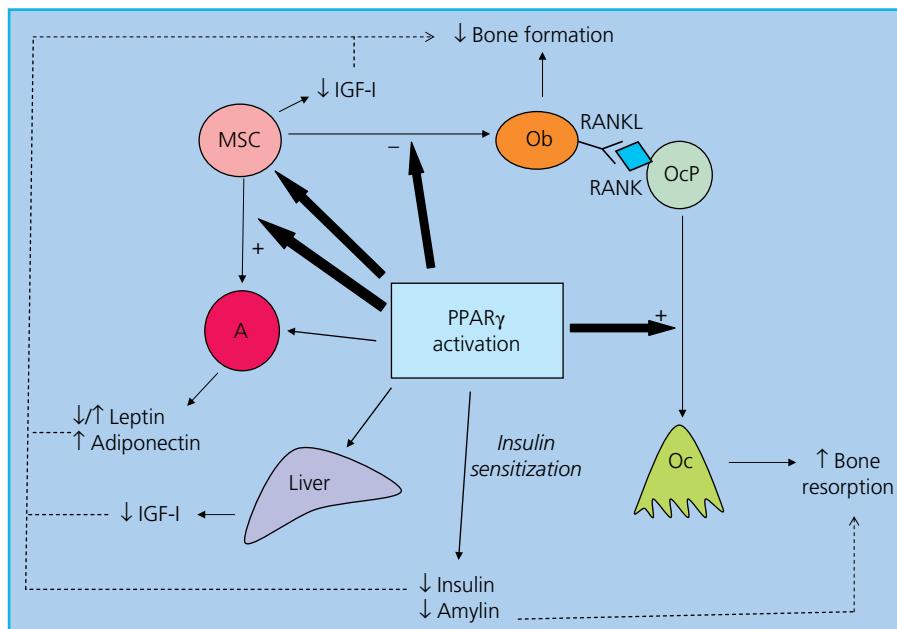

Figure 59.7 Mechanisms by which peroxisome proliferator-activated receptor (PPAR) γ regulates bone metabolism. Within the bone microenvironment (black arrows), activation of PPAR γ signalling promotes differentiation of mesenchymal stem cells (MSC) into adipocytes (A) at the expense of osteoblasts (Ob), decreases stromal cell production of insulin-like growth factor (IGF)-I, and promotes differentiation of osteoclast precursors (OcP) into mature bone-resorbing osteoclasts (Oc). The net effect is to decrease bone formation and increase bone resorption. Activation of PPAR γ signalling at extraskeletal sites such as adipose tissue and the liver, and the ensuing effects of insulin sensitization on the β cells of the pancreas (regular arrows), may have indirect impacts on the skeleton (interrupted arrows) by altering circulating levels of several hormones and cytokines, as indicated. RANK, receptor activator of NF- κ B; RANKL, receptor activator of NF- κ B ligand. Source: Courtesy of A. Grey.

Minimizing falls risk is an important component of skeletal management in diabetes; this can be achieved by targeting both macrovascular and microvascular disease complications, minimizing the risk of hypoglycaemia, optimizing visual acuity, and minimizing use of other medications known to be associated with falls. Although there are no data from interventional studies on the effects of pharmacological treatments on fracture risk in diabetes, it is reasonable to assume that agents known to prevent fractures in osteoporotic populations without diabetes, such as bisphosphonates, will also be effective in diabetes [188].

Fracture healing in diabetes

Some evidence suggests that fracture healing is abnormal in diabetes. In rat models of type 1 diabetes, the mechanical and structural properties of the healing bone are inferior in the diabetic rats when compared to control animals, findings that are accompanied by evidence of both decreased callus size and collagen content [254, 255].

Interventional studies demonstrate that insulin therapy to achieve normoglycaemia is associated with fracture healing that is indistinguishable from that observed in non-diabetic animals [256, 257]. Subsequently, administration of insulin at the site of skeletal injury was also shown to promote fracture healing, without altering serum glucose, implying a role for insulin in directly mediating bone repair [258]. Few data are available from human studies, but increased rates of fracture non-union in both type 1 diabetes and type 2 diabetes have been reported [259], as have higher than expected rates of serious complications in people with diabetes with open ankle fractures [260]. Diabetes is associated with a doubling of the risk of fracture-healing complications (delayed union, non-union, or malunion) [261], although long-term recovery might not be affected [262]. It is unknown whether interventions specifically targeted to populations with diabetes lead to improved post-fracture outcomes. Further investigation of the influence of diabetes and its treatment on fracture repair in humans is needed.

Diabetes and Cancer: Risk, Outcomes, and Clinical Implications

Ellena Badrick¹, Emily J. Gallagher², and Andrew G. Renehan¹

¹Division of Cancer Sciences, University of Manchester, Manchester, UK

²Division of Endocrinology, Department of Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, USA

Key points

- After accounting for confounding and biases, type 2 diabetes is causally associated with an increased risk of a limited number of types of adult cancer.
- In several Western countries, cancer is becoming the leading cause of death among people with diabetes as deaths from cardiovascular diseases decline.
- Two hypotheses seek to explain the pathophysiological mediation between diabetes and cancer risk, namely hyperglycaemia and hyperinsulinaemia.
- Earlier studies implicated several anti-diabetes drug classes in either increased (insulins, thiazolidinediones, incretin-based agents) or decreased (metformin) cancer risk. In hindsight, many of these earlier

analyses overestimated the effect sizes. Updated reviews, using methods to reduce biases, generally weaken these associations.

- People with diabetes who develop cancer have a poorer response to treatment and reduced survival compared to those without diabetes.
- Research is needed to develop a better understanding of the interactions between diabetes, treatments, and treatment-related morbidity, and to determine whether there is a true (direct) adverse effect of diabetes on tumour biology in clinical practice.
- There are three major areas of clinical implication: cancer screening in diabetes; discussing cancer risk when commencing new anti-diabetes drugs; and the management of cancer treatment-related effects in individuals with diabetes.

Diabetes and cancer are common chronic conditions, and they frequently coexist. Worldwide, there were 4.6 million people with diabetes in 2019 [1] and 19.3 million people with new diagnoses of cancer in 2020 [2]. In the UK, it was estimated that 4.7 million people had diabetes in 2019, of whom ~1 million had undiagnosed type 2 diabetes [3]. Over the next 10 years, ~120 000 of these people will develop new cancer diagnoses (personal estimates). Estimates of co-occurrence of prevalent diabetes and cancer are age-, sex-, population-, and cancer type-specific but, for example, in the Danish population 35% will have a diagnosis of diabetes in their lifetime, 44% a diagnosis of cancer, and ~15% both diagnoses [4].

A link between diabetes and cancer was noted in print as early as 1914 [5], but diabetes–cancer associations were only glimpsed as secondary findings over the subsequent 80 years. However, in a 1991 paper focusing specifically on this link, using population data from Sweden, Adami et al. [6] noted significant increases in the risk of liver, endometrial, and pancreatic cancer among people with diabetes. In hindsight the occurrence of pancreatic cancer may in many cases reflect reverse causality; that is, the cancer causes metabolic changes that manifest themselves as symptoms of diabetes. This is now referred to as pancreatogenic diabetes or type 3c diabetes [7]. Interest in the diabetes–cancer link accelerated again in 2009, after

four epidemiological studies evaluating links between cancer and diabetes therapies, in particular long-acting insulin analogues, were published simultaneously in *Diabetologia* [8]. The 2009 controversy brought together researchers from diabetes and oncology communities, and focused attention on the methodological complexities underpinning the links between diabetes and cancer [9].

This chapter will describe the epidemiological evidence evaluating associations between diabetes, cancer incidence, and mortality, and the emerging trends of cancer as a leading cause of death among people with diabetes. As a prelude, the challenge of epidemiological data interpretation is set out. The chapter then discusses the two prevailing mechanistic hypotheses linking diabetes and cancer, namely hyperglycaemia versus hyperinsulinaemia. The central tenet of anti-diabetes therapy is glucose management. From the pharmaco-epidemiological literature, there is evidence that anti-diabetes medications might influence cancer risk, but again, discussion is required around interpretation of these data. There is then a section on the impact of diabetes in individuals diagnosed with cancer. Here, there are additional complexities of treatment selection bias in the interpretation of the data. Finally, the chapter covers three major areas of clinical implication and the emergence of the subspecialty of *onco-diabetology*.

Interpretation of the epidemiological evidence

Diabetes and cancer: potential confounding

A schematic representation of the causal mechanisms between diabetes and cancer risk is shown in Figure 60.1. Excess body weight or fatness, commonly expressed as elevated body mass index (BMI), is a mutual risk factor for the development of type 2 diabetes and for several cancer types [10], and it is conceivable that the positive associations between type 2 diabetes and cancer incidence may simply reflect excess body weight, or obesity, as a confounder. There are many pathophysiological mechanisms in obesity that are common to type 2 diabetes and may be important mediators of tumorigenesis [11]. These include alterations in sex hormone pathways, adipokines, and subclinical inflammation, hyperinsulinaemia, and aberrations in the insulin-like growth factor (IGF) system.

There are several justifications, however, to support the tenet that there are relationships between type 2 diabetes and cancer risk independent of BMI [12]. First, while the list of diabetes-related cancers and obesity-related cancers overlaps, there are some exceptions. For example, there are associations between diabetes and bladder cancer, but in general associations between obesity and bladder cancer are absent or very modest [13]. Another example is advanced prostate cancer, which is associated with an elevated BMI [11], while diabetes appears to be inversely associated with prostate cancer, at least in Western populations.

Second, cigarette smoking is a mutual risk factor for the development of both diabetes and several cancer types. Although this question is understudied, as few diabetes-related cancers are smoking-related cancers, it would seem that smoking is not a major confounder.

A note on ethnicity is pertinent. In the USA, compared with non-Hispanic white Americans (11%), the age-standardized prevalence of diabetes is higher among non-Hispanic Black Americans (22%), non-Hispanic Asians (21%), and Hispanic people (23%) [14], but cancer incidences are generally lower in the latter three ethnic groups compared with white populations. An exception is the incidence of prostate cancer, which is higher among non-Hispanic Black Americans compared with white populations.

Finally, cancer screening is an additional confounder; there might be differential rates of cancer detection between populations with and without diabetes if there were differential rates of cancer screening. For example, there are several trial-proven effective approaches to colorectal cancer screening, including faecal occult blood testing, once-only flexible sigmoidoscopy, and colonoscopy. There is some evidence [15] that people with type 2 diabetes underutilize colorectal cancer screening programmes. Similarly, women with diabetes have lower rates of

attendance for mammographic screening for breast cancer than those without [15]. It is important to note that the risk estimates in Table 60.1 are relative (rather than absolute) risk. These are very modest elevated risks at an individual level and individuals with type 1 diabetes and type 2 diabetes do not require enhanced cancer screening.

Diabetes and cancer: potential biases

There are several specific biases important to the interpretation of the diabetes–cancer association, which include the following.

Detection time bias

This bias arises from the co-diagnosis of the disease exposure of interest (here, diabetes) and outcome of interest (here, cancer) in the same time window. Thus, there is a peak co-diagnosis of diabetes and cancer in the first 2–3 years after initial diagnosis of diabetes. However, these cancers diagnosed shortly after a new diagnosis of diabetes are generally not caused by diabetes. Inclusion of these cancers exaggerates the risk estimates for the diabetes–cancer associations (Figure 60.2). This co-diagnosis peak (and potential detection bias) is common for several cancer types after a new diagnosis of diabetes [18]. Some investigators refer to this as protopathic bias [19], and argue that it is a serious cause of inflated risk estimates between diabetes and cancer incidence. Within the co-diagnosis peak, there are at least three underlying causal relationships: reverse causality; heightened clinical investigations (ascertainment bias) from diabetologists; and heightened clinical investigations from the oncology team. The simple methodological solution is to use an incident diabetes cohort and exclude cancers diagnosed in the first 2–3 years. An alternative solution is to use time-varying hazard models, as shown in Figure 60.2.

Immortal time bias

This refers to a period of follow-up during which, by design, death or the study outcome cannot occur [20]. This bias is common and well known in the pharmaco-epidemiology literature, but not always appreciated in the general clinical epidemiology literature. In pharmaco-epidemiology studies, immortal time typically arises when the determination of an individual's treatment status involves a delay or wait period during which follow-up time is accrued. This wait period is considered immortal because individuals who end up in the treated or exposed group have to survive until the exposure definition is fulfilled, for example at least two prescriptions of an anti-diabetes therapy. If they have an event before starting treatment, they are placed in the untreated or unexposed group. Immortal time bias is particularly problematic because it biases the results in favour of the treatment under study by conferring a spurious survival advantage to the treated group (a misclassification

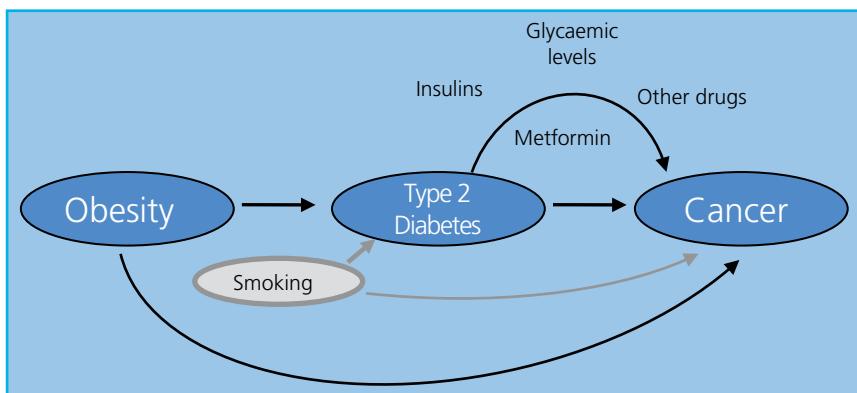

Figure 60.1 Schematic representation of the complexities of the link between obesity, diabetes, and cancer. Obesity is a mutual risk factor for type 2 diabetes and cancer, and might confound the relationship between diabetes and risk of incident cancer. Smoking is another potential mutual risk factor, though less well studied.

Table 60.1 Summary estimates from two large meta-analyses of risk of incidence cancers in populations with type 2 diabetes.

Cancer type	Tsilidis et al. 2015 [16] ^a				Ling 2020 et al. [17]		
	No. of studies	Summary risk estimates (95% confidence intervals)	I ²	Summary risk prediction intervals)	No. of studies	Summary risk estimates (95% confidence intervals)	Evidence for causal association
Hepatocellular carcinoma	42	2.31 (1.87 to 2.84)	97%	(0.66 to 8.02)	36	2.23 (1.99 to 2.49)	In bias analyses the proportion of studies with a true effect size larger than a risk ratio (RR) of 1.1 was nearly 100% for liver, pancreatic, and endometrial
Intrahepatic cholangio-carcinoma	9	1.97 (1.57 to 2.46)	54%	(1.11 to 3.49)		Not included	
Extrahepatic cholangio-carcinoma	9	1.63 (1.29 to 2.05)	64%	(0.86 to 1.95)		Not included	
Endometrial cancer	21	1.97 (1.71 to 2.27)	60%	(1.23 to 3.16)	15	1.63 (1.41 to 1.88)	
Pancreatic cancer	35	1.95 (1.66 to 2.28)	94%	(0.87 to 4.34)	38	2.09 (1.88 to 2.33)^b	
Gallbladder cancer	11	1.52 (1.26, to .84)	32%	(0.99 to 2.33)	17	1.61 (1.34 to 1.93)	^c
Renal cancer	18	1.38 (1.10 to 1.72)	93%	(0.55 to 3.44)	23	1.32 (1.21 to 1.44)	^c
Bladder cancer	36	1.35 (1.17 to 1.56)	95%	(0.61 to 3.02)	20	1.19 (1.09 to 1.29)	
Oesophagus cancer	17	1.30 (1.12 to 1.50)	41%	(0.86 to 1.95)	19	1.01 (0.89 to 1.15)	
Leukaemia	11	1.28 (1.05 to 1.57)	89%	(0.66 to 2.48)	12	1.19 (1.07 to 1.31)	^c
Colorectal cancer	30	1.27 (1.21 to 1.34)	48%	(1.07 to 1.52)	47	1.29 (1.23 to 1.36)	
Non-Hodgkin's lymphoma	21	1.27 (1.09 to 1.48)	85%	(0.70 to 2.30)	12	1.17 (1.09 to 1.31)	
Multiple myeloma	10	1.27 (0.98 to 1.64)	85%	(0.56 to 2.86)		Not included	
Melanoma		Not included		Not included	11	1.06 (0.95 to 1.19)	
Breast cancer	20	1.20 (1.12 to 1.28)	48%	(1.01 to 1.43)	32	1.10 (1.05 to 1.15)	
Ovarian cancer	18	1.17 (1.02 to 1.34)	41%	(0.79 to 1.72)	20	1.14 (1.03 to 1.26)	
Thyroid cancer	8	1.16 (0.97 to 1.39)	0%	(0.93 to 1.45)	14	1.20 (1.12 to 1.29)	
Gastric cancer	21	1.09 (0.98 to 1.22)	81%	(0.72 to 1.65)	28	1.19 (1.05 to 1.35)	
Lung cancer	24	1.03 (0.94 to 1.13)	95%	(0.70 to 1.52)	32	1.05 (0.99 to 1.12)	
Prostate cancer	45	0.91 (0.82 to 1.01)	95%	(0.49 to 1.69)	39	0.83 (0.79 to 0.88)	

Estimates in bold are considered to be causal.

^aTsilidis et al. [16] used assessment of between-study heterogeneity (I^2), assessment of small study effects, and evaluation of excess significance to interpret their data, and reported 95% prediction intervals in addition to the traditional reporting of 95% confidence intervals. I^2 values greater than 50% indicate a high level of between-study heterogeneity.

^bIt is unclear when reverse causality was taken into account properly in the meta-analysis.

^cIn bias analyses, assuming an unmeasured confounding associated with both type 2 diabetes and cancer with an RR of 1.5, the proportion of studies with a true effect size larger than an RR of 1.1 (i.e. 10% increased risk in individuals with type 2 diabetes) was 86% for gallbladder, 67% for kidney, 64% for colon, 62% for colorectal, and <50% for other cancer incidences.

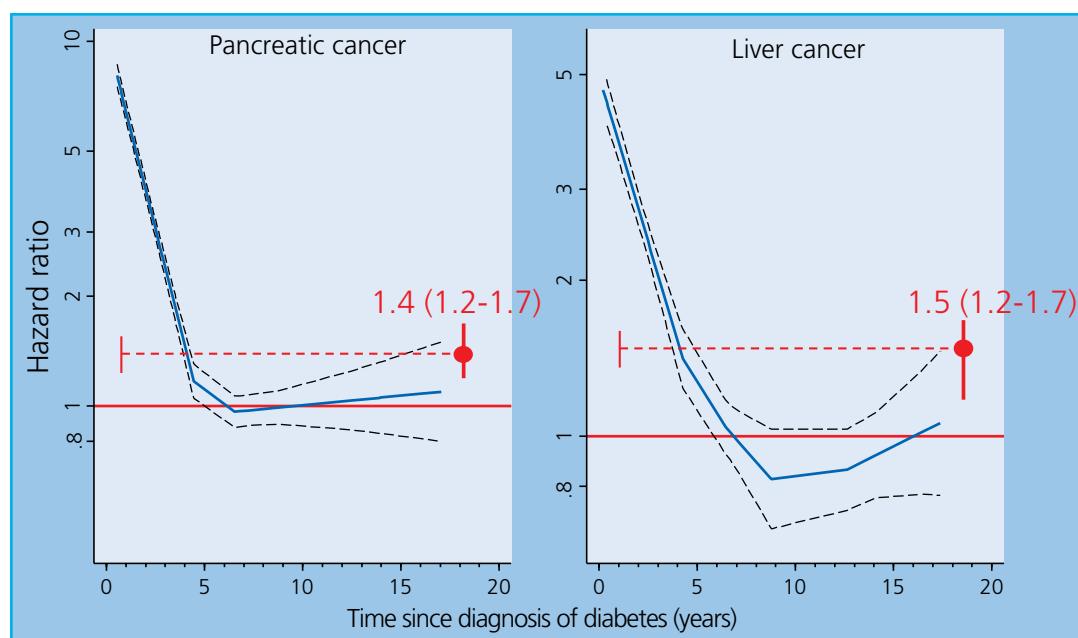

Figure 60.2 Detection time bias. This bias arises due to the co-diagnosis in time of the disease exposure of interest (here, diabetes) and outcome of interest (here, cancer). The hazard plots here are based on data from Adami et al. 1991 [6] and show how the hazard varies with time since diagnosis of diabetes, shown for pancreatic and liver cancers. There is a peak co-occurrence of diabetes and cancer in the first 2–3 years. However, these cancers are not caused by diabetes. If we include these cancers in the risk association model (fixed-cohort analysis, shown as a red

dotted line), the net risk estimates are 1.4 and 1.5, respectively, and 95% confidence intervals (CIs) are greater than 1, suggesting a significant positive association. However, in the preferred time-varying model (shown as a blue line, 95% CIs, and grey dotted lines), the hazard between 5 and 15 years after diabetes diagnosis is close to 1; that is, a null association. It is only 15 years after diabetes diagnosis that there is a suggestion of a positive 'causal' association between diabetes and risk of pancreatic and liver cancers.

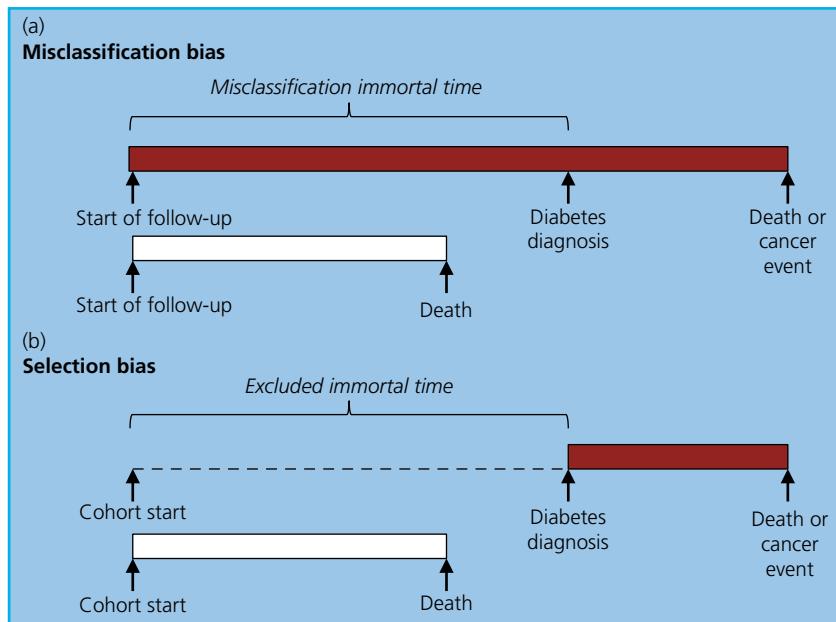

Figure 60.3 Immortal time bias is introduced in cohort studies when the period of immortal time is either (a) incorrectly attributed to the treated group through a time fixed analysis or (b) excluded from the analysis because the start of follow-up for the treated group is defined by the start of treatment and is, by design, later than that for the untreated group. Source: Modified from Levesque et al. 2010 [21].

bias); and because, by excluding the survival time in people who later take up the treatment, the survival time of the narrowly defined non-treatment group is disadvantaged (selection bias; Figure 60.3). These principles can be readily extended to diabetes as the exposure and incident cancer as the event of interest. Immortal time bias should be suspected in fixed-cohort analyses where the covariate diabetes is handled as an *ever/never* term. A methodological solution is to use time-varying models [21, 22].

Allocation bias

This is particularly prevalent in pharmaco-epidemiological studies and is sometimes referred to as confounding by indication, where for example insulin therapy is generally prescribed late in the course of diabetes when individuals are older and *sicker*. Unsurprisingly, these biases result in an apparent increased cancer risk [23]. Methodological solutions require advanced methods such as inverse probability weighting and modelling the data with two time-updated terms in the model [24].

Survival bias

This bias is due to differential survival (or differential loss to follow-up) in individuals undergoing the index exposure (here, diabetes or diabetes therapies) compared with that of the comparator group. In turn, this will differentially influence the number of individuals at risk to developing the index event of interest (here, subsequent incident cancer). This is sometimes referred to as susceptibility bias, and is a specific form of selection bias. The methodological solution here is to use competing risk analyses.

Diabetes and cancer risk: epidemiological evidence

Cancer incidence

In this chapter of the 2017 edition of this textbook, we summarized a large volume of epidemiological evidence evaluating associations between diabetes and cancer risk, and concluded that diabetes may be independently associated with many different types of

cancer [25]. That perception is changing in recent years, as indicated in two large reviews. One was an umbrella review reported by Tsilidis et al. [16] based on 18 meta-analysis papers (27 independent meta-analyses from 474 individual studies) and the other was reported by Ling et al. [17] based on 151 cohorts and incorporating over 32 million people and 1.1 million cancer cases. Both reviews used novel methods to take account of the likely confounding and many biases assumed to be operating in many previous meta-analyses. Specifically, Tsilidis et al. [16] used assessment of between-study heterogeneity, assessment of small study effects, and evaluation of excess significance to interpret their data. Additionally, they reported 95% prediction intervals as well as the traditional reporting of 95% confidence intervals. By contrast, Ling et al. [17] employed a bias analysis for unmeasured confounding, quantifying the proportion of studies with a scientifically meaningful effect size; that is, a true effect size above a pre-specified relative risk.

Table 60.1 summarizes the relative risks per cancer type for each of these two reviews. Applying the methodological frameworks just outlined, Tsilidis et al. [16] concluded that 'evidence could be substantiated only for the associations between type 2 diabetes and risk of developing breast, intrahepatic cholangiocarcinoma, colorectal, and endometrial cancer'. Similar, Ling et al. [17] arrived at a short-list, reporting that their findings 'strongly suggest a causal association between type 2 diabetes and liver, pancreatic, and endometrial cancer incidence'.

Type 1 diabetes and cancer risk

Whether there is a link between type 1 diabetes and cancer risk is not always readily answered, as studies often do not distinguish between type 1 diabetes and type 2 diabetes, and reviews on this question yield mixed results [26]. As type 1 diabetes presents in childhood, very long-term follow-up is required to detect sufficient numbers of common adulthood epithelial cancers for meaningful association analyses. Probably for this reason, when some shorter-term studies address this question, they tend to find increases in the risk of malignancies of early adulthood, such as lymphoma [27].

Large cohorts of people with type 1 diabetes are now surviving into their middle and late adulthood. A recent collaborative

analysis from five countries identified 8800 cancers in individuals with type 1 diabetes followed for 3.7 million person-years, and reported that the pattern of increased incident cancer types mirrors that for type 2 diabetes [28]. However, overall the effect sizes are very modest and smaller than those for type 2 diabetes and cancer risk. As all these individuals are on long-term insulin therapy, this study concluded that they could not exclude an effect from this medication.

Gestational diabetes and cancer risk

Women with gestational diabetes are a readily identifiable population of young women with early evidence of glucose dysregulation and insulin resistance, and are at high risk of subsequently developing diabetes and cardiovascular disease. Glucose intolerance subsides in the majority of women after delivery, but may persist. There are studies suggesting positive associations between gestational diabetes and later breast, ovarian, and uterine cancers [29], while others show no associations [30]. There are many potential confounders in these relationships, which might influence in complex directions. While pre-pregnancy obesity, number of pregnancies, and age are all risk factors for gestational diabetes, early adulthood obesity is relatively protective for postmenopausal breast cancer [31]. One Canadian group attempted to address some of these complexities in a matched study design of nearly 50 000 women with gestational diabetes and found no association between gestational diabetes and premenopausal breast cancer [32].

Diabetes and cancer mortality: evidence

Cancer mortality

Again, in this chapter of the 2017 edition of this textbook, we concluded that associations between diabetes and cancer-related mortality are broadly consistent with those for cancer incidence [25]. Similar to cancer incidence, recent evidence indicates that a revised conclusion should be considered. The Tsilidis umbrella review [16] reported summary estimates for cancer-related mortalities from the breast, colorectum, endometrium, stomach, liver, and kidney. In all these, there was considerable heterogeneity between studies with resulting wide prediction intervals, such that the authors concluded that 'none of the associations for mortality passed our assessment for robust associations without evidence of bias'. By contrast, the authors of the Ling review [17] concluded that their findings 'strongly suggest a causal association between type 2 diabetes and pancreatic cancer mortality'.

At a public health level, the mortality data are helpful as an index of disease burden. However, at a clinical level there are limitations, as mortality from cancer is conditional on the occurrence of cancer, such that these studies fail to disentangle the impact of diabetes on incidence versus treatment outcome, treatment-related morbidities, and impact of type 2 diabetes on quality of life in individuals with cancer.

Cancer as the leading cause of death in diabetes

In 2014, an Australian study reported on trends in causes of death in over 1.1 million people with diabetes between 1997 and 2010, noting that cardiovascular disease is the commonest contributor to death but has declined [33]. By contrast, cancer deaths have increased and have become the second commonest contributor to death. More recently, Pearson-Stuttard et al. [34] evaluated trends

in predominant causes of death in over 300 000 individuals with diabetes in England (2001–2018). They concluded that 'the decline in vascular death rates has been accompanied by a diversification of causes in individuals with diagnosed diabetes and a transition from vascular diseases to cancers as the leading contributor to diabetes-related death'. Similarly, trend data on causes of death from the Swedish National Diabetes Registry predict that cancer will be the leading cause of death among individuals with type 2 diabetes by 2030 [35].

Hyperglycaemia and hyperinsulinaemia in cancer

Metabolic derangements underlie the development of type 2 diabetes and these have been proposed to contribute to cancer development and progression [36]. Here we will examine two theories: the hyperglycaemic and hyperinsulinaemic hypotheses [37].

Hyperglycaemia is the clinical hallmark of diabetes and could be a major risk factor for cancer development [38]. Pre-diabetes, which is defined by glucose excursions above what is considered the normal range but not yet meeting the criteria for type 2 diabetes, is also associated with an increased risk of cancer [39]. In clinical practice, a radiolabelled glucose analogue (^{18}F -fluorodeoxyglucose) is frequently used to detect cancer by positron emission tomography-computed tomography (PET-CT) imaging, due to the known characteristic of certain cancer cells to take up more glucose than non-cancer cells [40]. This phenomenon is related to their high rates of glycolysis relative to normal cells, first recognized by Otto Warburg, who received the Nobel Prize in Physiology or Medicine in 1931.

It is conceivable that hyperglycaemic conditions provide more fuel to cancer cells and facilitate a relative growth advantage. However, most cancer cells express glucose transporters that have a constitutively high level of glucose uptake, and are able to fully satisfy their glucose requirements under normoglycaemic conditions [41]. *In vitro* studies have reported increased proliferation of breast and pancreatic cancer cell lines in high-glucose (25 mmol/l) compared with low-glucose (5.5 mmol/l) conditions. In addition, high-glucose conditions lead to molecular changes within cancer cells and the tumour-associated microenvironment, such as alterations in signalling pathways, greater production of reactive oxygen species, promotion of angiogenesis, and epithelial-to-mesenchymal transition. These molecular changes contribute to cancer cell growth, metastasis, and resistance to treatment [42].

Some population-based studies reported a dose-response relationship between glucose concentration and the incidence and mortality from pancreatic cancer across the pre-diabetes and diabetes range of glucose levels [43]. There is also some population-level evidence that high glycated haemoglobin ($\text{HbA}_{1\text{c}}$) is related to the incidence and mortality of some cancers [44], although not all studies have replicated these findings [45]. Interestingly, in US and European cohorts, the duration of diabetes was not associated with cancer risk [46]. Anti-diabetes therapy does not appear to diminish the risk of cancer in people with diabetes. For example, a meta-analysis of major trials examining intensive glycaemic management and cancer risk concluded that it is unlikely hyperglycaemia plays a role in cancer development [47]. Further evidence comes from data comparing anti-diabetes therapies and categorizing drugs that increase insulin levels (exogenous insulin or secretagogues) and

drugs that lower insulin levels, such as metformin and thiazolidinediones. If within-drug groups are stratified by glycaemic levels, no difference is observed by HbA_{1c} status. This evidence would dispute the hyperglycaemia theory [48]. These findings on cancer risk contrast with the risk of microvascular complications associated with diabetes, where longer diabetes duration increases the risk, which can be mitigated by treatment to reduce HbA_{1c} levels.

While measures of hyperglycaemia (glucose or HbA_{1c}) are the clinical biomarkers used to diagnose type 2 diabetes, endogenous hyperinsulinaemia is present for many years before hyperglycaemia develops, and has been associated with cancer risk and progression in population-based studies [49]. Insulin resistance was classically thought to be the cause of hyperinsulinaemia, but now it is appreciated that hyperinsulinaemia contributes to the development of insulin resistance [50]. Using the UK Biobank, a Mendelian randomization study found that genetically predicted fasting insulin levels were positively associated with uterus, kidney, pancreas, and lung cancers [51]. In women with early-stage breast cancer, fasting insulin levels are associated with worse outcomes [52].

Pre-clinical studies have found that hyperinsulinaemia contributes to tumour development and progression by enhancing the survival of cells that have acquired mutations, by increasing cell proliferation, and by promoting epithelial-to-mesenchymal transition [49, 53]. Cancer cells express a mitogenic form of the insulin receptor (IR-A) that is also expressed in fetal tissues, as well as the type 1 insulin-like growth factor receptor (IGF-IR). Hyperinsulinaemia may therefore directly act on tumour cells through IR-A, or may have indirect effects on cancer cells by increasing the bioavailability of IGF-I, which may activate the IGF-IR [49]. Insulin resistance may also promote cancer growth by altering the tissues and cells in the tumour microenvironment, including tumour-associated adipose tissue and immune cells. Systemically, insulin resistance is associated with decreased sex hormone-binding globulins leading to excess bioavailable oestrogen, dyslipidaemia with higher production of non-esterified fatty acids and other bioactive lipids, and higher levels of pro-inflammatory cytokines and adipokines [11]. Notably, cancers are heterogeneous and insulin responsiveness is not universal. Nonetheless, the accumulation of experimental and epidemiological evidence is consistent with a hyperinsulinaemia hypothesis, and hyperinsulinaemia may have synergistic effects with hyperglycaemia and other metabolic factors associated with insulin resistance to drive tumorigenesis.

Pharmaco-epidemiology: anti-diabetes agents and cancer risk

Interpretation

All the confounding and biases described, in relation to the interpretation of epidemiological studies evaluating diabetes and cancer risk, apply to the pharmaco-epidemiology of anti-diabetes therapies and cancer risk. These concerns have been addressed in a concept paper from the Diabetes and Cancer Research Consortium (DCRC), an international group mainly focusing on pharmaco-epidemiological queries in the complex relationships between diabetes, diabetes treatment, and cancer risk [23]. In this framework document, two important methodological features were emphasized: the need to account for detection time bias; and the need to set up data to account for time-varying exposures, namely immortal time bias. The interpretations of many early 'first-generation'

reports were limited by failure to take account of these key analytical issues [22].

Additionally, allocation bias deserves specific comment, here in relation to the pharmaco-epidemiology of anti-diabetes drugs and cancer risk. To address this bias, one solution advocated by the DCRC group is to model the data with two time-updated terms in the model: a binary term for ever exposure up to that time point; and a continuous term for cumulative exposure [24]. Further methodological work from DCRC members came when Walker and colleagues [54], who summarized the problems of capturing drug exposure from observational datasets and described optimal methodology to reduce bias. For instance, they illustrated that different anti-diabetes drugs are administered as type 2 diabetes progresses, making direct *trial-like* comparisons between drug classes uninterpretable. In this setting, the use of ever/never drug exposure categories only should be avoided, and cumulative exposure handled statistically as a time-varying covariate. We have referred to studies that use these methodologies as *second generation* [22]. These points are worth remembering when reading the next sections.

Anti-diabetes drugs and cancer risk

In this chapter in the 2017 edition of this textbook [25], we catalogued potential relationships between many anti-diabetes drug classes and cancer risk. At that time, there were residual concerns around insulin therapies, particularly long-acting insulin analogues, and increased cancer risk. There were extended concerns that other drug classes that enhanced insulin secretion might also carry these risks. Many of these concerns have subsided or at least been attenuated. They are summarized in Table 60.2 using data from various updated reviews and meta-analyses covering all anti-diabetes drugs [56, 57, 64] or selective drug classes, such as thiazolidinediones [58], α -glucosidase inhibitors [59], incretin-based drugs [60, 61], and sodium-glucose cotransporter 2 (SGLT-2) inhibitors [62, 63]. Here, we will limit the discussion to cancer risk associated with metformin, insulin, and pioglitazone.

Metformin and cancer risk

For over a decade, there have been suggestions in the epidemiological literature that, among people with type 2 diabetes, use of metformin is associated with a reduced risk of certain cancers [65]. Coupled with these observations, there are now many laboratories across the globe exploring the role of metformin in cancer, and several novel anti-cancer mechanisms have been demonstrated and validated, beyond its well-known clinical anti-diabetes effects [66]. Many oncology trials are now being developed to test metformin as a repurposed, inexpensive licensed drug with a potential anti-cancer effect in the clinic [67].

However, we now understand that many of the earlier epidemiological studies on this question contained time-related biases that artificially made metformin look *protective*. Most important of these was immortal time bias. The net result of this bias is an advantage to the users of the drug of interest (here, metformin) when the analysis is simply categorized by ever/never use. This was well illustrated by Suissa et al. [68], who found that immortal time bias was prevalent among many studies that reported a reduced cancer risk associated with metformin use. By contrast, those studies that used methods to avoid these biases reported no effect of metformin use on cancer incidence.

A more recent study by Farmer and colleagues [69] recognized that when studying time-varying exposure to metformin, covariates such as BMI and HbA_{1c} may act as both confounders and

Table 60.2 Summary of evidence evaluating anti-diabetes medications and cancer risk.

Drug class	Plausible cancer mechanism	Drug subclass	Summary risk estimates	Interpretation
Insulin	Increase in cell proliferation Anti-apoptotic Associated with weight gain May mimic insulin-like growth factor I (IGF-I)	Long-acting insulin analogues	CARING five-country cohort study (327 112 new insulin users) [55]: 'No evidence of consistent differences in risk for 10 cancers for insulin glargine or insulin detemir use compared with human insulin, at follow-up exceeding 5 years'	In well-designed analyses taking account of immortal time bias, there appears to be no increased risk between long-acting insulin analogues and cancer incidence
Insulin secretagogues	Enhances β-cell insulin secretion Associated with weight gain	Sulfonylureas	All cancers: meta-analysis of 72 studies found a 20% increased cancer risk [56]. High level of heterogeneity. Sub-meta-analysis of 38 randomized controlled trials (RCTs) found no association with cancer risk [56]	In analyses that take account of selection bias, there appears to be no increased risk between insulin secretagogues and cancer incidence
		Meglitinides	Meta-analysis of 8 studies found no association between meglitinide use and all-site cancer risk [56]	
Metformin	Metformin inhibits mitochondrial complex I, decreasing the adenosine monophosphate (AMP)/adenosine triphosphate (ATP) ratio and deactivating the energy sensor AMP-activated protein kinase (AMPK), in turn reducing blood glucose, hyperinsulinaemia, and IGF-I These may be indirect effects in cancer protection	Metformin	See main text for methodological time-related biases in pharmaco-epidemiology studies of metformin use and cancer risk Three studies (cited in [57]), attempting to account for time-related biases, particularly by comparing new users of metformin and sulfonylureas, did not find evidence for a protective effect of metformin	There is much written on the potential anti-cancer effects of metformin The main text summarizes the many potential methodological flaws Nonetheless, there are now several trials in the setting of cancer evaluating the many hypothesized benefits of metformin; results awaited.
Thiazolidinediones	Thiazolidinediones are insulin sensitizers acting via the peroxisome proliferator activated receptor-γ (PPAR-γ), inducing insulin secretion and improving insulin sensitivity	Pioglitazone	See main text for bladder cancer risk controversy in 2016	The finding for thiazolidinediones are often mixed
		Rosiglitazone	All cancers: a meta-analysis of 92 RCTs showed no association of thiazolidinediones with all-site cancer [56] A meta-analysis of 22 RCTs reported a significant reduction in the incidence of malignancies including rosiglitazone, but not pioglitazone, with reduced colorectal cancer risk; and an association of pioglitazone, but not rosiglitazone, with a reduced breast cancer risk [58]	RCTs in this field may be useful to reduce treatment selection bias, but they suffer from short follow-up and post-randomization selection biases
α-Glucosidase inhibitors	Increases plasma glucagon-like peptide 1 (GLP-1) levels Weight loss	Voglibose Miglitol Acarbose	A meta-analysis of four RCTs found no association with cancer risk [59]	Appears to be no association with cancer risk
Incretin-based drugs	Glucagon-like peptide 1 receptor agonists (GLP-1 RAs) mimic the action of endogenous GLP-1 Delay gastric emptying Enhance glucose homeostasis through stimulation of insulin secretion and inhibit glucagon secretion	Dipeptidyl peptidase 4 (DPP-4) inhibitors	Early report from US Food and Drug Administration database (2004–2009) showed an increased prevalence of pancreatic cancer among users of the DPP-4 inhibitor sitagliptin and the GLP-1 mimetic exenatide A Cochrane review (including 13 studies comparing DPP-4 inhibitors with placebo) concluded that the quality of evidence was too low to determine an effect of DPP-4 inhibitors on pancreatic cancer [60]	There is a link between incretin-based drugs and pancreatitis, and this might be a confounder for pancreatic cancer risk evaluation
		GLP-1RAs	All cancers: a meta-analysis of 72 RCTs found no association between DPP-4 inhibitors and increased cancer risk [61] A meta-analysis of 14 RCTs reported no association of GLP-1RAs with cancer risk [56].	
Sodium–glucose cotransporter 2 (SGLT-2) inhibitors	Increased urinary excretion of glucose	All SGLT-2 inhibitors	A meta-analysis of 27 RCTs found no association with bladder or other cancers [62]	No evidence for association, but follow-up is very limited
		Dapagliflozin	A meta-analysis of 21 RCTs (n = 20 308 on SGLT-2; median follow-up 52 wk) concluded that SGLT-2 inhibitors are associated with increased risk of skin cancers [63] A meta-analysis of 7 studies (n = 27 744 on SGLT-2; follow-up at least 52 wk) found no association with cancer [56]	No evidence for association, but long-term follow-up not captured

causal pathway variables, and so cannot be handled adequately by standard (statistical) regression methods. Using primary care data from the UK Clinical Practice Research Datalink (CPRD), they built marginal structural models with inverse probability of treatment weightings, which can correctly adjust for such confounders. They found no protective effect on metformin on cancer.

Second, treatment allocation bias is a potential pitfall to interpretation. For example, metformin is first-line treatment for diabetes, and is therefore used earlier in the disease course than other medications. Those who reach glucose targets with metformin alone differ in disease severity from those who require additional medication. Differential allocation of drugs based on such confounding factors tends to exaggerate the protective benefits of metformin. Differential allocation is an inevitable bias in observational studies and has to be addressed within a randomized trial framework.

The third key appreciation in the story of metformin and cancer lies in the biology. It has become clear that many pre-clinical studies use concentrations of metformin higher than those safely obtained in the clinical setting. Most *in vitro* studies report using doses of metformin between 1 and 40 mM, which is well above the feasible therapeutic plasma levels (0.465–2.5 mg/l or 2.8–15 mmol/l) in humans [70]. It is possible that metformin causes an energy stress in these studies that far exceeds effects seen clinically.

Insulins and cancer risk

There are hypothetical physico-chemical reasons why some insulins might be pro-tumorigenic. Specifically, molecular engineering of the insulin molecule to form insulin analogues results in a molecule that looks more like IGF-I, with high affinity for the IGF-IR [71] (Figure 60.4). This receptor and its downstream pathway are important for tumour development.

In the late 2000s, several observational studies evaluated the putative link between insulin glargine and cancer risk, and were subsequently meta-analysed in several reviews [72]. In general, there are many inconsistencies in the findings of these meta-analyses. In turn, these reflect important design differences in the included studies. For example, some studies evaluated any insulin use versus non-insulin therapies in people with diabetes, while others evaluated glargine versus non-glargine insulin use. As insulin is generally prescribed late in the course of diabetes, individuals are older and *sicker*, and not surprisingly these biases result in an apparent increased cancer risk. None of the meta-analyses directly addressed the problem of time-related biases. For similar reasons,

lumping data from case–controls (where time-varying exposures generally cannot be modelled) with cohorts is problematic.

The publication of the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial in 2012 brought some clarity to these inconsistencies. This trial randomly assigned 12 537 individuals with impaired glucose tolerance or type 2 diabetes to receive insulin glargine versus standard care in the largest trial of its type [73]. Although the protocol endpoints were cardiovascular non-fatal events or deaths, following concerns emerging about cancer links in the late 2000s, the investigators additionally detailed risk per cancer type by treatment allocation. Although follow-up was relatively short (median 6.2 years), the study concluded that there were no differences between treatment arms for all cancer incidence or deaths, and no differences between treatment arms for specific reported cancer types.

In 2017, a large consortium of national databases from five northern European countries, known as the CAncer Risk and INsulin analoGues (CARING) study [55], assembled over 327 000 new insulin users. Using second-generation study methodologies, it found no consistent signal of increased cancer risk associated with insulin use, and there were no differences between glargin or detemir long-acting insulin analogues.

Pioglitazone and bladder cancer risk

Pioglitazone and rosiglitazone are thiazolidinediones, which act as peroxisome proliferator-activated receptor- γ (PPAR γ) agonists and are used as second-line therapies in the treatment of type 2 diabetes. Their use has been questioned owing to safety concerns because in pre-clinical studies, exposure of male rats to pioglitazone was associated with an increased risk of bladder cancer. In 2005, the prospective pioglitazone clinical trial in macrovascular events (PROactive, a large European randomized controlled trial evaluating the effects of pioglitazones on cardiovascular outcomes) found a non-significant increase in the incidence of bladder cancer in the pioglitazone-treated group. Based on these animal studies and trial data, the US Food and Drug Administration (FDA) commissioned the manufacturer to carry out a 10-year observational cohort study to examine this risk further. An initial mid-term analysis showed that two or more years of cumulative exposure to pioglitazone were associated with an increased risk of bladder cancer [74]. Around the same time, a similar increase in risk was observed in a French cohort [75], which led to the withdrawal of pioglitazone from France and Germany.

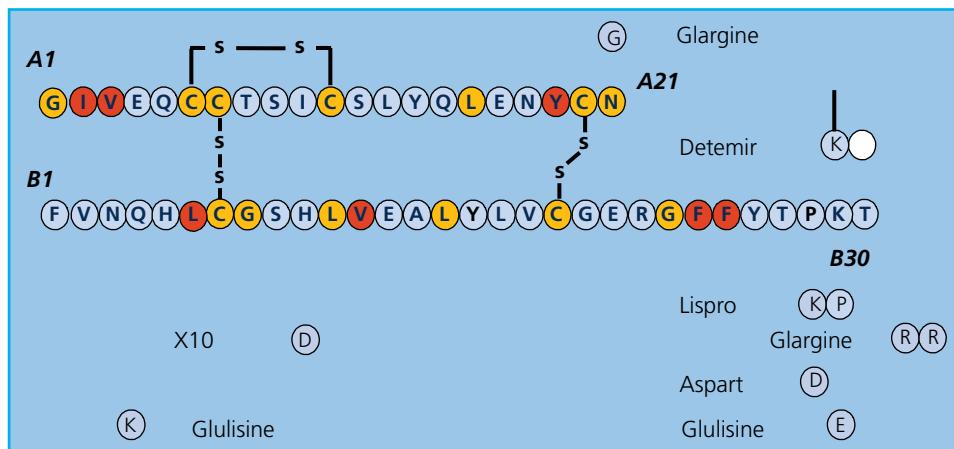

Figure 60.4 Schematic representation of molecular engineering of the insulin molecule. Most of the engineering is in the B-chain, except for glargine, which is an amino acid substitution in the A-chain. These molecular changes make insulin more insulin-like growth factor I (IGF-I) *like*. The net results are twofold: increased affinity for the mitogenic IGF-IR receptor (IGF-IR) and slower dissociation time off the IGF-IR. Source: Modified from Kaarsholm et al. 1995 [71].

More recently, two large analyses report a lack of association between pioglitazone and bladder cancer. Levin et al. [24], on behalf of the DCRC, performed an international (six populations) cumulative exposure analysis on 1.01 million people with diabetes with 3248 incident bladder cancers. Lewis et al. [76] explored associations between pioglitazone use in people with diabetes and incident bladder cancer in a 10-year follow-up of a Kaiser Permanente Northern California (KPNC) cohort (193 099 persons, 1261 bladder cancers). Both analyses found no associations between pioglitazone use and incident bladder cancer risk. An additional study from the KPNC group indicated that proteinuria testing in people with diabetes may be a confounder in studies of pioglitazone and bladder cancer [77].

Impact of diabetes on outcome after cancer diagnosis

While the link between diabetes and incident cancer risk is now established, it is less clear, and indeed more complex, to interpret whether diabetes at or after cancer diagnosis has an adverse impact on outcome. Generally, there are two distinctive study designs: inception cohort studies that evaluate the effect of baseline diabetes on cancer-related mortality in general populations; whereas the oncology literature often uses cohorts of people with a cancer diagnosis and pre-existing type 2 diabetes and evaluates the endpoints of cancer-specific survival (or mortality). Some epidemiologists refer to the latter as case fatality studies. The clinical implications of the findings from these study types differ considerably: in statistical terms, time zero is at baseline cohort entry in the former, whereas time zero is date of cancer diagnosis or cancer initial treatment in the latter.

Within the two study designs, there are multiple levels of potential confounding and biases of cancer morbidity and mortality studies. A methodological group of the DCRC has identified nine levels on the cancer pathway at which confounding may arise [15]: cancer screening use; stage at diagnosis; cancer treatment selection; cancer treatment complications and failures; peri-treatment mortality; competing risks for long-term mortality; effects of type 2 diabetes on anti-cancer therapies; effects of anti-diabetes treatments on cancer outcome; and differences in tumour biology.

In the face of these limitations, the current evidence on the impact of diabetes on outcome after cancer diagnosis is as follows:

- Diabetes is associated with increased all-cause mortality in individuals with cancer, but the evidence that it influences cancer-specific mortality is inconsistent [15].
- For some cancers, there is evidence that people with type 2 diabetes present with more advanced disease, receive suboptimal treatment, and have poorer oncological outcomes [78].
- Compared with individuals with cancer but without diabetes, people with cancer and diabetes have a poorer quality of life and reduced physical activity [79].

While diabetes negatively affects survival, it is unclear whether the presence of diabetes in individuals with cancer has an adverse impact on prognosis above and beyond that expected in a non-cancer (general) population. In other words, is there a diabetes–cancer interaction? Simulation studies indicate that it is plausible to have a scenario where cancer survivors with diabetes have a worse survival than those individuals with cancer without diabetes, but (in relative terms) these individuals are not disadvantaged beyond that expected in the presence of diabetes and without cancer [80].

Clinical implications

For day-to-day clinical practice there are several key messages, which are grouped here as cancer screening; starting new anti-diabetes drugs; and the emergence of the *onco-diabetes* clinic.

Cancer screening

Type 2 diabetes is associated with an increased risk of some adult cancer types, independent of common risk factors such as obesity. However, these elevated risks are generally very modest. While it is important that people with diabetes partake in cancer screening programmes, in common with the rest of the general population, they do not require enhanced cancer screening. This is best illustrated by colorectal cancer screening, where some commentaries have advocated high-risk screening colonoscopy for people with diabetes [81]. For the general populations, the British Society of Gastroenterology [82] classifies risk in individuals with a family history of colorectal cancer (and without a hereditary syndrome) as moderate and subdivide this into *high-moderate* risk (lifetime risk 1 in 6–10) and *low-moderate* risk (lifetime risk 1 in 12). The recommendation in these individuals is early colonoscopy. The lifetime risk for colorectal cancer in people with diabetes is 1 in 20–40. There is therefore no need for colonoscopy screening above and beyond that in the general population.

Commencing new anti-diabetes drugs

Two hypotheses seek to explain the pathophysiological mediation between diabetes and cancer risk, namely hyperglycaemia and hyperinsulinaemia. In terms of general management of people with diabetes and the minimization of cancer risk, the extrapolation of recommendations applicable to the risk reduction of cardio-metabolic complications seems appropriate. However, there is no strong case to have cancer prevention-specific recommendations among people with diabetes. Thus, shared (cardio-metabolic) recommendations including weight management, optimal glucose management, and treatment of elevated blood pressure and dyslipidaemia are applicable.

Several anti-diabetes drug classes have been implicated in either increased (insulins, thiazolidinediones, incretin-based agents) or decreased (metformin) cancer risk. Most of the recent evidence on these questions has been reassuring. This information can be conveyed to individuals already taking these medications or about to commence these as new therapies.

The onco-diabetes clinic

Within the field of clinical diabetology, the subspecialty of onco-diabetology is emerging. It relates to the management of diabetes and related metabolic conditions in individuals with cancer and cancer survivors.

Diabetes healthcare professionals are familiar with hyperglycaemia and weight loss as symptoms of pancreatic adenocarcinoma, as well as the glucose derangements that occur with functional pancreatic neuroendocrine tumours [83], and in individuals who have undergone pancreatectomy. Similarly, the management of glucocorticoid-induced hyperglycaemia in individuals receiving chemotherapy would be considered the ‘bread and butter’ of most practising diabetologists [84]. Diabetes management typically worsens when an individual is diagnosed with cancer, potentially due to the psychological impact of the cancer diagnosis on the

individual, the treating physician's pessimistic perception of the person's outcome, and/or the cancer treatment [85, 86].

The survival for various cancers has vastly improved in recent years due to the rapid approval of targeted therapies. Individuals with cancer and diabetes are more likely to develop infectious [87], haematological [88], and neuropathic complications [89] from their cancer treatments, weakness from skeletal muscle catabolism [90], in addition to diabetes complications, and death from cardiovascular disease compared with those without diabetes. It is important to recognize that non-oncologists are poor prognosticators of outcomes and there are no consensus guidelines on managing diabetes in individuals with cancer. Consequently, diabetes may consequently be undertreated in this population [91]. If hyperglycaemia does contribute to worse outcomes in individuals with cancer, undertreating the diabetes may worsen cancer outcomes, although to date there are no prospective clinical trials examining how diabetes management affects responses to cancer treatment.

A second challenge for diabetes healthcare professionals is staying abreast of the advances in therapeutics in oncology, and how new cancer medications may affect glycaemic levels. Somatostatin analogues are used to treat neuroendocrine tumours and can contribute to hyperglycaemia by reducing insulin secretion. However, in some individuals somatostatin analogues can increase insulin sensitivity and reduce gastrointestinal macronutrient absorption, thereby causing low glucose levels [92].

Small-molecule pharmacological agents that target proteins in the insulin receptor or IGF-IR and related signalling pathways can also cause glucose excursions. The insulin receptor and IGF-IR are members of the tyrosine kinase family of receptors, which also includes the epidermal growth factor receptor (EGFR) and vascular endothelial growth factor receptor (VEGFR). Some of the tyrosine kinase inhibitors (e.g. EGFR inhibitors) may have off-target inhibitory effects on the insulin receptor causing hyperglycaemia, while other multikinase receptor inhibitors may cause hypoglycaemia, potentially by inhibiting insulin clearance [93, 94]. Novel inhibitors of other intermediaries in the insulin signalling pathway, such as phosphatidylinositol 3-kinase (PI3K), Akt, and mechanistic targets of rapamycin (mTOR) inhibitors, can cause severe insulin resistance and hyperglycaemia by preventing insulin-mediated glucose uptake [95, 96]. Immune checkpoint inhibitors are a class of cancer therapies that 'take the brakes off' the immune system and allow T cells to kill cancer cells. These therapies are monoclonal antibodies that target cytotoxic T-cell antigen 4 (CTLA4), programmed cell death protein 1 (PD-1), or programmed death ligand 1 (PD-L1). An uncommon but well-recognized adverse effect of these treatments, particularly the anti-PD-1 monoclonal antibodies, is destruction of the β cells of the pancreatic islets, which causes a form of type 1 diabetes [97]. Recent studies have found that these immune checkpoint inhibitors may contribute to a range of diabetes phenotypes, from insulin deficiency to severe insulin resistance with lipodystrophy, and perhaps more commonly transient

hyperglycaemia [98]. Understanding the different classes of cancer treatments and the mechanisms through which these therapies contribute to glycaemic excursions is important to prevent diabetes-related complications, and in choosing the correct diabetes treatment strategy.

Finally, it is important for the onco-diabetologist to be mindful of the potential interactions between cancer therapies and diabetes medications, as well as the adverse effects of diabetes treatments that may specifically affect the oncology population. Therefore, a multidisciplinary approach involving the diabetes and oncology teams is important to improve outcomes and avoid preventable complications. The field of onco-diabetology is in its infancy and there are many aspects of this field that will likely develop over the coming years.

Conclusion

Type 2 diabetes is linked to an increased risk of several adult cancer types, though these associations are causal in probably a limited number of cancer types. Two hypotheses seek to explain the pathophysiological mediations between diabetes and cancer risk, namely hyperglycaemia and hyperinsulinaemia. Type 2 diabetes is also associated with increased cancer-related mortality, and in several countries cancer is surpassing cardiovascular disease as the commonest cause of death among diabetes populations. Several anti-diabetes drug classes are additionally implicated in either increased (insulins, thiazolidinediones, incretin-based drugs) or decreased (metformin) cancer risk, and there is a large volume of laboratory evidence to support plausibility for these putative links. However, updated large-scale epidemiological analyses, using methods to reduce biases, generally weaken these associations. Compared with people without diabetes, those with diabetes who develop cancer may have a poorer response to treatment and reduced survival, but it is unclear whether this is due specifically to the adverse effects of diabetes *per se* on cancer biology or other factors like selection biases. There are three major areas of clinical implication: cancer screening in diabetes; discussing cancer risk when commencing new glucose-lowering drugs; and the management of cancer treatment-related effects in persons with diabetes, which is now leading to the emergence of the subspecialty of onco-diabetology.

61 Diabetes and Infections

Andrea O.Y. Luk and Clive S. Cockram

The Chinese University of Hong Kong, Hong Kong SAR, China

Key points

- Diabetes is associated with an increased overall risk of infections.
- The presence of diabetes also modifies the course of many infections and increases morbidity and mortality.
- Multiple disturbances in innate immunity have a role in the pathogenesis of the increased prevalence of infections in people with diabetes. Impaired phagocytosis by neutrophils, macrophages, and monocytes; impaired neutrophil chemotaxis and bactericidal activity; and impaired innate cell-mediated immunity appear to be the most important disturbances of the immune system.
- Humoral immunity seems to be relatively unaffected, hence plasma levels of antibodies and responsiveness to most vaccinations are largely unaffected.
- Vascular disease can impair the expression of the immune response as well as affecting the overall function of the microcirculation. It is commonly a factor in severe infections such as malignant otitis externa, emphysematous pyelonephritis, and necrotizing fasciitis.
- Other factors that can predispose to infection include obesity, impaired kidney function, congestive heart failure, stroke, peripheral artery disease, and sensory neuropathy.
- Better regulation of blood glucose generally leads to an improvement in cellular immunity and function, and translates to a reduction in the incidence of severe infection.
- Some uncommon but life-threatening infections occur almost exclusively in people with diabetes. Examples include the rhinocerebral form of mucormycosis, malignant otitis externa, Fournier gangrene and emphysematous forms of cystitis, pyelonephritis, and cholecystitis.
- Increased skin and mucosal carriage of *Staphylococcus aureus* and *Candida* spp. may increase the risk of infection with these organisms. Some microorganisms become more virulent in a high-glucose environment; examples include certain *Klebsiella* serotypes and *Burkholderia pseudomallei*.
- Diabetes increases the risk of tuberculosis approximately threefold and also increases the risk of treatment failure. Unusual or extrapulmonary sites of infection may be important and cavitary disease is more common.
- Urinary tract infections and asymptomatic bacteriuria are more common in people with diabetes. Autonomic neuropathy is a common and important underlying factor.
- Skin and soft tissue infections are more common, with the infected diabetic foot as a prime example. Peripheral artery disease and diabetic neuropathy are important underlying factors in the vulnerability of the foot to infection. Skin infection or infections of the external genitalia are common presenting features of diabetes.
- Diabetes predicts a worse prognosis from coronavirus infection, including Covid-19, and people with diabetes are 2–3 times more likely to have adverse outcomes including death from Covid-19.
- Viral infections such as hepatitis C are associated with a higher prevalence of diabetes. Highly active antiretroviral therapy for human immunodeficiency virus/acquired immunodeficiency syndrome may also precipitate diabetes.

People with diabetes develop infections more often than those without diabetes and the course of the infections is also more complicated. Historically, infections have been well recognized as an important cause of death in people with diabetes and remain an important cause of morbidity and mortality. This is particularly true in low- and middle-income countries and areas, where infections are commonly the first manifestation of previously unknown diabetes. The infected diabetic foot remains a prime example of this phenomenon.

While the association between diabetes and infections is well recognized, the relationships are complex, not always clear-cut, and sometimes controversial. Data on the true incidence of certain infections are lacking and several factors complicate efforts to assess risk of infections and outcomes. Studies are often retrospective and uncontrolled in nature, with considerable between-study

differences in the identification or definition of infective episodes. Furthermore, the tendency for people with diabetes to seek medical attention for minor infections and a lower threshold to initiate treatment may overestimate the number of infective episodes in diabetes populations, depending on the methods used to capture the events.

Some infections that occur predominantly in people with diabetes are uncommon and inevitably have limited data. Examples include malignant otitis externa; mucormycosis; emphysematous forms of cholecystitis, cystitis, and pyelonephritis; and Fournier gangrene. In the case of more common infections that, while not limited to people with diabetes, have diabetes as a complicating factor, many variables make for considerable heterogeneity in the clinical course. Examples include duration of disease, comorbidities such as obesity and smoking, presence of diabetes-related

complications and other concurrent illnesses, glycaemic levels (both recent and longer term), and access to and provision of medical services.

One study, conducted in Canada, compared people with diabetes against matched individuals without diabetes for the occurrence of infection [1]. In this study, 46% of people with diabetes had at least one hospitalization or outpatient visit for infections compared with 38% of those without diabetes, with a risk ratio of 1.2. However, the risk ratios for infection-related hospitalization or death were noticeably higher, at 2.2 and 1.9, respectively. This may be attributable to increased severity and presence of complications. In the case of hospitalization, it could also reflect a lower threshold on the part of physicians to admit people with diabetes to hospital when they have intercurrent illnesses. Several other population-based studies have shown increased rates of infection in diabetes [2–5]. The rates of pneumonia were increased 1.3–1.7-fold, kidney infection 2.0–4.9-fold, skin infection 1.8–2.4-fold, osteomyelitis 4.4–15.7-fold, and general sepsis 2.1–3.2-fold in people with diabetes compared with the general population. The excess risks are in part due to the coexistence of other morbidities such as obesity, congestive heart failure, stroke, and peripheral artery disease, which are independent risk factors for infection [6]. Although the rate ratios were attenuated after adjustment for underlying medical conditions, the difference between individuals with and without diabetes remained significant, suggesting that mechanisms intrinsic to chronic hyperglycaemia and insulin resistance are also contributory.

Among studies that considered the rates in people with type 1 diabetes and type 2 diabetes separately, the risk ratios were generally higher for type 1 diabetes than type 2 diabetes [5]. In an analysis of a primary care database in the UK, the incidence rate ratio for hospitalization related to any infection was 3.7 for type 1 diabetes and 1.9 for type 2 diabetes, and death due to infection was increased 7.7-fold in type 1 diabetes and 1.9-fold for type 2 diabetes, relative to people without diabetes. Another study from Australia reporting standardized mortality ratios of deaths from infective causes revealed a 5.8-fold increase for death due to pneumonia, 29.6-fold for osteomyelitis, and 9.9-fold for sepsis in people with type 1 diabetes compared with those without diabetes [7]. The corresponding mortality ratios were 1.2, 3.3, and 1.9 for type 2 diabetes. Further evidence that the presence of diabetes can worsen the outcome of infections comes from various sources. In an early study of people hospitalized with pneumonia in Denmark, diabetes increased the risks of death at 90 days by 10% [8]. From the UK primary care database, rates of deaths related to infection were increased two-fold in people with diabetes after adjustment for confounding variables [5].

An age differential for excess infection risk has been detected in several studies. In a study in Hong Kong, the disparities in rates of infection-related hospitalization between people with diabetes and the general population were greater in the young [3]. For example, hospitalization due to sepsis was 6–11-fold higher in those aged 20–44 years with diabetes compared with age-matched counterparts without diabetes, while the relative risk difference was only 2-fold for people ≥ 75 years.

Trend analyses on infection rates among people with diabetes have shown stagnation in incidence rates over the past 15 years. In both the USA and Hong Kong, the incidence rates of most infections including pneumonia, kidney infection, and foot infection have remained unchanged or fluctuates, while the rates of influenza have increased [2, 3]. This is concerning, because

the incidence of other major diabetes complications such as cardiovascular diseases and end-stage kidney diseases have declined as a result of advances in medical care. The lack of improvements of infection rates suggests that current measures to control cardio-metabolic risk factors have not contributed to lowering infection rates.

Hyperglycaemia is an important predictor of infection and poor outcome from infection. Two independent studies of people admitted with pneumonia showed that admission glucose levels were associated with increased short-term mortality, independent of diabetes status [8, 9]. A study conducted in the UK investigated the relationships between glycated haemoglobin (HbA_{1c}) and hospitalization for infection [10]. Compared with the reference population without diabetes, people with diabetes and elevated glycaemic indices had significantly higher risks of infections than those with optimal glucose levels. In a population-based study in Mexico, death due to infectious diseases was increased fourfold in people with known diabetes and $\text{HbA}_{1c} < 9\%$ (75 mmol/mol), and close to sevenfold in those with $\text{HbA}_{1c} \geq 9\%$ (75 mmol/mol) [11]. People with diabetes were twice as likely to die from Covid-19 compared with counterparts without diabetes [12, 13]. During the outbreaks of severe acute respiratory syndrome (SARS) in 2003, diabetes was an independent risk factor for poor outcomes (intensive care unit admission, mechanical ventilation, and death) with a threefold increase in relative risk [14, 15]. A report from Saudi Arabia of Middle Eastern respiratory syndrome (MERS) coronavirus infection shows a 60% overall fatality rate, with underlying diabetes being present in 68% of cases, the commonest of several important comorbidities [16]. Increased severity of the clinical presentation of dengue fever has also been described, with increased representation of dengue haemorrhagic fever among people with diabetes [17]. These and other examples emphasize the importance of diabetes in both new and emerging infectious diseases and in those that are expanding their range in response to factors such as globalization and climate change.

Both host- and organism-specific factors appear to be implicated in the increased susceptibility and risk. From the host perspective, defects in innate immunity are particularly important, notably decreased functions of neutrophils, monocytes, and macrophages [18, 19]. Other factors include effects of obesity, diabetes-related complications, chronic kidney disease, poor wound healing, and frequent hospitalizations, with the attendant risk of nosocomial infection [6].

Infections may precipitate metabolic derangements, producing a bidirectional relationship between hyperglycaemic states and infection. Some infections may also be implicated more directly in the aetiology of diabetes.

Physicians working in primary care need to have high awareness of the relationships between diabetes and infection, and of the important infections that may be involved. Infections involving the foot, soft tissues, skin, and nails, as well as the urinary tract, are of particular importance as they are commonly encountered in people with diabetes, may be present at diagnosis, and may be the presenting feature that leads to the diagnosis of diabetes. Infections of the foot and skin will receive additional attention elsewhere in this textbook so, in order to avoid duplication, coverage in this chapter is curtailed. This should not be taken as an indication of lack of relative importance, the opposite being the case. The other chapters concerned should be taken as forming part of the overall coverage of the topic of diabetes and infections (Chapters 53 and 58).

Diabetes, the immune system, and host factors

Host immune response

The increased susceptibility of people with diabetes to infections is well established. Although the mechanisms remain incompletely understood, deficiencies in the host innate immune response appear to be relatively more important than changes in adaptive immunity. The innate immune system is present from birth and constitutes the first-line barrier against microorganisms. This includes physical barriers (e.g. skin, mucous membranes), phagocytes (neutrophils, macrophages, mast cells, natural killer cells), cytokines, and other inflammatory mediators. The adaptive immune system is specific to the invading microorganisms and is acquired throughout life on exposure to these pathogens. Adaptive immunity consists of T cells (cell-mediated immunity) and B cells (humoral immunity). Innate and adaptive immunity closely interact to maximize the body's defence against infection. The presence of diabetes has multiple effects on innate immune responses, including effects on neutrophils, monocytes, and other components of innate immunity, which have important roles in the increased prevalence and severity of infections. The effects include reduced chemotaxis, phagocytosis, and impaired bactericidal activity [20] (Figure 61.1).

Some disturbances in the complement system and in cytokine responses have also been described in people with diabetes (e.g. low complement factor 4 and decreased cytokine responses after stimulation), but their role in the increased susceptibility to infection is less clear [21]. Consistent defects have not been demonstrated. No clear disturbances in adaptive immunity have been described.

Cell-mediated immune disturbances may be minimized by optimal glycaemic management. Humoral adaptive immunity, in particular, appears to be relatively unaffected, as exemplified by the relatively normal antibody responses to most vaccinations and the fact that serum antibody concentrations and responses are generally normal, despite the potential for glycation of antibodies such as immunoglobulin G (IgG). For example, people with diabetes respond to pneumococcal vaccine just as well as those without diabetes [22, 23].

Many studies have used *in vitro* or animal model methodology to identify the mechanisms of immune impairment and a full review of these studies is outside the scope of this chapter. However, the following observations may serve as examples from within the range of observed abnormalities.

Neutrophil chemotaxis, neutrophil adherence to vascular endothelium, phagocytosis, intracellular bactericidal activity, opsonization, and other aspects of innate immunity are all depressed in hyperglycaemic individuals with diabetes [19, 24, 25]. For instance, hyperglycaemia impairs opsono-phagocytosis by diverting nicotinic acid adenine dinucleotide phosphate (NADPH) from superoxide production into the aldose reductase-dependent polyol pathway [26]. These changes lead to reduced host defence in response to infection with extracellular bacteria. Both impaired chemotaxis and phagocytosis have also been described in monocytes of people with diabetes [27].

Defects in innate immunity predispose *db/db* mice to *Staphylococcus aureus* infections. Interestingly, however, these mice showed a heightened inflammatory response, which occurs in association with an impaired neutrophil respiratory burst, and the recruited neutrophils fail to resolve the infection [28]. Such a heightened inflammatory response may be a factor in humans with tuberculosis. In this context also, while release of tumour necrosis

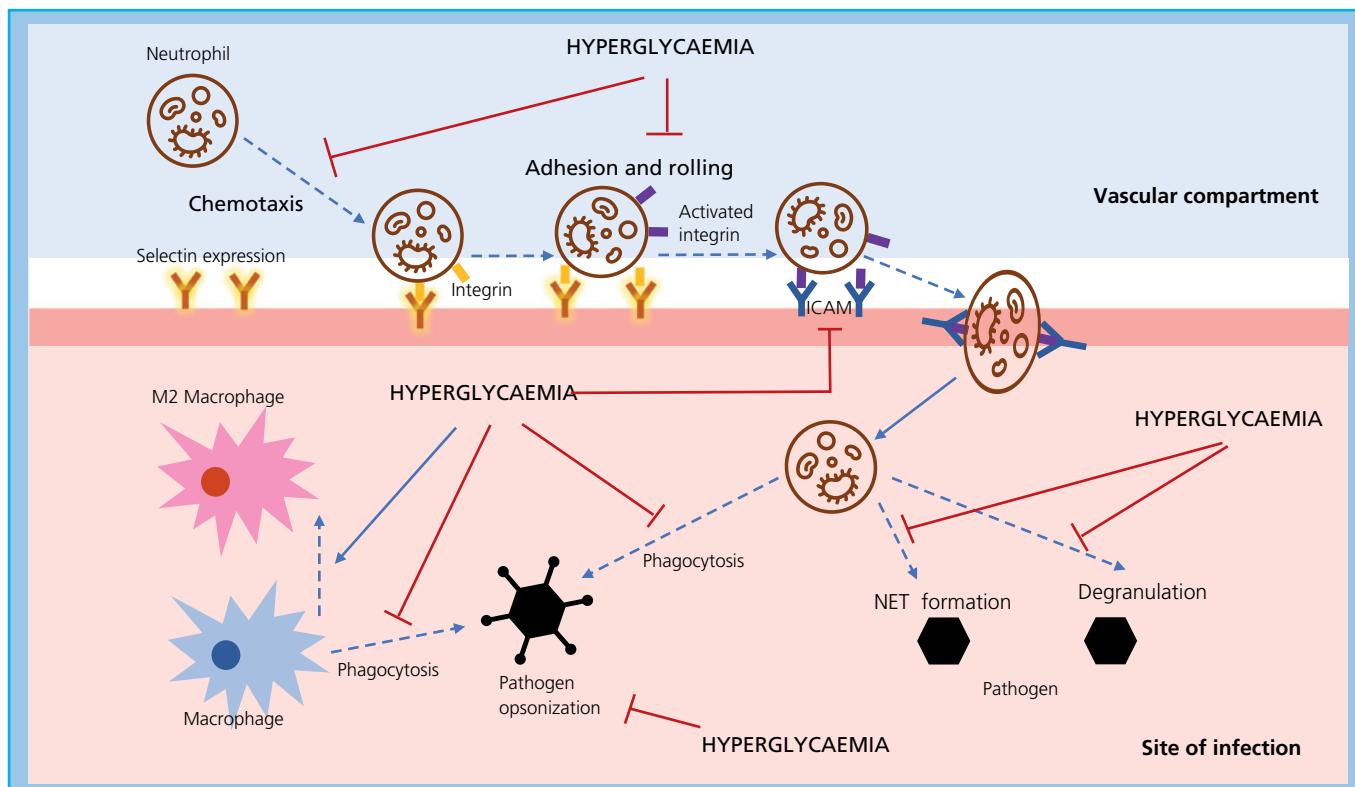

Figure 61.1 Impairment in immune response mechanisms during hyperglycaemia. Hyperglycaemia leads to impairment across a broad range of neutrophilic function, from chemotaxis, adhesion and rolling, to phagocytosis. Source: Modified by permission from Berbudi et al. 2020 [20].

factor (TNF) and interleukin 1 (IL-1) from lipopolysaccharide-stimulated macrophages is reduced in diabetic mice compared with control mice [29], study of monocytes from humans with diabetes indicates upregulation of the secretion of the same inflammatory mediators [30]. This further illustrates the difficulty of comparing studies conducted in different settings and species.

Some innate (e.g. cytokines, complement) immune functions are decreased while others remain unaffected. For example, while unstimulated cytokine concentrations may be higher, cytokine responses to stimuli are often reduced [21]. Interpretation of the complexity of the underlying mechanisms may also need to take into account potential underlying pro-inflammatory effects associated with diabetes itself. The level of macrophage inflammatory protein 2, a mediator of lung neutrophil recruitment, was significantly decreased in diabetic mice compared to control mice [31]. The deficiency causes a delay in neutrophil recruitment in the lungs. This may be one of the factors influencing the susceptibility of people with diabetes to infections of the lower respiratory tract.

Diabetic mice showed a >2-fold induction of genes that directly or indirectly induce apoptosis [32]. By contrast, blocking of apoptosis allowed for a significant improvement in wound healing and bone growth. This may influence many aspects of responses to infection, including impaired wound healing, which are important in the setting of diabetes.

These examples, while somewhat piecemeal, serve to demonstrate the range of abnormalities in the immune system that may result from hyperglycaemia. Of particular importance are those spanning macrophage, monocyte, and neutrophil function, which impair adherence to endothelium, chemotaxis, phagocytosis, and bactericidal activity. They also point to other abnormalities (e.g. involving apoptosis), wound healing, and cytokine responses to infection. The antioxidant systems involved in bactericidal activity may be compromised. These impairments, which are exacerbated by hyperglycaemia and acidosis, may be reversed substantially, if not entirely, by normalization of pH and blood glucose levels. However, the severity of effects correlates somewhat unpredictably with direct contemporaneous measures of glycaemic levels such as HbA_{1c}, perhaps reflecting longer-term or persistent changes such as accumulation of advanced glycation end-products (AGEs) [33]. A role for AGEs is postulated as a component in the pathogenesis of the impaired neutrophil function. In general, better regulation of the diabetes leads to an improvement of the cellular aspects of immune function, both innate and adaptive, despite variable correlations with HbA_{1c}.

Many questions remain as to the nature of the defects produced by diabetes, their effects on infection risk, and their exact relationship to both long- and short-term glycaemic levels, very much confounded by differences in experimental methodology.

Other host-related factors

Other host-specific factors, over and above impairment and disruption of immune defences, can further affect the predisposition to infection. These include peripheral artery disease, peripheral sensory neuropathy, autonomic neuropathy, and skin and mucosal colonization with pathogens such as *S. aureus* and *Candida* spp. Abnormalities of the structure and function of the microcirculation can also have additional indirect adverse effects on the immune responses themselves. Thus, immunological responses may be compromised by microangiopathy, and additional factors related to diabetes complications specifically increase the risks of

certain infections, especially those involving the foot and the urinary tract.

Obesity, which is commonly associated with diabetes, also increases the risk of certain infections. These include nosocomial infections, wound and surgical site infections, respiratory tract infections, and infections involving the gastrointestinal tract. The presence of obesity also correlates with infected diabetic foot ulcers in people with diabetes [34].

Diabetes-related complications

Peripheral artery disease contributes to the development and progression of the diabetic foot and the attendant complications of infection, ulceration, and gangrene. Vascular insufficiency results in local tissue ischaemia that can, in turn, enhance the growth of micro-aerophilic and anaerobic organisms, while simultaneously depressing the oxygen-dependent bactericidal functions of leucocytes. The antioxidant systems involved in bactericidal activity may be compromised by the combination of microvascular disease and metabolic derangement itself. Vascular insufficiency may also further impair the local inflammatory response and the tissue penetration of antibiotics.

Neuropathy, both peripheral and autonomic, also contributes to the risk of foot infections and ulceration, as well as to certain other infections. Peripheral sensory neuropathy masks the recognition of trauma. Minor local trauma in people with peripheral neuropathy may result in skin ulcers, which, in turn, can become infected. Skin lesions are often either unnoticed or ignored until infection occurs. Autonomic neuropathy contributes to the aetiology of foot infections by mechanisms such as decreased sweating, which predisposes to drying and fissuring of the skin, and by further exacerbating abnormalities in the control of the microcirculation. Both sensory and motor neuropathy can lead to deformity and alter the dynamics of the function of the foot. Fuller discussion of the aetiological factors related to sepsis and the diabetic foot is provided in Chapter 53.

People with diabetes-associated autonomic neuropathy may develop urinary retention and stasis in association with loss of innervation to the bladder. This predisposes them to urinary tract infections (UTIs). This risk is particularly high in women. Autonomic neuropathy can also affect the function of the gastrointestinal tract, predispose to certain gastrointestinal tract infections, and contribute to the risk of aspiration pneumonia in the context of gastroparesis. Renal papillary necrosis can contribute to the risk of renal failure as well as to infection within the urinary tract. People with a history of stroke are at a heightened risk of aspiration pneumonia. Chronic kidney disease as a complication of diabetes blunts the immune system and is an independent risk factor for infection.

Organism-specific factors

Certain organisms may show increased adherence to host cells [25] and others may demonstrate increased virulence in hyperglycaemic environments. Specific factors that predispose people with diabetes to infection with specific organisms include the following examples.

Candida albicans and fungi

Glucose-inducible proteins produced by *Candida albicans* are homologous to a complement receptor on phagocytes. These proteins may promote adhesion of *C. albicans* to buccal or vaginal epithelium. This adhesion, in turn, impairs phagocytosis, giving the organism an advantage over the host [25]. Ketone reductases produced by *Rhizopus* species allow these species to thrive in the high-glucose, acidic conditions typically present in diabetic ketoacidosis [35].

***Klebsiella* spp.**

A bacterial genus of note in the context of diabetes is *Klebsiella*. *Klebsiella* infections are the second most common causes of Gram-negative sepsis (after *Escherichia coli*). In a report from Taiwan, diabetes was the most commonly associated underlying condition in people presenting with community-acquired *Klebsiella pneumoniae* bacteraemia [36]. The percentage of individuals with underlying diabetes was 49%, which was higher than in earlier reports [37, 38]. Apart from the high proportion with diabetes, associations were also observed with serotype K1 (associated with impaired phagocytosis), liver abscess, and other metastatic complications (endophthalmitis, meningitis, brain abscess) [36]. Primary liver abscess due to *K. pneumoniae* in other parts of Asia is also increasing in incidence, with 40% reportedly associated with diabetes [39].

Melioidosis

A combination of organism-specific factors together with the changes in innate immunity may explain the increased susceptibility of people with diabetes to melioidosis. About 50% of cases of melioidosis occur in people with diabetes. The responsible organism, *Burkholderia pseudomallei*, is selectively resistant to phagocytosis in the presence of diabetes.

In a study from Thailand, where melioidosis is relatively common, neutrophil responses to *B. pseudomallei*, in people both with and without diabetes, showed that *B. pseudomallei* displayed reduced phagocytosis by neutrophils compared to *Salmonella enterica typhimurium* and *E. coli*. In addition, intracellular survival of *B. pseudomallei* was detected throughout a 24-hour period, indicating intrinsic resistance of *B. pseudomallei* to killing by neutrophils. Furthermore, neutrophils from people with diabetes displayed reduced migration in response to IL-8 and an inability to delay apoptosis. Thus, *B. pseudomallei* appears to be intrinsically resistant to phagocytosis and killing by neutrophils. When added to the impaired migration and apoptosis seen in diabetes, the combination seems sufficient to explain the increased susceptibility to melioidosis [40].

Bidirectionality: the effect of infections on diabetes

Bidirectionality exists in the relationship between diabetes and infections. The effect of infections on diabetes includes the effects of certain infections on the pathogenesis of diabetes itself, effects on blood glucose levels in people with pre-existing diabetes, and exacerbation of diabetes-related complications. Infections remain an important predisposing cause of both diabetic ketoacidosis and hyperosmolar hyperglycaemia syndrome. Therefore, a careful search for underlying infection is an important part of the clinical management of acute hyperglycaemic complications.

The importance of certain viral infections in the possible aetiology of diabetes has received increasing attention in recent years with respect to both type 1 diabetes and type 2 diabetes. Viral infections have been implicated in the aetiology of type 1 diabetes for many years. Although this complicated topic is beyond the general scope of this chapter and is considered in detail in Chapters 4 and 14, it is noteworthy that the incidence of autoimmune diabetes is increasing in some regions, providing strong evidence that environmental factors are involved in the clinical expression of the disease. Viruses have long been included in the list of putative environmental trig-

gers. Enteroviruses (especially Coxsackie B viruses), rubella, mumps, rotavirus, parvovirus, and cytomegalovirus have all been implicated and continue to be reported [41–43]. Although correlations between the presentation of diabetes and the occurrence of a preceding viral infection have been recognized, a direct causal relationship, with fulfilment of Koch postulates, remains difficult to prove, possibly because other inflammatory factors are also required. However, limited studies examining pancreatic biopsies of people with newly diagnosed type 1 diabetes have found enterovirus RNA in these specimens, strengthening the postulation that viral infection contributes to the development of type 1 diabetes [44]. In this context, the process may be associated with a dominant CD4 T-helper type 1 immune response, whereas the dominance of a T-helper type 2 response, as seen in the face of certain infectious and parasitic agents, may protect against type 1 diabetes and other autoimmune diseases. Lack of exposure to infection and infestation in early childhood appears to dilute the ability of the innate immune system to withstand autoimmune responses and challenges. Type 1 diabetes is not alone in this respect and the general concept has become known as the *hygiene hypothesis* [45]. The potential role of alterations in the gut microbiome is also receiving increasing attention and is discussed further in Chapter 19.

The high prevalence of type 2 diabetes in association with hepatitis C infection [46, 47] and the progression of certain diabetes complications, such as diabetic kidney disease, in association with hepatitis B infection are other noteworthy examples [48]. The treatment of human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) with protease inhibitors (PI) predisposes to diabetes, metabolic syndrome, and increased cardiovascular risk. Severe hyperglycaemia and higher than expected incidences of diabetic ketoacidosis among people with diabetes admitted with Covid-19 raise the possibility that severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) may impair β-cell function [49–51]. The public health implications of these issues are considerable given the concordance of the diabetes epidemic with these other highly prevalent diseases.

All infections, especially if severe, have the potential to exacerbate hyperglycaemia by several mechanisms. During these periods of physical stress, the release of counter-regulatory hormones and production of cytokines such as IL-1 and TNF will worsen insulin resistance [52]. Infection remains a major factor in the pathogenesis of diabetic ketoacidosis or hyperosmolar hyperglycaemia. Infections can precipitate hypoglycaemia if symptoms, such as anorexia, nausea, and vomiting, lead to reduced food intake. Malaria and its treatment with quinine can also induce hypoglycaemia.

Hepatitis C

Reports from North America, Europe, and the Middle East consistently demonstrate an increased prevalence of diabetes (ranging from 24% to 62%) among people with chronic hepatitis C virus (HCV) infection compared both with people with other forms of liver disease and with other control groups [46, 47, 53–57]. Older age, non-white ethnicity, and the presence of metabolic abnormalities are major risk factors for type 2 diabetes in people with HCV infection [58]. The social behaviour and lifestyle of people at risk for HCV infection (e.g. intravenous drug use) could also affect the risk of diabetes. The prevalence of type 1 diabetes appears to be unaffected [58].

The suggestion that HCV infection predisposes to type 2 diabetes as a result of progressive liver damage is supported by observations that the association is most marked in older age groups

(>40 years) and that there is a higher risk among those with advanced HCV cirrhosis. The higher prevalence of diabetes in comparison with that seen in other liver diseases suggests an additional mechanism specific to hepatitis C. For instance, HCV down-regulates insulin receptor substrate-1, which may contribute to insulin resistance directly. An insulin-resistant state may be further exacerbated by stimulation of proinflammatory cytokines such as TNF- α [59]. Eradication of HCV in infected individuals improves insulin sensitivity and lowers blood glucose levels [60]. In a study of people with type 2 diabetes who received direct-acting antiviral treatment for HCV infection, those who achieved a sustained virological response experienced a larger reduction in HbA_{1c} and decreased insulin requirement compared with the group who did not respond to treatment [60].

HCV infection is strongly associated with diabetes among intravenous drug users and this is independent of HIV infection or use of highly active antiretroviral therapy (HAART) [61]. Thus, it is important to monitor people with chronic HCV infection for the development of diabetes. Bidirectionality again applies with weight loss and optimal glycaemic management improving hepatitis outcomes.

HIV/AIDS

Both HIV and treatment of HIV with antiretroviral therapy predispose to type 2 diabetes, other metabolic risks, and premature cardiovascular disease [62–64]. In the Multicenter AIDS Cohort Study, men infected with HIV had a greater odds of insulin resistance than HIV-negative men, regardless of antiretroviral therapy exposure, and the incidence of diabetes was fourfold higher among HIV-infected men on antiretroviral therapy compared with uninfected men [65, 66]. In another study of over 6500 people with HIV infection, 123 developed diabetes over 28 000 person-years of follow-up, with a diabetes incidence rate of 4.4 cases per 1000 person-years [67]. An increased incidence rate ratio was found for men versus women, older age, obesity, and African American or Asian ethnicity. Strong associations were further observed with treatment using nucleoside reverse-transcriptase inhibitors (NRTI), NRTI/PI combination, and NRTI/PI/non-nucleoside reverse-transcriptase inhibitors (NNRTI) combination, but not with NRTI/NNRTI.

Diabetes and metabolic syndrome have become a major challenge in the management of this already very complicated infection [68, 69]. The effects occur via disturbances in lipid homeostasis and fat partitioning (lipodystrophy), insulin resistance, insulin secretion, and mitochondrial dysfunction. Insulin resistance is more important than impaired insulin secretion. Antiretroviral therapy for HIV-1 infection is frequently complicated by lipodystrophy (peripheral fat loss and relative visceral obesity), dyslipidaemia (high triglyceride and low high-density lipoprotein [HDL] cholesterol levels), and insulin resistance, especially with zidovudine, stavudine, and didanosine [70]. Adults infected with HIV receiving antiretroviral therapy have an increased incidence of hypertension as well as cardiovascular morbidity. Whether individuals who are naïve to antiretroviral therapy have an altered risk of subsequent cardiovascular disease or type 2 diabetes remains unclear, although insulin resistance has been reported among PI-naïve persons with HIV infection, in association with fat redistribution. People with HIV infection are more prone to hypothalamic dysfunction leading to hypogonadotropic hypogonadism and growth hormone deficiency, which predisposes to metabolic abnormalities. The key predictors of diabetes include long duration of HIV, weight gain, presence of metabolic-associated fatty liver disease, and hypertension [71].

Although the risk associated with antiretroviral therapy is greatest among individuals treated with PI attributed to a direct inhibitory effect on cellular glucose transport by PI medications, there is also an increased prevalence of diabetes among those receiving a PI-sparing regimen. Nucleoside analogue-induced mitochondrial toxicity is probably of importance. Cessation of PI appears to have little beneficial effect in reversing lipodystrophy, although it may improve the glucose levels in diabetes. Alteration of thymidine analogue nucleoside reverse transcriptase inhibitors may, however, confer benefit on lipodystrophy [72, 73]. Another study in people infected with HIV initiating antiretroviral therapy reported that higher levels of the inflammatory markers high-sensitivity C-reactive protein, soluble tumour necrosis factor receptor (sTNFR)-1, and sTNFR2 were associated with an increased risk for diabetes despite suppressive antiretroviral therapy. These data suggest that the inflammatory milieu of HIV infection may also contribute to the development of insulin resistance [74].

Lipodystrophy is a crucial aspect of the association of antiretroviral therapy with insulin resistance, leading to a relative preponderance of visceral fat, hepatic steatosis, and fat deposition at other *ectopic* sites, but loss of fat peripherally. It is of note that body mass index is not a reliable indicator of lipodystrophy. People with HIV infection and lipodystrophy, compared with those without lipodystrophy, have a reduction in plasma adiponectin and adipose tissue adiponectin mRNA levels of approximately 50%, correlating with insulin resistance and increased cytokine levels [69].

Given that baseline and incident metabolic syndrome identifies individuals at risk for both type 2 diabetes and cardiovascular disease, evaluation in all people commencing antiretroviral therapy is warranted. A fasting plasma glucose concentration should be checked before initiation of therapy and monitored every 3–6 months, especially in those receiving changes in treatment or who have significant risk factors for insulin resistance. An oral glucose tolerance test may be required, particularly in the presence of risk factors or equivocal glucose concentrations. Dietary guidelines established for the general population remain relevant for the management of glucose disorders in the context of HIV infection. Weight loss through increased activity and caloric restriction should be recommended for overweight individuals with HIV infection.

Metformin improves insulin sensitivity in people with HIV lipodystrophy and is an effective anti-diabetes medication; however, it should be used with caution in those receiving an NRTI (in particular zidovudine, didanosine, and stavudine), and in people with impaired renal function because of the possibility of lactic acidosis. The newer integrase strand transfer inhibitor dolutegravir will increase the level of metformin by decreasing renal clearance. Close monitoring is warranted and dosage adjustment of metformin may be needed. Thiazolidinediones (pioglitazone) may also improve insulin sensitivity in people with HIV lipodystrophy. Insulin therapy should be used according to standard recommendations. Substitution of an NNRTI for a PI improves insulin resistance, but this needs to be balanced against any risk to virus control. Careful discussion with HIV physicians is therefore essential and it may be deemed safer to increase the diabetes treatment rather than changing the components of the antiretroviral therapy [75–77].

Hepatitis B

Although, in contrast to HCV, hepatitis B virus (HBV) has been less consistently associated with an increased prevalence of diabetes, the presence of hepatitis B markers may nevertheless influence the

natural history of diabetes and its complications. The relationship may be bidirectional, as the presence of diabetes is associated with more severe fibrosis and cirrhosis. However, there is uncertainty as to cause and effect given the general association of diabetes with liver cirrhosis [78].

Chinese people with HBV infection and type 2 diabetes are more likely to develop end-stage kidney disease than non-HBV-infected people with type 2 diabetes (8.7% vs 6.4%), with a hazard ratio of 4.5 [48]. The association of chronic HBV infection with increased risk of end-stage kidney disease was independent of other potential confounding factors. People with HBV infection also reported earlier onset of diabetes and had a higher frequency of diabetic retinopathy than those without HBV infection (28% vs 22%). Cardiovascular complications appeared to be unaffected [48].

Specific infections either strongly associated with diabetes or in which the presence of diabetes is important

Infections involving the head and neck

Two head and neck infections that are associated with high rates of morbidity and mortality, malignant otitis externa and rhinocerebral mucormycosis, are particularly noteworthy in people with diabetes.

Malignant otitis externa

Malignant otitis externa is an invasive infection of the external auditory canal and skull base that typically arises in older people with diabetes. An early series was described in 1968 [79]. Most cases (86–90%) have been reported in people with diabetes. *Pseudomonas aeruginosa* is nearly always the causal organism (>98% of cases), although *Aspergillus* spp. or other fungi are occasionally responsible. Microangiopathy in the ear canal is a possible predisposing factor.

Presenting features include severe intractable headache and otalgia, otorrhoea, and deafness, often over a period of weeks to months. Intense cellulitis is combined with oedema of the ear canal. Focal neurological signs and cranial nerve palsies may occur. The pain may involve the temporomandibular joint and be aggravated by chewing. Osteomyelitis of the skull base and temporomandibular joint is a potentially life-threatening complication and the mortality in the pre-antibiotic era exceeded 50%. On otoscopy, granulation tissue may be seen in the floor of the ear canal, often in association with oedema and intense cellulitis. The tympanic membrane is usually intact. Computed tomography (CT) and magnetic resonance imaging (MRI) studies are essential for defining the extent of bone and soft tissue involvement, together with the bony destruction of the skull base that may be seen in advanced cases.

Systemic antipseudomonal antibiotics are the primary therapy. Early referral to an otorhinolaryngologist is essential and allows diagnostic confirmation by surgical biopsy. Debridement of necrotic tissue can also be carried out if necessary, although the introduction of effective antibiotic therapy has reduced the requirement for surgery. With the introduction of quinolones the cure rate has increased to 90%, with few adverse effects reported and oral therapy rendered possible. Prolonged treatment for 6–8 weeks is recommended, as for osteomyelitis [80]. Thus, treatment comprises prolonged administration (6–8 weeks) of an antipseudomonal agent (typically, an orally administered quinolone). The emergence

of ciprofloxacin resistance is a potential problem. It is recommended that systemic quinolone use be reserved for treatment of invasive ear infections caused by susceptible pathogens. For otitis externa caused by *Aspergillus* spp., treatment would include surgical debridement and treatment with voriconazole, posaconazole, or amphotericin B. An example of invasive aspergillosis involving the skull base is shown in Figure 61.2.

Mucormycosis (zygomycosis)

The term mucormycosis is used to describe a variety of infections caused by fungi of the *Rhizopus* and *Mucor* spp. that belong to the order Mucorales (class Zygomycetes). These fungi are ubiquitous saprophytes and infections produced by them are essentially confined to immunocompromised individuals. The fungi have a predilection to invade blood vessels. Ketone reductases produced by *Rhizopus* spp. allow them to thrive in high-glucose, acidic conditions, as are typically present in diabetic ketoacidosis [35]. Rhinocerebral, pulmonary, gastrointestinal, cutaneous, and disseminated forms of the infection are described. The rhinocerebral manifestation (and with sinus involvement) has the highest frequency and is potentially the most lethal in the context of people with diabetes.

The close connection with diabetes is becoming increasingly diluted as other causes of immunocompromise become increasingly common or survivable (notably haematological cancer and bone marrow transplant recipients). Nevertheless, diabetes remains the most common underlying factor in most reports. In a review of 49 cases of pulmonary mucormycosis, diabetes was the underlying cause of the immunocompromised state in 9 (25%) [81]. In another study, the prevalence of zygomycosis and related mortality in people with diabetes was 36% and 44%, respectively [82]. It typically, although not exclusively, occurs in association with ketoacidosis, severe hyperglycaemia, and/or a debilitated state.

Rhinocerebral mucormycosis is a life-threatening fungal infection. Untreated it is universally fatal; if recognized early there is a 20% survival rate. Presenting features include facial or ocular pain and nasal stuffiness. Generalized malaise and fever may also be present. Intranasal black eschars or necrotic turbinates may be found and, if present, provide sites that can be biopsied. Treatment comprises surgical debridement of the involved sinuses and prolonged intravenous therapy with amphotericin B or alternative antifungal agents such as some newer azoles.

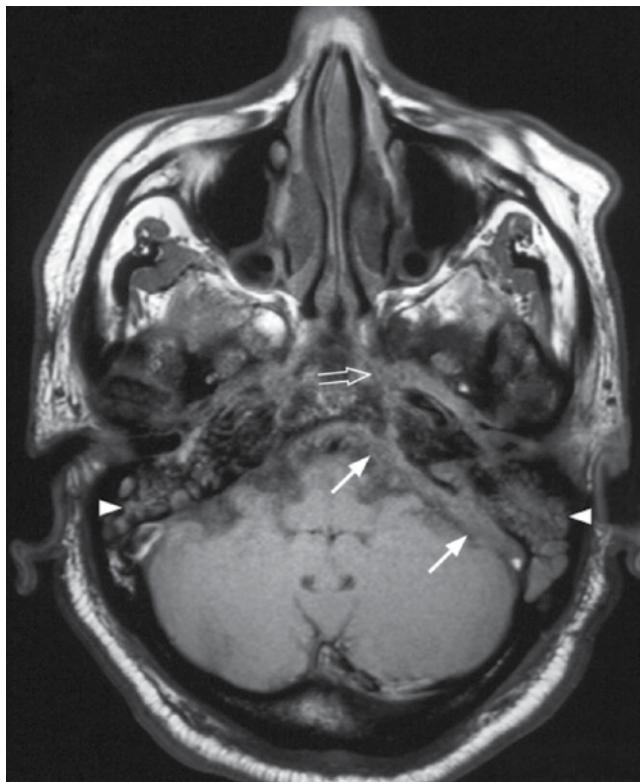

Acute invasive fungal sinusitis can also result from aspergillosis, as can malignant otitis externa. Biopsy is therefore useful to confirm the microbiological diagnosis [83].

Endophthalmitis

Secondary endophthalmitis may occur as a rare but devastating metastatic complication of septicæmia and in this setting is almost entirely confined to people with diabetes. Endophthalmitis can lead to acute vision loss and is therefore an ophthalmic emergency. Individuals typically present with progressive deterioration in visual acuity and eye pain. *E. coli* and *Klebsiella* are the more likely pathogens and UTI is reported as the most common underlying source of infection [84].

People with diabetes are also more prone to postoperative infections following eye surgery or infections secondary to eye trauma. Overall, the most common cause of endophthalmitis is as a postoperative complication of cataract surgery [85], a procedure commonly carried out in people with diabetes.

(b)

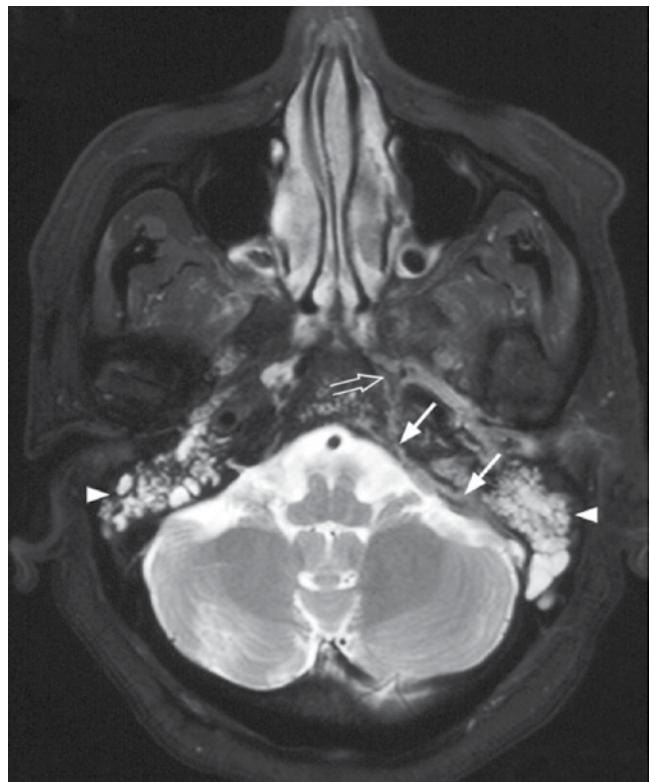

Figure 61.2 Magnetic resonance imaging (MRI) scan of skull base in a 59-year-old man with a 20-year history of diabetes (with nephropathy), treated with insulin, who developed severe extensive invasive aspergillosis. He presented with headache and vertigo followed by left sixth and seventh nerve palsies. He subsequently developed bilateral sensorineural hearing impairment and blindness secondary to extensive skull base infiltration by the invasive aspergillosis. MRI demonstrated enhancing soft tissue closely related to the left posterolateral wall of the nasopharynx with parapharyngeal, skull base, perineural, and dural infiltration. Biopsy showed inflamed fibrous tissue with degenerated fungal filaments.

Culture confirmed *Aspergillus flavus*. He is receiving lifelong therapy with voriconazole. He remains blind. MRI of skull base in the axial plane with (a) T1-weighted and (b) post-gadolinium T1-weighted sequences. These show marked dural thickening (arrows) with enhancement in the left posterior cranial fossa. An abnormal signal with enhancement is also noted in the adjacent left petrous apex (open arrow). Note also the presence of inflammatory fluid within both mastoid air cells (arrowheads). Source: Courtesy of Dr K.T. Wong and Professor A. Ahuja, Department of Diagnostic Radiology and Organ Imaging, the Prince of Wales Hospital, the Chinese University of Hong Kong, Hong Kong.

Periodontal disease

People with diabetes are very prone to periodontal disease compared to the general population, with a 2–4-fold relative increase in prevalence and a particular predilection for those with elevated glucose levels.

The associated periodontitis, if left untreated, can result in loss of attachment of ligament fibres and supporting alveolar bone, which in turn can increase the mobility of teeth and necessitate extraction. Tooth abscesses and episodes of bacteraemia also become more likely. Diabetes may complicate the pathogenesis of periodontitis by causing abnormalities in the vasculature of the gingival tissues, in addition to the effects on immune responses described earlier. Aggressive and difficult-to-treat forms of periodontitis are also more common in adults with diabetes. Periodontal health is influenced by glycaemic levels to the extent that the prevalence of periodontal diseases among people with optimal glycaemia is not increased [86]. A bidirectional relationship has also been suggested whereby the presence of periodontal disease adds to the overall burden of chronic inflammation, thereby adversely affecting glycaemic levels as well as overall risk of cardiovascular disease and diabetic nephropathy [87]. Further details of periodontal disease are covered in Chapter 56.

Respiratory tract infections, coronavirus, and tuberculosis

The increased risk of mortality and morbidity from community-acquired pneumonia has been described earlier and includes pneumonia either directly resulting from, or secondary to, common infections such as influenza and *Streptococcus pneumoniae*, as well as *Legionella* infections [88]. The risk of bacteraemia following pneumococcal infection is increased [89]. Viral shedding may be more prolonged following influenza infections in people with comorbidities including diabetes, which may influence decisions regarding initiation and duration of antiviral therapy [90].

Lower respiratory tract infections, resulting from *S. aureus* and Gram-negative organisms such as *K. pneumoniae*, are more common in people with diabetes. Melioidosis has also been discussed earlier as an example of organism-specific factors that interact with diabetes to increase the risk of infection. People with diabetes are at increased risk for *S. aureus* pneumonia and this may result from higher rates of nasal carriage of *S. aureus* in people with diabetes (up to 30%) compared to healthy individuals (11%) [91]. The importance of diabetes as the most common underlying predisposing factor for thoracic empyema has also long been recognized. *Klebsiella* spp. are again notable as the most common pathogens,

while other important pathogens include streptococci, *S. aureus*, and anaerobes [92].

Respiratory infection in people with diabetes is associated with increased mortality. In the USA, people with diabetes are reportedly fourfold more likely to die from pneumonia or influenza than people without diabetes [93]. Pneumonia and influenza significantly increase the risks of acute cardiovascular events including acute myocardial infarction, and the increases in susceptibility are sustained for months after the initial infective episode [94]. Given that people with diabetes are themselves at a heightened risk of cardiovascular disease, superimposing infections are potentially detrimental.

Diabetes and coronaviruses

Covid-19 caused by SARS-CoV-2 first emerged in December 2019 and rapidly evolved into a global pandemic [95]. This medical catastrophe overwhelmed healthcare facilities worldwide. Social containment measures and travel bans caused significant disruption to daily living and the economy. Similar to severe respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV), SARS-CoV-2 is a RNA virus and originated from animals. Clinical presentation ranges from no or mild symptoms of the respiratory and gastrointestinal tracts, to acute respiratory distress syndrome, multiorgan failure, and death [96, 97].

Diabetes was previously reported to be an important predictor of severe disease and death in people infected with SARS-CoV and MERS-CoV [14–16]. Observational studies from China, the USA, and other countries indicated that diabetes was associated with adverse outcome and mortality from Covid-19 [12, 13], although it remains unknown whether diabetes increases the opportunity of acquiring the viral infection, as high-quality data related to the diabetes status of people with Covid-19 managed in the community are not available. Among cohorts of people hospitalized with Covid-19, the prevalence of diabetes ranged between 7% and 24%, which overlapped with diabetes prevalence among the general population [95, 98]. However, diabetes was present in between 13% and 58% of people who required admission to intensive care units, and between 17% and 35% of people who succumbed had pre-existing diabetes [99–102]. Overall diabetes was associated with a 2–3-fold hazard of mortality related to Covid-19 [12, 13].

Several mechanisms may explain the worse prognosis from Covid-19 in people with diabetes. People with diabetes have a dysregulated inflammatory response to infection with SARS-CoV-2. Compared with infected counterparts without diabetes, those with diabetes had higher levels of pro-inflammatory biomarkers, including C-reactive protein, IL-2 receptor, IL-6, IL-8, TNF- α , and proc-alcitonin [103, 104]. The exaggerated inflammatory response facilitates the development of cytokine storm, severe pulmonary damage, and multiorgan failure. Furthermore, endothelial dysfunction and prothrombotic state in diabetes might contribute to disseminated intravascular coagulation, which may be the terminal event in Covid-19. The coexistence of obesity in people with diabetes further exacerbates severe progression [105]. Obesity predisposes to altered ventilatory mechanics and function, such as reduced lung compliance and apnoea.

The overexpression of angiotensin-converting enzyme 2 (ACE2) in people with diabetes has been implicated in their propensity for Covid-19 and SARS [106]. ACE2 is an aminopeptidase expressed in the respiratory tract and other organs. ACE2 on the alveolar cells is the primary receptor for both SARS-CoV and SARS-CoV-2, and

increased ACE2 expression may potentiate viral entry [107]. However, ACE2 counters the pro-inflammatory and vasoconstrictive action of angiotensin II by converting angiotensin II into angiotensin [1–7], the latter having an antioxidant function. The use of renin–angiotensin–aldosterone system (RAAS) inhibitors, which augment ACE2 levels, lowers the risk of pneumonia in people with or without diabetes [108]. In the context of Covid-19, available research indicates a neutral effects of RAAS inhibitors on mortality or critical outcome [109–111].

ACE2 is also present on pancreatic β cells and it is possible that these viral infections can induce diabetes by direct damage to the pancreatic endocrine tissues. Based on clinical reports, insulin requirement in people with Covid-19 was disproportionately high to the level of physiological stress when compared with other critical infections or acute medical illnesses [49–51]. Several groups also reported a high frequency of diabetic ketoacidosis among hospitalized people with Covid-19, suggesting virus-induced acute insulinopaenia and metabolic decompensation [49]. Other explanations for the severe hyperglycaemia include lapses in glucose-lowering medications during city lockdown and quarantines, and the use of high-dose corticosteroid as part of Covid-19 management. Some but not all studies found increased incidence of diabetes post-Covid-19. In a study conducted in the USA, people who previously had Covid-19 had a 1.5-fold higher risk of receiving a diagnosis of diabetes over a one-year observation, and the excess risks were similar across age groups, BMI, and diabetes risk scores [112]. In another population-based study conducted in Germany, exposure to SARS-CoV-2 was associated with a 28% increased risk of type 2 diabetes compared to exposure to non-Covid-19 respiratory tract infections [113]. In contrast, longitudinal follow-up of people discharged after Covid-19 in England did not find an increase in diabetes incidence versus admission for non-Covid-19 pneumonia [114]. Whether or not Covid-19 can induce diabetes remains unclear and further work is needed to understand the virus's long-term metabolic impact.

Data are conflicting regarding the effect of glycaemic levels on the risk of coronavirus infection and outcome. There was a positive association between HbA_{1c} before hospitalization and mortality from Covid-19 in some but not all studies [13, 115]. However, high blood glucose on admission was most consistently predictive of severe disease, irrespective of diabetes status. A small study comparing insulin infusion versus no insulin infusion in people with in-hospital hyperglycaemia showed that insulin treatment reduced inflammatory and coagulation indices and improved outcome [116]. Limited evidence also indicated that in-hospital use of dipeptidyl peptidase 4 inhibitors lowers fatality [117].

Diabetes and tuberculosis

An association between diabetes and tuberculosis has been widely accepted in the past, and solid epidemiological evidence has emerged in the last decade to establish firmly a close link. Systemic reviews have confirmed that people with diabetes are approximately threefold more likely to develop active tuberculosis than people without diabetes, albeit with varying estimates of overall risk (ranging from 2- to 11-fold) [118, 119].

The importance of the association is often neglected in the larger arena of public health, for example when compared with the risk of tuberculosis associated with HIV. The increase in risk appears consistent across geographical regions, regardless of both study design and background incidence of tuberculosis. It appears greatest among younger people in areas of high tuberculosis incidence and

in non-North American populations [118]. The public health impact may be particularly high in low- or middle-income countries or areas that are at the forefront of the diabetes epidemic and where tuberculosis remains endemic [119–121], and may therefore be particularly high in countries such as China and India. In Hong Kong, the risk differential for tuberculosis between people with and without diabetes has remained unchanged over a 10-year period [3]. Moreover, the excess risk for tuberculosis was two- to threefold for middle-aged people with diabetes, but climbed to sevenfold for those aged 20 and 44 years.

The impact of the diabetes epidemic on tuberculosis incidence in India has been previously modelled [122]. Diabetes accounted for 15% of pulmonary tuberculosis and 20% of smear-positive tuberculosis, with an excess risk of the latter in urban areas. This can be compared to an overall estimate of 3.4% for the proportion of adult tuberculosis incidence ascribed to HIV/AIDS in India [123]. Given the vast number of people living with diabetes, the impact of diabetes on tuberculosis incidence will be immense at a population level.

The association of tuberculosis with diabetes reflects impaired innate immunity as well as a reduced adaptive T-helper type 1 response, with reduced secretion of T-helper type 1-related cytokines, thereby increasing the risk of progression from tuberculosis infection to active disease as well as increasing the risk of latent tuberculosis following initial primary infection. Regarding the clinical presentation, extrapulmonary or unusual manifestations of tuberculosis are more common in the context of diabetes. People with tuberculosis and diabetes are more likely to develop opacities over the lower lung fields, extensive parenchymal lesions, any cavity, multiple cavities, and large cavities compared to those

without diabetes, and these radiological abnormalities are more common in the presence of suboptimal glycaemic levels [124, 125].

In addition to the increased risk of tuberculosis, people with diabetes are at increased risk of worse outcomes, including treatment failure, relapse, and mortality [126]. People with diabetes are more likely to remain smear positive after 2–3 months of treatment, as shown in six of nine studies evaluating sputum conversion [126]. A study from Indonesia indicated a doubling of the risk of remaining smear positive at the end of treatment [127]. The same group has also shown that the presence of type 2 diabetes may adversely affect the bioavailability of rifampicin and lead to an increase in dose requirement [128]. A study from Brazil found that those with tuberculosis and diabetes had poorer treatment outcomes even after adjusting for confounding factors [129].

One of the options to improve treatment outcomes might be to extend the period of treatment. In Hong Kong, an area with much pioneering experience of tuberculosis treatment since the 1950s, the Centre for Health Protection recognizes the risk of a worse outcome, and its guidelines recommend a more prolonged period of treatment for people with diabetes compared to those without. For example, when treating pulmonary tuberculosis using a standard regimen of four drugs for the first two months followed by two drugs, a total treatment duration of nine months, rather than six months, is recommended. Two examples of individuals with tuberculosis in association with diabetes are shown in Figure 61.3. It is perhaps noteworthy that neither was receiving regular follow-up care for the diabetes.

Bidirectionality again needs to be considered, because the presence of tuberculosis is likely to worsen hyperglycaemia. Tuberculosis, as

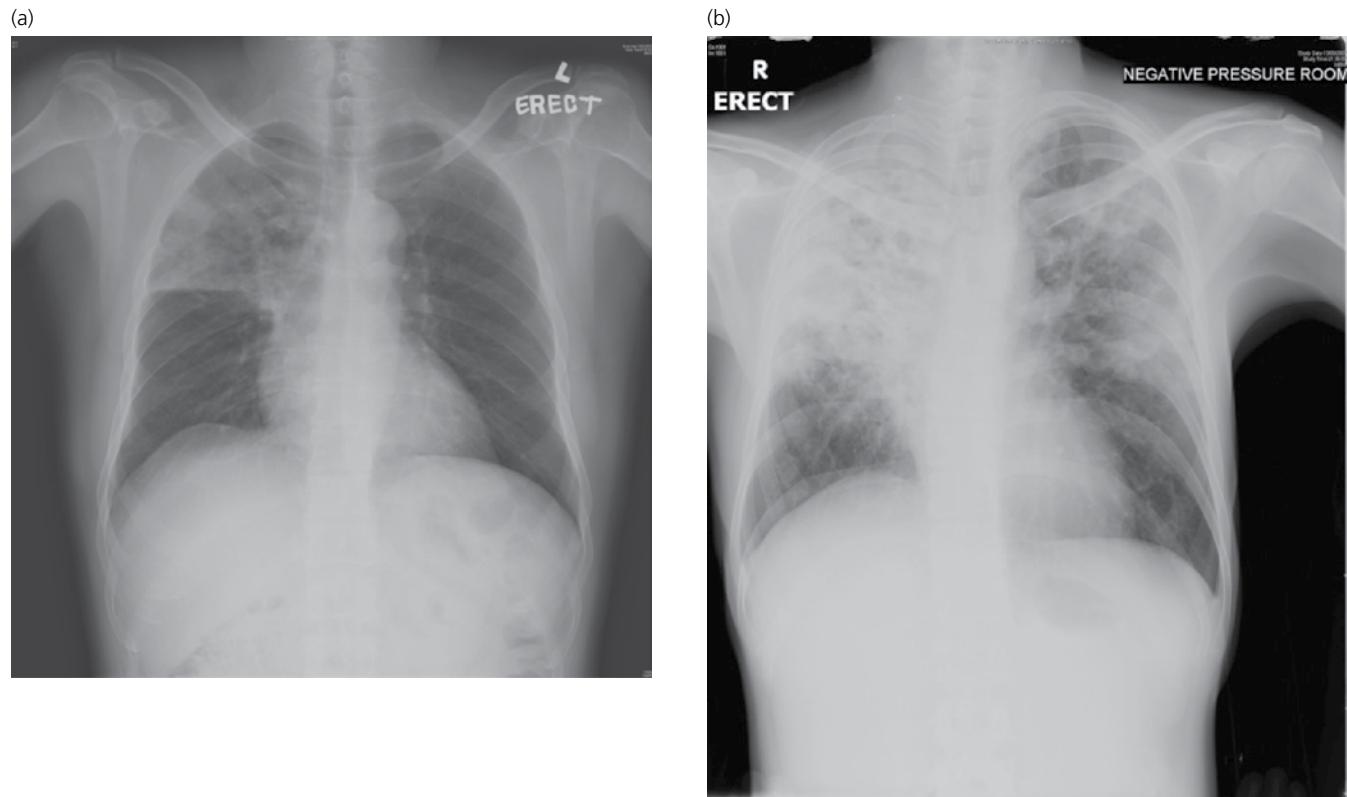

Figure 61.3 (a) A 49-year-old man with diabetes and obesity, not receiving regular follow-up, and presenting with haemoptysis and sputum smear positive for tuberculosis. Chest X-ray shows extensive right upper lobe pneumonic changes. (b) A 30-year-old man with diabetes but no regular follow-up presenting with a cough for four months with weight loss, and sputum smear positive for tuberculosis. Chest X-ray shows extensive bilateral and cavitatory disease.

with other infectious diseases, can lead to deterioration of glycaemic levels and complicate the management of diabetes. Unpredictable effects on glycaemic levels may result from alterations in inflammatory processes, changes in appetite and body weight, and, importantly, drug–drug interactions. In this connection, acute deterioration of glycaemic levels without other obvious explanations should prompt investigation for occult infections such as tuberculosis, especially in areas of high prevalence. Rifampicin, the most important drug, increases the hepatic metabolism of sulphonylurea drugs, although with large inter-individual variation. It may also lead to an enhanced glucose-lowering effect of metformin [130]. Some national treatment guidelines (e.g. in Indonesia) strongly recommend the use of insulin therapy, since insulin has no direct pharmacokinetic interactions with rifampicin or other anti-tuberculous agents. Thus, people with concurrent diabetes and tuberculosis may have specific needs during treatment, including close monitoring of glycaemic levels and renal and hepatic function, as well as counselling and education. There is a strong case to be made for integrated care linked with service and policy development [130]. The issue of screening is pertinent, both for diabetes in people with tuberculosis and for tuberculosis in people with diabetes.

Diabetes and influenza

Influenza is responsible for half a million deaths globally every year, and older people and those with chronic diseases are at particularly high risk of death from influenza. In an earlier study conducted in the working population in the USA, prevalent diabetes increased the odds of death from influenza or pneumonia fourfold [93]. In a large multinational study of people hospitalized with influenza, the odds of severe disease, defined as the requirement for mechanical ventilation, admission to the intensive care unit, or in-hospital death, increased 3.9-fold in those with concurrent diabetes aged 15–50 years, although no disparity was detected between older individuals with and without diabetes [131]. In addition to causing respiratory distress, influenza also increases the risk of acute coronary events. The reasons are multifactorial, related to systemic inflammation causing activation of inflammatory cells in atherosclerotic plaques, a prothrombotic state triggering coronary thrombosis, and increased metabolic demand causing cardiac decompensation.

Annual vaccination against seasonal influenza is recommended for people with diabetes. There were concerns on whether seroprotection may be suboptimal in people with diabetes, but available studies showed no differences in immune responses to influenza vaccination between people with and without diabetes [132]. Studies on vaccine effectiveness were mostly observational in nature, with inherent limitation of residual confounding. For instance, people who received vaccination were more likely to engage in health-seeking behaviours, which could biased towards favourable health outcomes. Nonetheless, several studies have reported protection against influenza- and pneumonia-related hospitalization and all-cause hospitalization [133]. Using population-level data from a Danish diabetes registry, people who have received vaccination for seasonal influenza had a 17% lower risk of all-cause death and a 16% lower risk of cardiovascular death, adjusted for sociodemographics and comorbidities [134]. Despite these benefits, vaccine coverage varies considerably across countries. Generally, high-income countries with established guidelines and influenza vaccination programmes have higher coverage than middle- or low-income countries. Ongoing efforts are required to increase awareness among healthcare professionals and the public to reduce the burden of vaccine-preventable diseases.

Infections of the urinary tract

Epidemiology

Urinary tract infections are frequently encountered in people with diabetes. Asymptomatic bacteriuria also occurs with a higher frequency [135]. One study has demonstrated a prevalence rate for asymptomatic bacteriuria of 26% in women with diabetes, compared to 6% in women without diabetes [136, 137]. An increased prevalence of asymptomatic vaginal *E. coli* colonization has also been reported in postmenopausal women receiving insulin treatment. This colonization may be mediated by greater adherence of type 1 fimbriated *E. coli* to uroepithelial cells in women with diabetes, may be related to impaired cytokine secretion, or may reflect a reduced polymorphonuclear inflammatory response [136, 138]. A randomized controlled trial of antibiotic treatment for asymptomatic bacteriuria revealed no differences in the development of symptomatic UTI, time to onset of symptoms, risk of pyelonephritis, or need for hospitalization [136]. On this basis, diabetes does not warrant either screening for or treating asymptomatic bacteriuria. However, this remains a controversial issue and, from the practical standpoint, ascertaining *asymptomatic status* with confidence, particularly in older women with diabetes, can be difficult.

Studies confirm the increased risk of symptomatic UTI in association with diabetes. In one study of more than 600 women, those with type 2 diabetes had an overall risk of 20% [139]. A recent study has extended the risk to include recurrence rates as well as risk to men [140]. Diabetes also increases the risk of complications of UTI, serious or unusual forms of infection, and need for prolonged hospitalization [141]. It is a risk factor for acute pyelonephritis in women and is the strongest of the various risk factors examined. Among hospitalized individuals, 16.7% reported having diabetes compared with 5.8% of non-hospitalized people [136].

Diabetic autonomic neuropathy is an important predisposing factor to UTI. This affects the sympathetic and parasympathetic afferent fibres to the bladder and causes decreased reflex detrusor activity. Impaired bladder sensation results in bladder distension, increased residual urine volume, vesicoureteric reflux, and recurrent upper UTI [142, 143]. Some cases are related to urinary catheterization or instrumentation [136, 142, 143]. Additional factors predisposing to UTI include glycosuria, sexual intercourse, a history of previous UTI, obstruction, longer duration of diabetes, hyperglycaemia, decreased urinary cytokine excretion, increased *E. coli* adhesion, macroalbuminuria, and neutrophil dysfunction [142, 143]. Renal papillary necrosis and chronic renal failure also contribute to the complex array of risk to the urinary tract. Lastly, the use of sodium–glucose cotransporter 2 (SGLT-2) inhibitors is associated with increased risk of genital tract infections but not urinary tract infections [144].

Microbiology

E. coli is the most commonly reported organism. *Klebsiella* is also a problem, especially among individuals with uncommon severe forms of UTI, such as emphysematous pyelonephritis. Other organisms include *Acinetobacter* spp., group B streptococci, and *P. aeruginosa* [135]. The latter should be suspected particularly if there is a history of recent instrumentation or hospitalization.

C. albicans in the urine can be associated with incomplete bladder emptying and high glucose concentrations in the urine. Diabetes is present in 39% of hospitalized individuals with funguria [135]. Candiduria may signify contamination of the urine specimen, benign saprophytic colonization (\pm catheter), or be indicative of true invasive infection of the upper and/or lower urinary tract [145].

Diabetes is a risk factor for multidrug-resistant UTI, perhaps related to recurrent or increased exposure to antibiotics [146].

Clinical features of urinary tract infection in diabetes

Uncomplicated UTIs may be asymptomatic. Symptoms, when present, are generally similar to those experienced by people without diabetes. Infection of the lower urinary tract usually presents as dysuria, frequency, or urgency. Fever, flank pain, chills and rigours, vomiting, and costovertebral angle tenderness raise the suspicion of upper tract infection with renal involvement. Bilateral renal involvement is also more frequent and bilateral pyelonephritis is twice as common in people with diabetes. Bacteraemia may be present.

A poor response to appropriate antibiotic therapy should raise the suspicion of the presence of complications. These may include renal papillary necrosis and perinephric abscess. The symptoms of renal papillary necrosis include flank and abdominal pain (which mimic both pyelonephritis and ureteric colic), together with fever. Renal impairment is commonly found. Features such as a persisting high fever despite antibiotic treatment, hypotension or septicaemia shock, and a palpable tender renal mass may point to the presence of a perinephric abscess. In one series of people with perinephric abscess, 36% had diabetes [147].

Emphysematous cystitis and emphysematous pyelonephritis

Although these infections are uncommon, their severity warrants their special consideration. Emphysematous cystitis is an uncommon complication of lower UTI characterized by the presence of gas in the bladder wall (Figure 61.4). It presents with haematuria, pneumaturia, and abdominal pain. Plain abdominal radiography or CT scan is indicated to detect the presence of gas. Surgical intervention may be required in up to 20% of cases and mortality is reportedly up to 10%. Emphysematous cystitis requires aggressive treatment in hospital and intravenous antibiotic therapy [149].

Emphysematous pyelonephritis is an infection that is almost exclusively limited to people with diabetes, who account for 90% of cases (Figure 61.5). It predominantly occurs in women and carries a grave prognosis [151]. It is a necrotizing infection of the renal parenchyma and surrounding areas that can be focal or diffuse and may spread to the collecting system or perinephric tissues. The formation and presence of gas in the renal parenchyma, collecting system, or perinephric area may be contributed to by fermentation of glucose, when present at high concentrations, by the presence of gas-forming organisms, and by impaired renal perfusion. Mixed acid fermentation of glucose by *Enterobacteriaceae* has been suggested as a major pathway of gas formation [152].

A lengthy list of pathogens has been reported; however, as with other UTIs in the context of diabetes, the most common pathogens are *E. coli* (in 70%) and *Klebsiella* (in 30%). Vascularopathy of the renal circulation is a major factor in the pathogenesis, once again emphasizing the importance of vascular disease in the clinical manifestation of the more severe forms of infection related to diabetes. Presenting features include fever, abdominal pain, nausea and vomiting, and drowsiness or stupor. As a result of these non-specific symptoms, the diagnosis is often delayed. The presence of features such as renal angle tenderness, pyuria, or pneumaturia should lead to a high index of suspicion. A flank mass may be detected, often accompanied by crepitus. Disseminated intravascular coagulation, septicaemic shock, and acute renal failure are all associated with a poor prognosis.

The diagnosis is established by radiological identification of gas in renal tissue. Ultrasonography can also be used, but CT should be

Figure 61.4 Example of emphysematous cystitis in a 67-year-old woman with diabetes and end-stage kidney disease requiring haemodialysis. She developed septic shock with lower abdominal tenderness. Blood and urine cultures showed *Escherichia coli*. Computed tomography scan shows air pockets inside the urinary bladder (arrows). Source: Sun et al. 2009 [148]. regarded as the investigation of choice. The plain abdominal X-ray sensitivity is lower. In a report of 46 cases in Taiwan, 96% had diabetes with HbA_{1c} higher than 8% (64 mmol/mol), and 22% also had features of obstruction [153]. Mortality can exceed 50% in people treated only with antibiotics. Medical therapy alone is therefore not recommended. People with diabetes may require percutaneous drainage (for localized cases with abscess formation or obstruction) or nephrectomy (in extensive cases). The advent of CT has allowed a more rational approach to the use of these surgical interventions, by allowing more accurate delineation of factors such as gas distribution, obstruction, and abscess formation [154].

Treatment of urinary tract infection

Treatment should be tailored to take account of local antibiotic resistance patterns (if known), as well as previous history of UTI, previous antibiotic exposure (and possible allergies), together with other risk factors such as recent instrumentation or catheterization. Uncomplicated UTI may be treated with co-trimoxazole (if the local resistance rate is <15% to 20%), fluoroquinolones, nitrofurantoin, ampicillin, amoxicillin ± clavulanate, or sulbactam. Increasing

resistance to fluoroquinolones has been noted recently. Co-trimoxazole may potentiate the hypoglycaemic effect of some anti-diabetes drugs and should be used with caution.

Complicated infections require hospitalization and parenteral antibiotics. Intravenous therapy is continued until fever resolves, following which oral antibiotics can be substituted to complete at least two weeks of treatment. Second- or third-generation cephalosporins, β -lactam/ β -lactamase inhibitor combinations, or fluoroquinolones may need to be considered in individuals with risk factors. The possibility of infection with *Pseudomonas* may influence this choice, particularly in the setting of nosocomial exposure or recent instrumentation.

Upper urinary tract involvement with UTI may be up to fivefold more frequent in people with diabetes compared with people without diabetes and may be unsuspected or asymptomatic. More prolonged courses of antibiotics (7–14 days) may be considered wise even in the context of apparently uncomplicated UTI. This may also reduce the risk of subsequent relapse. Repeated urine culture to document bacteriological cure 2–4 weeks post-treatment is advisable given high rates of relapse or treatment failure.

Distinguishing *Candida* infection from colonization is difficult. Removal of an indwelling catheter, if present, is recommended as an initial intervention. Antifungal agents such as fluconazole may be considered in people with invasive disease.

Intra-abdominal infections other than those within the urinary tract

The potential for interaction between diabetes and various infections of the gastrointestinal tract is considerable and a few examples are considered here. In this context, although the presence of increased risk of *Helicobacter pylori* infection in people with diabetes remains controversial, the presence of diabetes may, in turn,

reduce the effectiveness of antibiotic regimens aimed at eradicating the infection. The presence of gastritis may also influence the endocrine functions of the gut, as well as the absorption and handling of oral anti-diabetes drugs such as metformin.

Emphysematous cholecystitis

Cholecystitis is probably no more common in people with diabetes than in the general population. However, severe fulminating infection, especially with gas-forming organisms (enteric Gram-negative rods and anaerobes), is more common. An association between gallbladder stones and the use of glucagon-like peptide-1 receptor agonists has been reported [155]. Given the increasing use of this drug class in people with diabetes, a rising trend in the incidence of cholecystitis or other gallstone-related diseases may be anticipated.

Emphysematous cholecystitis is a rare variant of acute cholecystitis caused by ischaemia of the gallbladder wall and infection with gas-producing organisms. It is strongly associated with diabetes (35–55% of cases have underlying diabetes) [156]. Gangrene and perforation of the gallbladder are more frequent, and the overall mortality is substantially higher (at least 15% compared to less than 4%) in individuals with emphysematous cholecystitis when compared with those with acute cholecystitis. *Clostridium perfringens*, *E. coli*, and *Bacillus fragilis* are the most frequently encountered pathogens. Emphysematous cholecystitis results from acalculous cystic duct obstruction, associated with inflammatory oedema, which can eventually lead to cystic artery occlusion. Colonization by gas-forming organisms contributes to necrosis of the mucosa, venous congestion, gangrene, and eventually gallbladder perforation. Gallstones are present in only about half of the individuals.

The early clinical manifestations may be indistinguishable from those of acute cholecystitis. Right hypochondrial pain and fever are present in all cases, and other important features include nausea and vomiting, septic shock, jaundice, and peritonitis. Toxicity is marked, and jaundice may develop in the later stages from biliary obstruction. The gallbladder may be palpable in 25–50% of individuals. It should be remembered that Murphy's sign (pain and inspiratory arrest on palpation of the right upper quadrant) might be absent in people with underlying diabetic neuropathy. Crepitus on palpation is an ominous sign. Additional complications include pericholecystic abscess, gallbladder necrosis, generalized or biliary peritonitis, and localized perforation sealed by the omentum.

Plain abdominal X-ray or ultrasound can lead to diagnosis in 95% of cases. In a plain radiograph, gas may be visible in the gallbladder lumen or within the gallbladder wall as a gaseous ring. Abdominal CT is the most sensitive modality for the detection of intraluminal or intramural gallbladder gas and also demonstrates local complications such as pericholecystic inflammatory changes, abscess formation, or perforation. Initiation of appropriate antibiotics and early cholecystectomy are crucial. Emergency surgery is needed because of the high incidence of gangrene and perforation [157, 158].

Liver and other intra-abdominal abscesses

Although liver abscesses may occur in many situations not involving diabetes, the issue is of sufficient importance to justify inclusion in this section. In keeping with the susceptibility to *Klebsiella* infections described earlier, associations between diabetes and *K. pneumoniae* liver abscess have been reported, notably from Taiwan and Korea [159–161]. In Korea, invasive liver abscess is particularly associated both with *K. pneumoniae* (78% of the total, 40% of whom have diabetes) and with the K1 serotype (60%) [39]. Examples from Hong Kong are shown in Figure 61.6.

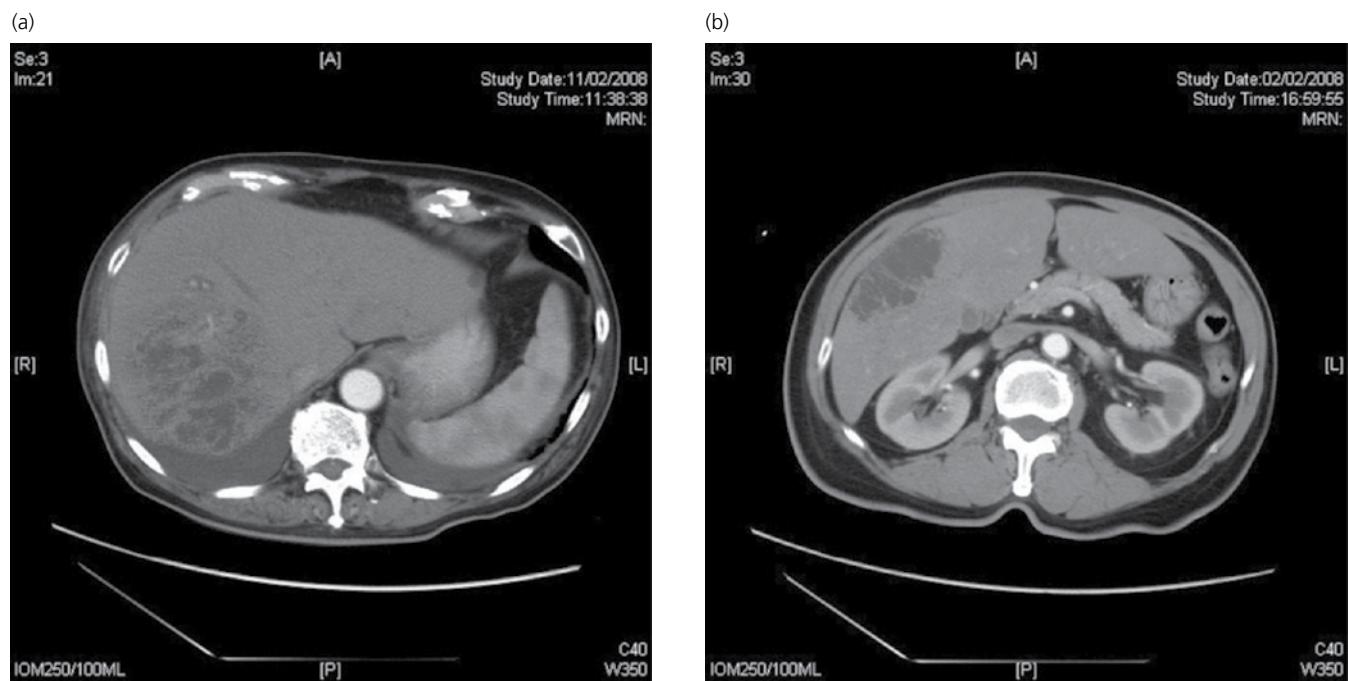

Figure 61.6 (a) Computed tomography (CT) scan of an 82-year-old man with fever and newly diagnosed diabetes. Blood culture grew *K. pneumoniae*. The scan shows an 8 × 8.2 cm heterogeneous lesion in the right lobe of the liver composed of multiple rim-enhancing lesions, with septation and hypodense cystic components. A further three smaller similar lesions (1–2.5 cm) were seen inferiorly. Overall features are suggestive of liver abscesses. He recovered with drainage and antibiotics. (b) CT scan of a 77-year-old woman with underlying diabetes, fever,

and right upper quadrant pain. Both blood culture and pus (from the liver abscess) grew *K. pneumoniae*. The CT scan shows an irregular ovoid lesion with multiple locules and thin intervening septations in the periphery of liver segment V and measuring 7.3 × 3.2 × 6.1 cm. The features suggest liver abscess with signs of early liquefaction. The woman recovered with drainage and antibiotics. Source: Courtesy of Department of Diagnostic Radiology and Organ Imaging, the Prince of Wales Hospital, the Chinese University of Hong Kong.

Diabetes is the most common underlying risk factor specifically for the virulent K1 serotype, but not for non-*Klebsiella* abscesses [162]. In a population-based series of pyogenic liver abscess reported from Taiwan and including 29 703 participants [163], diabetes was a risk factor in 33%, leading to a relative risk of 9.1. Liver abscess in people with diabetes was not, however, associated with increased mortality, particularly if therapeutic percutaneous drainage procedures were performed. In 80% there was an association with *K. pneumoniae* and not as a mixed infection with other organisms. Primary liver abscess in other parts of Asia is also increasing in incidence [39], with 40% reportedly associated with diabetes. Bacteraemia is present in 50%, and 8–10% of these cases have metastatic complications (e.g. endophthalmitis, meningitis, brain abscess, pneumonia, or skin and soft tissue lesions).

In a series from Europe ($n = 1448$), the presence of diabetes was associated with a 3.6-fold increase in risk for pyogenic liver abscess, and also with a higher 30-day post-discharge mortality rate compared with people who did not have diabetes [164]. In the context of the K1 serotype of *Klebsiella* species, a pathogenic role for the *magA* gene in the serotype-specific region of the K1 capsule gene cluster, together with a K1 capsular polysaccharide *per se*, is considered as one of the virulence determinants essential for the development of invasive liver abscess. MagA, an outer membrane protein contributing to capsular polysaccharide formation, coexists with serotype K1 and is the major virulence factor of *K. pneumoniae* [163]. Suboptimal glycaemic levels also have a role by impairing neutrophil phagocytosis of K1/K2-type *K. pneumoniae*, whereas it does not significantly affect the phagocytosis of non-K1/K2 *K. pneumoniae*. A regulator of mucoid phenotype A-associated

hypermucoviscosity phenotype has also been reported in invasive purulent diseases caused by *K. pneumoniae*.

Most isolates are susceptible to cephalosporins (especially third-generation agents) and fluoroquinolones; however, therapeutic drainage is also needed and assists with obtaining specimens for culture and susceptibility testing. Metastatic abscesses may occur elsewhere in the abdomen, either singly or in combination with other sites, as well as within the urinary tract. A notorious, although uncommon, example is psoas abscess, where responsible organisms are likely to be *S. aureus*, *Mycobacterium tuberculosis*, *E. coli*, or *Klebsiella*.

Skin and superficial soft tissue infections

Skin and subcutaneous tissues

Infections involving the skin, nails, and subcutaneous tissues are very common, and the skin and subcutaneous tissues are frequent targets of infection in diabetes, particularly in association with sub-optimal glycaemic levels. Candidal infections, bacterial infections such as furunculosis, dermatophyoses, and onychophyoses are all commonly seen and may be the reason for diabetes being identified. Cutaneous forms of mucormycosis or other fungal infections may occur and be diagnosed following skin biopsy. More detailed consideration is given to these disorders in Chapter 58.

Sensory neuropathy, atherosclerotic vascular disease, and hyperglycaemia predispose people with diabetes to skin and soft tissue infections. Additional risk factors for the development of cellulitis include a past history of cellulitis, oedema, peripheral vascular disease, tinea infection, and dryness of the skin. The predominant

organisms involved are group A streptococcus and *S. aureus*. Cellulitis can also occur in less usual settings. For example, with *S. pneumoniae* (pneumococcal) infections, cellulitis may occur in association with extracutaneous foci of disease, the suggestion being that, in this setting, the cellulitis results from haematogenous spread rather than local infection [165].

People with diabetes, particularly those who inject insulin, often have asymptomatic nasal, mucosal, and skin colonization with potential pathogens such as *S. aureus*. Nasal colonization may contribute to an increased risk of staphylococcal pneumonia, for example in association with influenza. According to data from the US National Health and Nutrition Examination Survey, people with diabetes who were colonized with *S. aureus* were also more likely to have a methicillin-resistant *S. aureus* isolate than a susceptible one (odds ratio 2.6) [166]. A previous increase in community-associated methicillin-resistant *S. aureus* (CA-MRSA) gives additional cause for concern. A report evaluating CA-MRSA in three communities found that 77% of skin or soft tissue infections were methicillin resistant [167]. The underlying conditions identified included smoking (35%), previous skin infection (21%), and diabetes (19%). As people with diabetes are more frequently hospitalized or attend healthcare facilities, they are at increased risk of being exposed to more virulent strains of these bacteria and hence more likely to be colonized.

Mucosal and skin colonization with *C. albicans* are also common and may involve numerous sites, including the genitalia of both sexes as well as the mouth, skin, and nails [168]. Balanitis and vulval candidiasis are common presenting features of diabetes. Colonization may predispose to cutaneous or incisional staphylococcal (or other bacterial) infections as well as transient bacteraemia. Entry sites may also include areas of fungal skin infection (e.g. intertrigo). Infection at distant sites with abscess formation or septicaemia may then ensue. In two relatively early studies (each from the 1960s), older people with diabetes were shown both to be at greater risk of staphylococcal septicaemia and also to suffer a substantially higher mortality (69% in those with diabetes vs 42% overall) [169, 170].

Deeper soft tissue infections

Deeper soft tissue infections also occur with increased frequency in people with diabetes. Examples include pyomyositis, necrotizing fasciitis, and Fournier gangrene. Pyomyositis, usually associated with infection by *S. aureus*, occurs in muscles that have undergone trauma, especially when associated with haematoma formation. Of note is that skin abscesses are a common initial presentation of type 2 diabetes in susceptible individuals.

Necrotizing fasciitis

Necrotizing fasciitis is a deep-seated life-threatening infection of subcutaneous tissue. Progressive destruction of fascia, fat, and muscle ensues. Although relatively uncommon, necrotizing fasciitis is a life-threatening condition. Necrotizing fasciitis and Fournier gangrene (a form of necrotizing fasciitis involving the perineum), as well as other necrotizing soft tissue infections resulting from a variety of organisms, all have reported associations with diabetes. Diabetes is the most common of several conditions predisposing to necrotizing fasciitis, all of which are associated with compromise to the immune system.

As its name indicates, necrotizing fasciitis spreads initially along fascial planes. As infection and inflammation progress, necrosis of muscle, subcutaneous tissues, and overlying skin

occurs. Necrotizing fasciitis usually follows identifiable episodes of trauma such as burns, insect bites, or abrasions, or can result from exposure of non-intact skin to a source of infection. The most common sites are the limbs, abdominal wall, and perineum. Involvement of the vulva in women with diabetes may begin as a Bartholin gland ductal abscess, usually associated with obesity [171].

Polymicrobial infection is most commonly observed, with streptococci and *Enterobacteriaceae* being the most common isolates. The great majority of cases result from infection with anaerobes together with one or more facultative aerobes, whereas about 10% are associated with group A streptococcus, with or without *S. aureus*. Thus, group A streptococcus is the most common cause of infection by a single organism and can also occur in combination with staphylococci, including CA-MRSA. A recent article describing necrotizing fasciitis caused by CA-MRSA showed that although current or past intravenous drug abuse underlay 43% of cases, 21% occurred in people with diabetes [172]. *Vibrio*, *Aeromonas*, *Haemophilus*, and *Salmonella* infections have also been reported. An interesting example is infection by halophilic marine *Vibrios*, either following exposure of non-intact skin to seawater [173] or following bites by marine organisms, such as crabs, and this should be considered when a history of appropriate exposure is present.

Necrotizing fasciitis carries a high mortality, particularly when affecting the lower extremities or perineum, and is rapidly fatal unless diagnosed promptly and treated aggressively. It may be initially misdiagnosed as a benign soft tissue infection and a high index of suspicion is therefore required. Skin changes may be minimal in the early phase of infection.

Early disease may be characterized by severe local pain, which is either disproportionate to or precedes other clinical features such as local inflammation and cellulitis, fever, and systemic toxicity. Cellulitis may spread rapidly, unseen in deeper fascial planes. Crepitus is present in about half of cases. Violaceous discolouration of the skin may be noticed and may progress into blistering and bullae. Thrombosis and vasculitis both contribute to necrosis of the superficial fascia and suppuration from liquefactive necrosis. Gangrene and ulceration can result. Anaesthesia of overlying skin may indicate destruction of subcutaneous nerves.

Plain radiographs, ultrasound, CT, and MRI scan can assist in both diagnosis and management by identifying the presence of gas in the tissues and by delineating the extent of the disease. Aerobic and anaerobic cultures should be taken from within the lesion, as should blood cultures.

Surgical debridement and fasciotomy are the mainstays of therapy. The single most important issue influencing mortality is time to surgical debridement. Thus, timely diagnosis, empirical broad-spectrum antibiotic therapy (including anaerobic cover), and aggressive surgical debridement of affected tissue are crucial components of management. The antibiotic cover can subsequently be tailored according to culture and sensitivity results. Additional supportive therapy in an intensive care environment should be provided where possible and as necessary.

Fournier gangrene

Fournier gangrene is a specific form of necrotizing fasciitis involving the perineum, scrotum, and penis. Overall mortality is very high. As with other forms of necrotizing fasciitis, diabetes is the most common of potential predisposing conditions, with a reported presence ranging between 32% and 60% of cases [174, 175]. Infection is usually polymicrobial, with a lengthy list of potential pathogens that is similar to that seen in other forms of necrotizing

fasciitis (*E. coli*, *Bacteroides* spp., staphylococci, streptococci, *Proteus* spp., *Pseudomonas* spp., enterococci). *C. perfringens* is present in the great majority (>90%) of cases in which myonecrosis is present.

Initial malaise and scrotal discomfort or pain is followed by systemic toxicity. Blistering ulceration and necrosis of the skin occur and in the later stages progress to scrotal swelling and a foul purulent discharge. Crepitus may be present. Sources of infection include abnormalities of the urogenital system (most notably urethral trauma, instrumentation or a chronic indwelling catheter, scrotal abscess or injury, insect bite) and local gastrointestinal abnormalities (e.g. ischiorectal or perianal abscess, incarcerated inguinal hernia).

Diagnosis is predominantly clinical. Imaging techniques may reveal subcutaneous gas and delineate the extent of involvement, as with other forms of necrotizing fasciitis.

Fournier gangrene is a surgical emergency, and extensive debridement is required. Urinary or faecal diversion may be required, as may laparotomy. Broad-spectrum antibiotic therapies with anaerobic cover, as well as general supportive measures, are indicated as with other forms of necrotizing fasciitis. The results of microbiological investigation may allow subsequent tailoring of antibiotics.

Infected diabetic foot

Foot infection is the most common soft tissue infection associated with diabetes and therefore is a topic of the utmost importance to all who deal with people with diabetes. A specific chapter (Chapter 53) is devoted entirely to this topic. Thus, in order to avoid duplication, the subject receives only brief discussion in this chapter.

Foot infection occurs as a complication of diabetic foot ulcer, for which peripheral neuropathy and peripheral artery disease are both important factors, although the clinical presentations of the *predominantly ischaemic* and the *predominantly neuropathic* foot differ. Serious complications include osteomyelitis, amputation, or even death. Infection often begins after minor trauma, which may be unnoticed, especially in the presence of sensory neuropathy. Cellulitis, soft tissue necrosis, and extension into bone, leading to osteomyelitis, may then follow. Involved organisms most commonly include group A streptococcus and *S. aureus*, as well as aerobic Gram-positive cocci, Gram-negative rods, and anaerobes.

The mainstays of management include exploration and debridement of the necrotic tissue and administration of appropriate antibiotics. In moderate to severe cellulitis or in the presence of osteomyelitis that places the limb at risk, the person should be hospitalized for broad-spectrum antibiotic therapy and surgical intervention.

As in most diabetes-related infections, suboptimal glycaemic management plays an important part, and foot infections remain a common presenting feature of newly diagnosed diabetes, particularly in low- and middle-income countries. Prevention of foot ulcers involves a multidisciplinary team approach. Foot care is an essential component of all diabetes education programmes and should include proper foot care habits, protective footwear, and pressure reduction.

Bone and joint infections

Bone and joint infections remain a significant problem for people with diabetes and can be very difficult to treat. Diabetes is a risk factor for both osteomyelitis and septic arthritis. The different types of osteomyelitis require differing medical and surgical therapeutic strategies. The three main types, classified according to aetiology, include osteomyelitis secondary to a contiguous focus of infection (e.g. after

trauma, surgery, or insertion of a joint prosthesis); osteomyelitis secondary to vascular insufficiency (e.g. diabetic foot infections); or osteomyelitis secondary to hematogenous spread of infection. The most common reason for septic arthritis is following insertion of joint prostheses. All are more common in people with diabetes, with osteomyelitis of the foot at the forefront. Taking as an example osteomyelitis of the spine, a recurring theme occurs with a combination of both increased risk of haematogenous vertebral osteomyelitis (2–6-fold) and predisposition to infection involving unusual organisms [176]. Acute osteomyelitis can respond to antibiotics alone, but prolonged courses are required for bone and joint infections given the physiological and anatomical characteristics of the tissues involved. Early imaging using MRI or CT, together with bone sampling for microbiological and pathological examination to allow targeted and long-lasting antimicrobial therapy, provides the best outcomes. As with the diabetic foot, a multidisciplinary approach is required for success, including expertise in orthopaedic surgery and infectious diseases, together with vascular surgery. Surgical intervention should be considered if medical treatment fails, for diagnostic confirmation, or in the presence of complications.

Chronic osteomyelitis may be associated with avascular necrosis of bone and formation of sequestrum (dead bone), and surgical debridement is then necessary for cure in addition to antibiotic therapy. It is important to remember the possibility of infection by *M. tuberculosis* [177].

Iatrogenic and surgical site infections

Insulin injections

Infections at the site of insulin injections are very uncommon and remain so even when traditional hygienic practices are not applied. Although not advised, administration of insulin through clothing is also not associated with increased risk of infection. Abscesses at needle sites are occasionally seen in individuals receiving subcutaneous insulin infusions [178]. Likewise, pulp infection over the distal phalanges in association with self-blood glucose monitoring is exceedingly unusual.

Surgical site infections

An association between diabetes and an increased risk of surgical site infections has been recognized for many years. The association has been generally assumed to be causally related to the deleterious effect of hyperglycaemia on immune function [179]. Some studies showed a reduced risk of infectious complications such as pneumonia and wound infection in people with satisfactory preoperative glycaemic levels compared with those with less optimal levels [180]. Other studies found glucose levels in the postoperative period to be more strongly related to infection risks than preoperative glycaemic measures [181–183]. In a retrospective study of 995 people with or without pre-existing diabetes undergoing general or vascular surgery, the risk of infection was increased 30% with every 40 mg/dl (2.2 mmol/l) increase in postoperative glucose level from normoglycemia (110 mg/dl [6.1 mmol/l]) [184]. In a clinical trial evaluating continuous intravenous insulin infusion versus intermittent subcutaneous insulin injection, the former resulted in lower post-operative glucose levels and reduced incidence of deep wound infection [185].

Both allograft rejection and risk for infection appear to be higher in transplant recipients with diabetes. In one study, the risk of serious infection was higher in heart transplant recipients with diabetes in the early postoperative period [186]. In another study,

kidney transplant recipients had a greater risk of both acute allograft rejection and infection when perioperative glycaemic levels were elevated [187].

Dialysis

Ambulatory peritoneal dialysis is a common form of treatment for end-stage kidney disease in people with diabetes, especially in Asia. For those receiving continuous ambulatory peritoneal dialysis, episodes of catheter-related peritonitis are common, although variable from individual to individual, with some developing multiple episodes. Overall, however, the rate of infection does not appear to be greater in people with diabetes than those without diabetes, perhaps reflecting the impairment of immunity associated with end-stage kidney disease *per se*.

The issue of peritonitis in people receiving continuous ambulatory peritoneal dialysis is an important one given the large number of those with diabetes receiving this treatment. It is well recognized that peritonitis, despite significant reductions in the last two decades, remains the most important complication of continuous ambulatory peritoneal dialysis with an overall mortality of about 3.5%, irrespective of both the underlying cause of the infection and the renal failure [188]. The degree to which the presence of diabetes adds to the already considerable infection risk remains uncertain. People with diabetes may, however, be generally more unwell and have additional factors and complications such as cardiovascular disease, need for hospitalization, and predilection to certain infections, such as candidiasis. All of these may, in principle, contribute to the already very considerable risk.

Principles of treatment, prevention, and general care

General principles

A high level of awareness is required in people with diabetes and in all healthcare providers, both to allow prevention and to enable early, prompt recognition and diagnosis. Education, good glycaemic management, and general steps to maintain health and nutrition are all important measures aimed at minimizing risk. Careful attention to foot care is particularly emphasized. Vigilant measures should be instituted to prevent infection. This includes personal hygiene and avoidance of crowds, especially during peak influenza seasons. When infections do occur, evolving antibiotic resistance patterns and other local factors must be considered, with CA-MRSA and tuberculosis both providing obvious examples of the importance of this.

The choice of antibiotic therapy follows the same general principles as for any other individual. Use of empirical broad-spectrum antibiotics is generally recommended until microbiological results can guide treatment. Due caution should be applied in the presence of diabetes-related complications. For example, the use of potentially nephrotoxic agents in the context of diabetic kidney disease may aggravate kidney impairment and, in turn, people with kidney disease require caution with doses and monitoring of blood levels. The presence of gastroparesis or autonomic neuropathy may hinder, or render unreliable, the absorption of oral drugs. People who are blind or partially sighted as a result of eye complications may also be at increased risk, for example when exposed to drugs that impair hearing or balance. Longer courses of antibiotic therapy may be appropriate, for instance in treating UTI.

Antiviral agents are recommended in the setting of influenza, and a more aggressive treatment approach may be appropriate even when presentation is relatively late [90]. Responses to treatment should also be carefully monitored (e.g. in the case of tuberculosis) [127]. The importance of appropriate referral to surgical or other specialist colleagues has been stressed repeatedly. Examples include surgical debridement in the case of necrotizing fasciitis, and incision and drainage of abscesses.

People with diabetes generally have a normal response to vaccines and should receive immunizations according to established guidelines. None of the vaccines currently available is contraindicated on the basis of diabetes alone. Because of increased susceptibility to complications, routine immunization against pneumococcus and influenza is recommended, particularly for older people with diabetes and for those with additional comorbidity such as chronic respiratory disease. Influenza vaccination reduces influenza- and pneumonia-related hospital admissions as well as all-cause death during influenza outbreaks [133, 134]. Hepatitis B vaccination is also important, although some populations may require additional or booster doses over and above standard recommended regimens.

Glycaemic management

All physicians need to be aware of the importance of careful monitoring of glycaemia in the presence of infection and should be on guard against destabilization of glycaemic levels or development of complications. Interestingly, in people without diabetes following hospitalization, even mild degrees of hyperglycaemia are associated with increased mortality in association with severe illness. Although depressed immune function correlates somewhat variably with traditional glycaemic measures, there is sufficient evidence to indicate an inverse relationship between the two that is potentially reversible. Previously undiagnosed diabetes may also be first detected following hospitalization and then needs to be distinguished from hospital-related hyperglycaemia that later reverts to normal.

People with type 1 diabetes or others receiving insulin need to be aware of the probability of changing insulin requirements in response to infection and to the risk of severe consequences such as diabetic ketoacidosis. Many people with type 2 diabetes who are not using insulin need to be transferred temporarily to insulin therapy as the stress of illness frequently adversely affects glycaemic levels. Hospital admission is mandatory if severe destabilization of glycaemia occurs, or if symptoms such as nausea and vomiting interfere significantly with oral food intake. In this situation, intravenous insulin–glucose regimens are recommended. People using SGLT-2 inhibitors should be informed to temporarily withhold this medication during sepsis. While optimal glycaemic levels are important, it is also important to avoid hypoglycaemia. Interaction between the diabetes care team and other involved specialists should be initiated as early as possible.

The importance of perioperative glycaemic management in people with diabetes undergoing surgery needs to be emphasized in order to minimize negative impacts on postoperative infection rates and wound healing (Chapter 58). Attention to other risk factors (e.g. neurological and vascular complications) is also important to minimize the risk of infections and infection-related complications. The importance of the presence of vascular disease and neuropathy in the risk of the more severe forms of infection is again stressed. For more detailed description of these aspects of care, readers are referred to clinical practice recommendations, for example those of the American Diabetes Association, or to other national or international guidelines, as well as to other relevant chapters in this textbook.

Key points

- Sleep quality and duration are associated with diabetes progression and management.
- The association between sleep and diabetes is complex and incorporates behavioural, environmental, physiological, and psychological factors.
- Sleep apnoea, restless leg syndrome, insomnia, and long and short sleep duration are common sleep problems associated with diabetes.
- Renal dysfunction, neuropathy, and retinopathy are common complications in diabetes that are associated with sleep disorders.

- Depression frequently co-occurs with both sleep disorders and type 2 diabetes and may also function as a mediator between poor sleep and diabetes self-management difficulties.
- People with diabetes may benefit from the screening of sleep impairments as they are common comorbidities, influence well-being, and complicate diabetes management.
- Large longitudinal observational studies, using objective sleep measurements, are needed to further shed light on the role of sleep in the development and progression of diabetes and its complications.

Sleep, a behavioural process that is influenced by circadian, neurohormonal, and homeostatic processes [1, 2], is critical for optimal functioning and well-being. The important role of sleep can be highlighted by the consequences when it is deficient. Sleep deficiency is linked with adverse effects on behaviour and cognition [3], increased risk of road traffic incidents [4], impaired immune function, increased pain, impaired performance, increased errors [5], and increased risk of disease [5–7]. The fast-paced, 24/7 nature of modern society, with increasing use of technology and on-demand entertainment in the home, may be compromising the population's ability to obtain adequate sleep. Some evidence suggests that these lifestyle and social changes have happened concurrently with an increase in complaints of sleep problems and symptoms of sleep disorders [8, 9]. However, other research suggests mixed findings regarding the changes in global patterns of sleep duration [10], particularly in studies with adults [11]. Nevertheless, suboptimal sleep and sleep disorders are now considered as modifiable factors having adverse impacts on global health [12, 13].

The relationship between sleep and health outcomes appears to be reciprocal and complex. Sleep problems and disorders co-occur frequently in chronic health conditions [14, 15], and can also serve as potential pathways to chronic disease through their effects on bodily systems such as the endocrine, metabolic, and immune sys-

tems [16, 17]. Among those with diabetes, sleep disorders and atypical sleep duration have been associated with diabetes complications [18], while complications of diabetes can, in turn, impair sleep [19, 20]. This chapter will discuss common sleep problems and disorders, their relationship with diabetes and diabetes complications, and their associations with diabetes management.

Sleep problems

Sleep problems are often used as a general term for having trouble falling asleep, difficulty maintaining sleep, or the subjective experience that sleep has not been sufficiently refreshing or restorative. Sleep problems can leave a person feeling exhausted and take a serious toll on their health and well-being. Worldwide, studies have reported the prevalence of sleep problems in the general population as ranging from 1.6% to 56% [21, 22]. Sleep problems are typically assessed using self-report questionnaires such as the Pittsburgh Sleep Quality Index [23]. Polysomnography is considered the gold standard for the assessment of sleep problems [24]. However, it is often impractical to assess sleep habits and patterns over multiple consecutive days in non-clinical settings. Actigraphy-based sleep measures have been suggested as alternative measures for the identification of sleep problems [25].

Sleep disorders

Sleep disorders are conditions that affect an individual's ability to obtain quality sleep on a regular basis and, when chronic, can have long-term effects on health. The most recent edition of the International Classification of Sleep Disorders lists 83 sleep disorders [26]. The International Classification of Diseases 11th Revision (ICD-11) codes categorize sleep–wake disorders into insomnia disorders (i.e. difficulty in falling and staying asleep), sleep-related breathing disorders, sleep-related movement disorders, hypersomnolence disorders (i.e. excessive sleepiness), circadian rhythm sleep–wake disorders (i.e. disorders of the sleeping schedule), and parasomnia disorders (i.e. abnormal physiological or behavioural events that happen while sleeping) [27].

Insomnia

Insomnia is the commonest sleep disorder in the adult population [28]. Insomnia involves both nocturnal and diurnal symptoms and is characterized by a dissatisfaction with quality and/or quantity of sleep, difficulty falling asleep, frequent or early-morning awakenings, mood disturbances, daytime fatigue, and impaired attention and concentration [26, 29]. Worldwide, the proportion of the general population self-reporting that they experience symptoms of insomnia is approximately 30% [30]. However, the percentage meeting the criteria for a diagnosis of insomnia has been estimated between 5.8% and 15.8% [31, 32].

Sleep apnoea

Sleep apnoea, a relatively common sleep disorder, is characterized by the absence of inspiratory airflow for at least 10 seconds during sleep [33]. The two main types of sleep apnoea are obstructive sleep apnoea (OSA) and central sleep apnoea (CSA). OSA syndrome involves recurrent episodes of partial or complete upper-airway obstruction during sleep [27]. These obstructions often cause reductions in blood oxygen saturation and end with a brief awakening from sleep [27]. CSA is characterized by reduced or ceased airflow due to a lack of respiratory effort [27] from a reduction or cessation in the central neural outflow to the muscles of the respiratory system during sleep [34]. In a review of population-based studies, the prevalence of OSA was reported as approximately 22% (range 9–37%) in men and 17% (range 4–50%) in women [35]. While there is less research on the prevalence of CSA, it has been estimated as less than 1% in the general population [36], and is higher in chronic opioid users [37] and those with heart failure [38].

Restless leg syndrome

Also known as Willis-Ekbom disease, restless leg syndrome is diagnosed based on five diagnostic criteria:

- An urge to move legs due to discomfort when resting.
- The urge usually being accompanied by pain or paraesthesia.
- Temporary relief of symptoms with movement.
- A circadian aspect, wherein the symptoms worsen during the evening or night.
- The symptoms not being the result of another medical condition [39, 40].

A recent 2018 aggregate of studies found a mean prevalence of 4.6% (range 2–9.4%) in men and 8.6% (range 2.3–15.4%) in women [41]. The strong urge to move the legs at night makes it difficult to fall and stay asleep, leading to sleep deprivation and, thus, significant distress and diminished quality of life [27, 42].

Sleep duration (long and short sleep)

Sleep duration is often defined as the total amount of time spent asleep over a 24-hour period [43]. Optimal sleep duration varies between individuals. Recent guidelines from the US National Sleep Foundation recommend 7–9 hours of sleep for young and middle-aged adults and 7–8 hours of sleep for older adults [44]. However, the prevalence of short sleep duration is common. In 2017 in the USA, an estimated 32.9% of people slept less than 6 hours, 59.8% slept between 7 and 8 hours, and 7.3% slept over 9 hours [45]. While there are regular reports in the popular and academic literature that we are sleeping less now than in the past, recent reviews indicate more inconsistent findings: sleep duration is declining in some countries but increasing in others, with no certain social or economic explanations for international differences [11].

Sleep timing and consistency

Sleep timing refers to the time of day when sleep occurs (i.e., bedtime and wake-up time), while sleep consistency refers to the intra-individual variability in sleep timing and sleep duration, with high consistency characterized by an individual's regularity in sleep timing and duration [46]. Alternative shift work and rotating night work are becoming increasingly common in industrialized countries [47], which can lead to sleep inconsistency. Shift work can lead to circadian dysregulation or disruption of circadian rhythms (normal sleep–wake cycle) due to inconsistent sleep times. As circadian alignment of sleep is an important factor for metabolic health [48], individuals with inconsistent sleep are at risk for experiencing adverse metabolic consequences [49]. A recent meta-analysis [50] reported that atypical sleep duration was associated with various poor health outcomes [51–53]. It concluded that regularity in sleep patterns, with a consistent wake-up and sleep time, should be encouraged for maintaining good health. However, the review also stated that existing studies have focused on linear associations. Quantifying what is considered acceptable sleep variability and healthy sleep timing remains unclear. It was recommended that future research focus on exploring the dose-response relationship between sleep and health outcomes, such as mortality, quality of life, work productivity, and other chronic diseases [50].

Sleep problems or disorders and diabetes

The association between sleep disorders and diabetes is multifaceted and bidirectional (Figure 62.1). Diabetes can lead to sleep disturbances through polyuria, nocturia, and painful neuropathy [54]. Some of the most common sleep disorders and problems among those with diabetes are sleep apnoea, insomnia, restless leg syndrome, and short and long sleep duration [55]. Emerging research has demonstrated associations between diabetes complications and sleep disorders [18]. Renal dysfunction, neuropathy, and retinopathy

are common diabetes complications associated with sleep disorders [55]. Most research has focused on sleep problems in people with type 2 diabetes, but several studies support the role and influence of sleep on poor outcomes in people with type 1 diabetes, although evidence from high-quality clinical and observational studies is lacking [56]. A summary of the evidence on sleep problems in people with type 1 diabetes is presented first, followed by a discussion of the associations between sleep and type 2 diabetes.

Sleep duration and type 1 diabetes

Of the few existing studies examining the prevalence of short and long sleep duration in type 1 diabetes, one found that 16% of adults with type 1 diabetes obtained less than six hours of sleep per night [57], although another study found no significant differences in sleep duration between adults with type 1 diabetes and matched participants without diabetes [58]. In addition, longer sleep duration has been associated with decreased insulin sensitivity [59]. Shorter sleep duration is associated with greater glycaemic variability [60] and higher glycated haemoglobin (HbA_{1c}) levels [61]. A meta-analysis revealed a relationship between self-reported sleep duration and glycaemia, with average HbA_{1c} levels 0.24% (3 mmol/mol) higher among those sleeping less than six hours [62].

Sleep quality and type 1 diabetes

A study by van Dijk and colleagues [58] suggested that 35% of adults with type 1 diabetes self-reported poor sleep quality compared with 20% of those without diabetes. However, no significant association was found between individual sleep quality and HbA_{1c} . Similarly, Denic-Roberts [57] found that 41% of adults with type 1 diabetes reported poor sleep quality (51% in women, 30% in men) and Martyn-Nemeth et al. found poor sleep quality in 46% of adults with type 1 diabetes [63]. Poor sleep quality also seems to be associated with decreased insulin sensitivity [59].

Obstructive sleep apnoea and type 1 diabetes

A high prevalence of OSA has been reported in adults with type 1 diabetes. For instance, of 200 individuals with type 1 diabetes attending an outpatient clinic, OSA was newly diagnosed in 87

individuals and 5 people had known OSA [64]. OSA was more prevalent in individuals with overweight (60%) and obesity (61%) compared to those with normal weight (32%). A similar prevalence rate of OSA in adults with type 1 diabetes (52%) was reported in a meta-analysis of four studies [62]. Neuropathy may be a risk factor for OSA in type 1 diabetes, as neuropathy may compromise upper-airway reflexes and control of the pharyngeal dilator muscles, which might increase the risk of obstructive events [65].

Type 2 diabetes and insomnia

Insomnia is more common in people with type 2 diabetes than those without diabetes [66]. Insomnia could also be an important risk factor for type 2 diabetes [67] and this risk is stronger when short sleep duration is present [68, 69]. A meta-analysis of prospective cohort studies found that the insomnia symptoms associated with the highest risk of developing type 2 diabetes were difficulty in initiating sleep and difficulty in maintaining sleep, with relative risks of 1.57 (95% confidence interval [CI] 1.25 to 1.97, $p < 0.0001$) and 1.84 (95% CI 1.49 to 2.43, $p < 0.0001$), respectively [70]. A recent cross-sectional study reported an association between insomnia and type 2 diabetes, and the association remained after adjusting for covariates such as age, sex, smoking, body mass index (BMI), alcohol consumption, other disease history, and depression [71]. Individuals with type 2 diabetes were twice as likely to have self-reported insomnia than individuals without type 2 diabetes. Once stratified by age, the middle-age group had the strongest association between insomnia and diabetes status, followed by the older-age group.

Type 2 diabetes and sleep apnoea

Reviews that have pooled type 2 diabetes risk in people with OSA have provided evidence identifying OSA as an independent risk factor for diabetes development [72, 73]. A recent meta-analysis used a dose-response analysis to suggest that the risk of type 2 diabetes is 40% higher in individuals with OSA [74]. This study also found a linear association, with an 8% increase in risk of type 2 diabetes for each 5-events/h increase in the apnoea-hypopnoea index, an indicator of OSA severity. OSA severity has been associated with measures of hyperglycaemia in type 2 diabetes, after

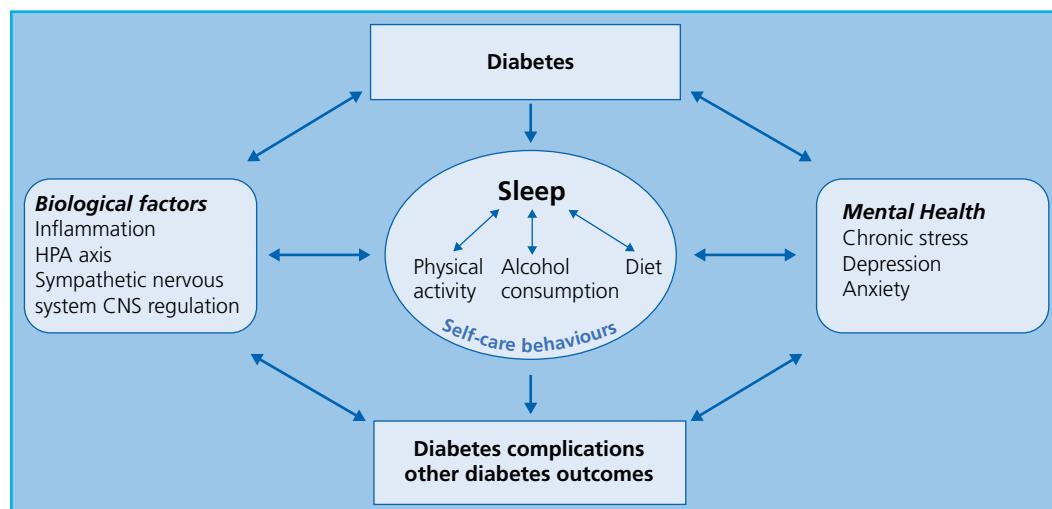

Figure 62.1 The multifaceted relationship between sleep and diabetes and its complications. CNS, central nervous system; HPA axis, hypothalamic–pituitary adrenal axis.

controlling for age, sex, BMI, race, number of diabetes medications, sleep duration, level of exercise, and diabetes duration [75]. People with type 2 diabetes have been found to have higher HbA_{1c} levels by 0.72% (8 mmol/mol; p < 0.001) if they have severe OSA than if they do not have OSA [76]. The relationship between CSA and diabetes is less understood [77].

Sleep apnoea is independently associated with insulin resistance and impaired glucose tolerance [78, 79]. Sleep apnoea leads to hypoxia (i.e., lack of oxygen to part of the body), which is implicated in insulin resistance, and this, along with sleep fragmentation, is potentially a pathway to type 2 diabetes in sleep apnoea [80, 81]. A recent meta-analysis determined that there is insufficient evidence to support the hypothesis that sleep apnoea increases the risk of diabetes merely through the common risk factor of obesity [74]. When they excluded studies without BMI or body fat percentage adjustment, the risk remained. Only one of the included studies further examined the role of obesity in this association and found that sleep apnoea was a risk factor for type 2 diabetes in individuals both with and without obesity, suggesting that sleep apnoea increases the risk of diabetes through other mechanisms as well as obesity [74]. Additional studies are needed to examine how variability in BMI plays a role in the association between sleep apnoea and type 2 diabetes.

Type 2 diabetes and sleep duration

The link between short sleep duration and incident diabetes has been supported with evidence from meta-analysis: less than six hours of sleep per night is associated with an approximate 30% increased likelihood of developing type 2 diabetes, compared with seven hours of sleep per night [7]. However, this relationship is a U-shaped one, with both long and short sleep duration contributing to the risk of type 2 diabetes [70, 82, 83]. Sleeping seven to eight hours per day has been associated with the lowest risk of type 2 diabetes [84].

From studies examining the effects of sleep duration on health outcomes among healthy individuals, we can elucidate the possible mechanisms through which sleep duration contributes to diabetes risk. Restricted sleep has been shown to reduce insulin sensitivity and increase insulin resistance in healthy individuals [85, 86]. Long sleep duration has been associated with higher insulin resistance and higher insulin and glucose values in an oral glucose tolerance test in people without diabetes, and these associations remained statistically significant after adjusting for age, sex, family history of diabetes, and other confounding factors (such as obesity, depression, and physical activity), and after excluding participants with severe sleep apnoea and insomnia [87].

Type 2 diabetes and sleep timing and consistency

Only a few studies have examined the association of sleep timing and consistency with diabetes [50]. Results from a cross-sectional study suggested that one-hour increments in sleep duration were inversely associated with type 2 diabetes, while each one-hour increment in sleep variability was positively associated with type 2 diabetes [88]. An earlier study came from the Nurses' Health Study, which followed approximately 70 000 women aged 42–67 years (NHS I, 1988–2008), and 107 915 women aged 25–42 years (NHS II, 1989–2007) without diabetes for a period of approximately 20 years [49]. Duration of shift work was associated with an increased risk of type 2 diabetes in both cohorts, with the women who had been rotating night-shift work for more than 20 years being at the highest risk for type 2 diabetes with a hazard ratio (HR) of 1.58 (95% CI 1.43 to 1.74, p value for trend <0.001). Similarly, another study in women reported an association between greater

bedtime variability and insulin resistance, even after adjusting for sleep duration [89]. This study did not focus on shift workers but rather measured four qualities of sleep timing: mean bedtime, bedtime variability, bedtime delay, and bedtime advance. Their findings provide evidence that it is not necessarily shift work that causes the changes that place individuals at risk for metabolic conditions and diabetes, but rather the associated disruption to sleep timing and consistency. However, the existing literature examining the association between sleep timing and consistency and diabetes has produced inconsistent findings, and more research is needed to better understand this relationship [50].

Type 2 diabetes, sleep problems, and depression

Depression is a highly comorbid condition in type 2 diabetes [90] and has been classified as an important risk factor for complications and disability in people with type 2 diabetes [91]. Sleep difficulties (i.e., insomnia and hypersomnia) are diagnostic symptoms for mania and depression [92] and depression is often accompanied by impairments in sleep quality or duration [93]. Depression and sleep problems might interact with each other and increase the risk of diabetes complications in a synergistic way. A prospective large-scale community study found that depression and diagnosed sleep disorders or long sleep duration were independent risk factors for heart disease and were associated with a stronger risk of heart disease when occurring together [94]. Health behaviours (e.g., smoking and physical inactivity) and biological pathways (e.g., chronic inflammation and alterations in hypothalamic–pituitary–adrenal activity) may explain the associations between depression symptoms, sleep problems, and the onset of heart disease [94]. Given that heart disease is a common complication of type 2 diabetes [95], and that those with type 2 diabetes are more vulnerable to depression [90] and sleep problems [93], these findings might be exacerbated among those with type 2 diabetes. However, further research is needed to examine the interactions between sleep and depression in type 2 diabetes.

Type 2 diabetes, sleep duration, and mortality

Wang and colleagues [96] evaluated data from the National Health Interview Survey and found a J-shaped association between sleep duration and all-cause mortality risk in people with type 2 diabetes. Compared with the reference group (7 hours' sleep per day), both longer and shorter durations were associated with increased risk of all-cause mortality: ≤5 h/d: HR 1.24 (95% CI 1.09 to 1.40); 6 h/d: HR 1.13 (95% CI 1.01 to 1.28); 8 h/d: HR 1.17 (95% CI 1.06 to 1.30); ≥10 h/d: HR 1.83 (95% CI 1.61 to 2.08). The association was more prominent in those with a younger age at type 2 diabetes onset and those receiving treatment with both oral glucose-lowering medication and insulin. They suggested that this population may benefit from targeted sleep-related interventions to reduce the risks of adverse health outcomes.

Type 2 diabetes, sleep disorders, and cardiovascular outcomes

A meta-analysis reported that the pooled prevalence of hypertension among individuals with type 2 diabetes and diagnosed sleep disorders was 89% (95% CI 81% to 97%), while the pooled prevalence of hypertension among individuals with type 2 diabetes without diagnosed sleep disorders was 82% (95% CI 80% to 84%) [55]. Hermans et al. [97] evaluated the association between OSA and cardiovascular events and coronary artery diseases in men with type 2 diabetes. The prevalence of cardiovascular events and

coronary artery diseases in men with type 2 diabetes and OSA (61% and 44%, respectively) was significantly higher compared to men with type 2 diabetes without OSA (38% and 27%, respectively). The same study reported that the prevalence of stroke was 15% in men with type 2 diabetes and OSA compared to a prevalence of 8% for men with type 2 diabetes and no sleep disorder.

Type 2 diabetes, sleep disorders, and renal function

There is evidence for a potential relationship between sleep and renal function in people with type 2 diabetes. One study reported a prevalence of 43% for albuminuria and 53% for microalbuminuria among people with type 2 diabetes and comorbid OSA, compared to a prevalence of 34% for albuminuria and 38% for microalbuminuria for those with type 2 diabetes without comorbid OSA [98]. Farghaly et al. reported that people with type 2 diabetes and sleep apnoea had significantly higher serum urea and creatinine levels (7.25 mmol/l and 80.7 µmol/l, respectively) compared to those with type 2 diabetes without sleep apnoea (4.37 mmol/l and 59.0 µmol/l, respectively) [99].

Type 2 diabetes, sleep disorders, and neuropathy

A meta-analysis of 11 studies with 1842 individuals found that OSA was not correlated with neuropathy in people with type 2 diabetes [100]. However, there was significant heterogeneity that might have affected the results. In contrast, the authors found an association between OSA and neuropathy in people with type 1 diabetes. Painful diabetic peripheral neuropathy has been associated with sleep impairment [19, 20].

Type 2 diabetes, sleep disorders, and retinopathy

A cross-sectional study evaluated the association between OSA and the presence and severity of diabetic retinopathy in a sample of 317 individuals [101]. It found an increased risk of diabetic retinopathy in people with severe OSA (odds ratio 2.18, 95% CI 1.14 to 4.18), whereas individuals with mild to moderate OSA were not at an increased risk of diabetes-related eye complications. The authors concluded that those with both severe OSA and type 2 diabetes should be identified as higher-risk individuals in the clinical setting. An association between OSA and advanced diabetic retinopathy was also reported in two UK-based studies [102, 103].

Sleep and diabetes self-management

One of the ways in which sleep disturbance may be linked to diabetes outcomes is via less effective diabetes self-care behaviours, which are vital for diabetes management and prevention of complications. Sleep disturbance may be a critical barrier to proper diabetes self-care and self-management regimens in type 2 diabetes and type 1 diabetes.

In a study of adults with type 2 diabetes, poor self-reported sleep quality was associated with suboptimal diabetes self-care behaviours, assessed by self-reported items related to diet, exercise, and medication taking, with a medium effect size ($r = -0.21$). This study also found a similar association between poor sleep quality and a less healthy diet, which included deviating from meal plans suggested by healthcare providers [104]. In another study of adults with type 2 diabetes, those self-reporting insomnia symptoms had significantly worse diabetes self-care behaviours than those reporting no insomnia symptoms [105]. One study, using actigraphy-measured sleep over eight days in adults with type 2 diabetes, found

that more awakenings at night, in addition to fatigue and daytime sleepiness, were associated with suboptimal self-reported diabetes self-management [106]. Sleep continuity disruptions may impair self-regulatory capacities and thus lead to poorer diabetes self-management [106].

Fewer studies are available on sleep and diabetes self-management in paediatric samples and in those with type 1 diabetes [107]. However, disturbed sleep, including poor sleep quality and duration, is associated with suboptimal diabetes self-management in youths and adults with type 1 diabetes. For instance, in a study of 159 adolescents with type 1 diabetes, short sleep durations and lower self-reported sleep quality were associated with a lower frequency of blood glucose monitoring [108]. McGonough et al. examined the associations between self-management regimens and sleep according to daily diary ratings over two weeks in adolescents with type 1 diabetes [109]. Short sleep duration on one night corresponded to a reduced frequency of blood glucose self-monitoring on the following day. In a two-week daily diary sleep study of 236 adolescents with type 1 diabetes, impaired perceived sleep quality was associated with poorer self-regulation around blood glucose self-monitoring [110]. Similar findings were reported in a study of adults with type 1 diabetes [111]. However, long sleep duration may also play a role. One study of adolescents with type 1 diabetes found that those who slept longer hours were less likely to follow self-management regimens and undertake blood glucose monitoring [112]. Therefore, both short and long sleep may disrupt diabetes self-management behaviours, though further research from prospective cohort studies is needed.

Excessive daytime sleepiness may be an explanation for these associations. In a sample of veterans with type 2 diabetes from the USA, there was a 21% increased odds of sedentary activity for those self-reporting daytime sleepiness [113]. Notably, however, sedentary activity was defined as walking <150 min/wk, and thus only physical activity related to walking was measured.

Increased emotional eating may also play a role, as this behaviour is associated with poor sleep quality and fatigue in adults with type 2 diabetes [114]. As evidence from the general population additionally suggests that unhealthy diets and low physical activity are linked with sleep disturbance [115], a reciprocal pattern of associations between sleep and health behaviours may best characterize people with diabetes. For instance, findings from a five-year prospective cohort study in middle-aged and older adults from the USA suggest that higher levels of weekly physical activity were associated with a lower risk of polysomnography-assessed sleep disturbances [116]. However, the bidirectional and potential reciprocal associations between sleep and diabetes self-management behaviours, to date, have not been directly investigated.

Depression may be another potential mechanism linking sleep disturbance with difficulties in diabetes self-management. Depression is associated with short and long sleep durations [93]. Sleep disturbance is a symptom of a major depressive disorder according to diagnostic criteria [29], and sleep disturbance is associated with the incidence of depressive symptoms [117]. Depression is also associated with suboptimal diabetes self-care behaviours [118–120]. Therefore, depression might mediate the association between sleep disturbance and diabetes self-management behaviours, though this has not been directly examined. There may also be a synergistic interaction between the combination of depression and sleep disturbance, with depression potentially acting as a catalyst leading to worse diabetes self-management. Depression may enhance the effect of sleep disturbance on diabetes self-management through

impaired glucose measures and fatigue. There could additionally be bidirectional effects, where sleep disturbance influences poor diabetes self-management, and where suboptimal diabetes self-management and sleep disturbance [121] may lead to metabolic changes that are linked with the incidence of depression [122]. The relationship between sleep disturbance, depression, and diabetes self-management is likely to be complex. Addressing depression and related mental health factors such as diabetes distress in individuals with sleep disorders might play an important preventive role in terms of diabetes management, though further research is needed.

Several knowledge gaps remain in understanding the role that sleep disturbance plays in the behaviours that are needed to optimize diabetes self-care, and these gaps may stem largely from the lack of prospective cohort studies examining these associations with large samples of people with type 1 diabetes and type 2 diabetes. Several putative mechanisms may explain the associations between sleep disturbance and less effective diabetes self-management regimens, but the formal tests of mediation in prospective cohort studies that are necessary to better understand the nature of this association are lacking. Despite these limitations, there is evidence to suggest that sleep disturbance in people with type 1 diabetes and type 2 diabetes can impede efforts at optimal diabetes self-management, and therefore that addressing sleep disturbance as part of the clinical management of diabetes may be beneficial.

Clinical implications

Diabetes healthcare professionals can screen for sleeping problems using brief questionnaires during routine care appointments. For example, the Patient-Reported Outcomes Information System (PROMIS) Sleep Disturbance Scale [123] is a brief six-item measure that assesses sleep disturbance over the past seven days. This tool, which can be completed either online ahead of an appointment or during an appointment, can help healthcare professionals working with people with diabetes to identify sleep problems. If a person has a positive screen for sleep disturbances, then a more

comprehensive assessment could follow, including the Pittsburgh Sleep Quality Index [23].

Minor sleep issues can be addressed directly with brief psychosocial interventions conducted by healthcare professionals, such as promoting and educating on sleep hygiene. Individuals with moderate to severe sleep disturbances could be referred to appropriate specialists, who might include psychologists, psychiatrists, and other sleep and behaviour specialists. Individuals with sleep disturbances should be reassessed for sleep disturbance and diabetes management difficulties more frequently. Otherwise, screening should take place yearly as part of regular diabetes care. Finally, we recommend that sleep should not be considered in isolation, as there could be important interactions with other symptoms and conditions, such as depression.

Conclusion

The relationship between sleep and diabetes is complex: sleep impairments seem to be both affected by, and risk factors for, diabetes and its complications, while also being a barrier to effective diabetes self-management. People with diabetes may benefit from the screening of sleep problems to avoid adverse cycles of the behavioural, physiological, and mental health effects of poor sleep on health and well-being. Given the high prevalence of sleep-related problems in type 1 diabetes and a strong link between OSA and markers of glucose metabolism, identification, and evaluation of sleep problems and disorders in people with type 1 diabetes may facilitate diabetes management and glycaemic levels. The epidemiology of sleep disorders in type 1 diabetes and its relation to glycaemic indices require further examination. Future research should aim to focus on isolating the role of individual sleep disorders in type 2 diabetes from sleep duration and clarifying the contribution of sleep consistency and timing. A clearer understanding of the role of obesity and depression in the sleep–diabetes relationship is warranted. Longitudinal studies using objective sleep assessments are needed to clarify the role of sleep in the development of diabetes complications and its interaction with behaviour and mental health comorbidities.

10 Psychosocial Aspects of Diabetes

63

Psychosocial and Behavioural Aspects of Diabetes

Frans Pouwer^{1,2,3} and Jane Speight^{1,3,4}

Key points

- Both type 1 diabetes and type 2 diabetes can affect psychological well-being and quality of life. In most instances, these effects are modest and are most likely to be associated with certain adverse events that occur during the course of diabetes or its management.
- Diabetes-specific distress and fear of hypoglycaemia are both common among people with diabetes.
- For most people with diabetes, generic health status and health-related quality of life do not differ markedly from people with other chronic conditions, such as arthritis. Lower health-related quality of life is associated with diabetes complications, being female, physical inactivity, low income, and recurrent hypoglycaemia.
- Diabetes-specific quality of life can be impaired by intensive diabetes management, hypoglycaemia, and complications. It can be improved with flexible approaches to intensive treatment.
- Diabetes-related stigma is common. This includes perceived or experienced judgement, blame, rejection, exclusion, and discrimination due to diabetes. Sources of stigma include the media, general public, family, and health professionals and this can be internalized as self-stigma. It is apparent that the way in which we communicate about diabetes (the language and imagery used) can fuel or reduce diabetes stigma. Diabetes stigma is associated with impaired psychological well-being, diabetes self-care, and quality of life, and less frequent healthcare access. Diabetes stigma should be countered wherever it occurs.
- Psychological factors contribute to the risk of developing type 2 diabetes; these include adverse childhood experiences, chronic stress, high job strain, low stress resilience, insomnia, depression and anxiety disorders, and schizophrenia. The mechanisms remain poorly understood.
- Around 50% of type 1 diabetes is diagnosed in childhood, but children show remarkable psychological resilience to the diagnosis. About one-third report some psychological distress shortly after diagnosis, but this generally subsides within six months. Problematic adjustment is characterized by increased depressive symptomatology, more anxiety, social withdrawal, and sleep disturbances. A similar adjustment reaction is

often seen in parents, particularly mothers, of children with newly diagnosed type 1 diabetes. Diagnoses of post-traumatic stress disorder are also more common in parents, occurring at rates comparable with those reported among parents of children diagnosed with cancer.

- During the first 5–10 years of living with type 1 diabetes, most children and adolescents have adequate psychological functioning; however, after 10 years, rates of anxiety, depression, and eating disorders increase markedly, with as many as one-third of adolescents with diabetes meeting the criteria for one or more psychiatric disorders. Diabetes distress is more common in adolescence than at any other life stage.
- Macrovascular disease, chronic foot ulceration, and proliferative retinopathy increase the risk of psychopathology, an understandable reaction to serious complications; however, lifetime psychiatric disorders such as depression may also increase the risk of later development of both macrovascular and microvascular complications. Recurrent diabetic ketoacidosis, particularly in young women, is also predicted by psychological problems such as disordered eating, and by high rates of family dysfunction.
- Diabetes management and health outcomes are influenced by reciprocal relationships between glycaemic levels and psychological variables. The latter include enduring psychological traits such as locus of control, coping style, temperament, and transitory psychological states (stress, anxiety, depression). Diabetes outcomes are also strongly related to family functioning, especially in children and adolescents: low family conflict, good communication, cohesion, and marital satisfaction relate to more optimal glycaemic outcomes.
- Self-care behaviours (medication taking, glucose monitoring, healthy eating, physical activity) are only weakly related to glycaemic outcomes. This may reflect the inaccuracy of self-reported behaviours, the crudeness of the self-report measures, the discrepancy between typical recent behaviours (e.g. past two weeks) and glycated haemoglobin (HbA_{1c} , a measure of the average blood glucose over the past 8–12 weeks), or the inherent complexity, relentlessness, and challenges of manual self-management of diabetes.
- Several interventions are effective in improving psychological well-being. These include individual or group therapy, counselling based on the

- principles of cognitive behavioural therapy (CBT), or mindfulness-based therapies and web-based CBT, as well as psychotherapy and family therapy.
- Other interventions, effective for improve psychological well-being, self-care, and health outcomes, include empowerment-based approaches

and structured training or education programmes. The components of effective programmes include (with varied emphasis) goal-setting, problem-solving, coping, managing stress, self-motivation, and self-management skills.

Diabetes and psychology have long been linked: Areteus of Cappadocia (first or second century) described life with diabetes as 'disgusting and painful'. In the seventeenth century, Thomas Willis mentioned long grief and melancholia as potential causes of diabetes. More than three centuries later, a meta-analysis of modern longitudinal epidemiological studies confirmed that Willis was right. This chapter examines five major themes:

- Psychological risk factors for diabetes.
- Psychological impact of living with diabetes and its complications.
- Impact of psychosocial factors on diabetes self-management.
- Impact of behaviour on diabetes management.
- Interventions to reduce psychological distress and improve self-care, glycaemic outcomes, and quality of life.

Psychological risk factors for developing diabetes

A range of psychiatric and psychological risk factors for type 2 diabetes has been investigated. An umbrella review of 25 systematic reviews of longitudinal epidemiological studies showed that several psychiatric conditions are associated with increased risk of developing type 2 diabetes [1]. The following psychiatric disorders and treatments were associated with an increased risk of incident type 2 diabetes:

- Treatment with antipsychotic medication (odds ratio [OR] 1.93–1.94).
- Insomnia (relative risk [RR] 1.55–1.74).
- Depression (RR 1.18–1.60) and anxiety disorders (OR 1.47).
- Treatment with antidepressant medication (RR/OR 1.27–1.50).

Chapter 65 provides further details on the relationship between common mental disorders and severe mental illness and an increased risk of developing type 2 diabetes.

Psychological risk factors for type 2 diabetes

Several psychological risk factors have been linked to an increased risk of type 2 diabetes. These include general emotional stress, job stress, adverse events in childhood, sleeping problems, anger, and hostility [1–3]. Using data from over 9000 participants in the British Household Panel Survey, Mommersteeg et al. [4] found that, compared to adults reporting a low level of psychological distress, those with higher levels were at a 33% increased risk of developing type 2 diabetes during the 18-year follow-up. Additional analyses showed that this association might be mediated by a low energy level and impaired health status. Both sleep quality and quantity (too much and too little) predict the onset of type 2 diabetes. In a systematic review of 10 longitudinal studies, involving >107 000 men and women without diabetes at baseline [5], short sleep duration ($\leq 5\text{--}6\text{ h/night}$) increased diabetes risk by 28%, while long duration ($>8\text{--}9\text{ h/night}$) increased risk by 48%; difficulty in initiating and maintaining sleep increased diabetes risk by 57% and 84%, respectively [5]. A systematic review of nine longitudinal studies showed

that high baseline job strain (high job demands and low control) was associated with a 16% higher risk of incident type 2 diabetes compared with no job strain (all other combinations), particularly in women (RR 1.48) [6]. Another systematic review investigated whether adverse childhood experiences were associated with a higher diabetes risk. The review included four cohort studies and three cross-sectional investigations. Adverse childhood experience was positively associated with a 32% increased risk of type 2 diabetes. The association was strongest for neglect (pooled OR 1.92) and less strong for sexual abuse (OR 1.39) and physical abuse (pooled OR 1.30) [7]. Chronic emotional stress is common in individuals with a psychiatric condition and might be an important common denominator for the elevated risk for type 2 diabetes.

Most studies have focused on emotional problems or psychological factors as transient states, such as current depression or stress levels. However, if psychological factors have an impact on the development of type 2 diabetes, this is most likely a process over several years. Therefore, personality factors or traits may also play an important role. The role of stress resilience in the onset of type 2 diabetes was investigated prospectively in a national cohort study of 1.5 million male military conscripts in Sweden (from 1969 to 1997) with follow-up over 25 years (from 1987 to 2012) [8]. Stress resilience was assessed using a *gold standard* interview by psychologists (with high inter-rater reliability). Controlling for family history of type 2 diabetes and baseline body mass index, those with low stress resilience were 51% more likely to be diagnosed with type 2 diabetes than those with a greater ability to cope with stress [8]. Chronic stress was associated with a number of unhealthy behaviours (e.g. physical inactivity, unhealthy diet, sleep problems, smoking) as well as activation of the innate immune system (increased interleukin 6 and other cytokine mediators of stress response, which may mediate insulin resistance). A recent systematic review of 10 longitudinal and 13 cross-sectional studies investigated whether various personality characteristics are associated with having, or the risk of developing, metabolic syndrome, but there is conflicting evidence for high hostility, neuroticism, or type D (distressed and socially inhibited) personality as risk factors, possibly reflecting publication bias [9]. Consequently, we need new epidemiological cohort studies with a prospectively published study protocol to further our knowledge about the role of chronic emotional stress, depression and anxiety, and personality traits as risk factors for the development of type 2 diabetes. One example is the Maastricht Study [10], which will investigate not only depression and anxiety, but also various personality factors in relation to type 2 diabetes. Future research also needs to focus on identifying behavioural and physiological mechanisms linking various forms of stress and incident type 2 diabetes.

Psychological risk factors for type 1 diabetes

Psychological stress might be an environmental risk factor for type 1 diabetes. The incidence of type 1 diabetes is increasing by 3–5% per year [11] and researchers are investigating both psychological and environmental risk factors to explain this increase. In their

recent review, Ilchmann-Diounou and Menard [12] hypothesize a role of stress-induced intestinal barrier disruption in the development and/or course of different autoimmune diseases, including type 1 diabetes, multiple sclerosis, and systemic lupus erythematosus. A population-based study comparing 67 young people (aged 0–14 years) with type 1 diabetes and 61 age-matched people without type 1 diabetes showed that type 1 diabetes was more commonly associated with a history of negative life events in the first two years of life, life events with difficult adaptation, child behavioural deviances, and more chaotic family functioning [13]. In the prospective All Babies In southeast Sweden (ABIS) study, 58 out of 10 495 children developed type 1 diabetes, with childhood experience of a serious life event being associated with higher risk (hazard ratio [HR] 3.0; 95% confidence interval [CI] 1.6 to 5.6) [14]. Using register-based data covering all children (>2 million) born in Denmark between 1980 and 2015, Bengtsson et al. found that a larger number of adversities in childhood had a significant but small effect on the risk for type 1 diabetes among women (adjusted HR per adversity increase: 1.07), but not among men (adjusted HR per adversity increase 0.99) [15]. However, caution is needed, because observational data often come with important methodological problems such as selection bias and recall bias. Furthermore, multiple issues can arise in the analytical stage, such as residual confounding and multiple testing error [16].

Psychosocial impact of living with diabetes and its complications

Psychological distress shortly after diagnosis

The term psychological distress refers not only to depressive and anxiety symptoms, but also to diabetes-specific distress. Depression and anxiety are both common mental disorders, while diabetes-specific distress reflects a person's negative emotional response to the burden of living with diabetes, not the presence of a psychiatric condition [17]. Depression, anxiety, and diabetes-specific distress partly overlap, but are not interchangeable constructs.

People with diabetes live with a condition that can shorten their life expectancy, can lead to debilitating complications (e.g. blindness or neuropathy), and requires them to take daily responsibility for managing their condition (e.g. with medications or insulin injections, healthy habits, and careful monitoring of glucose levels) for the remainder of their lives.

Children and their parents

In contrast to expectation, children and adults show remarkable psychological resilience to a diagnosis of diabetes. In what may be the most comprehensive prospective psychological study of children with type 1 diabetes and their families, Kovacs et al. [18] assessed 95 children, 8–13 years of age, shortly after discharge from their initial hospitalization, and followed them for 6–10 years. Within three months of diagnosis, 36% of the children experienced sufficient psychological distress to meet criteria for a diagnosable psychiatric disorder [19]. Most had *adjustment disorder*, defined as a transient reaction that exceeds the normal and expected response to a stressor, which develops within three months of onset of the stressor and lasts no more than six months. The occurrence of such a disorder signals that the child is beginning to come to terms with the diabetes, and can be considered a component of the *mourning process* that often accompanies the development of any chronic

illness [20]. As expected, recovery was rapid, with 93% showing complete remission of psychiatric symptoms within nine months.

Greatly elevated rates of post-traumatic stress disorder (PTSD) have been reported in a prospective study of parents evaluated at 6 weeks, and 6 and 12 months after their child's diagnosis. Depending on the time point, 16–22% of mothers and 8–14% of fathers met Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) criteria for a PTSD diagnosis [21]. These rates were significantly higher than symptoms in the general population, but are comparable with those seen in mothers of children diagnosed with cancer. The best predictor of PTSD severity at 12 months was PTSD severity at 6 months; episodes of hypoglycaemia were also associated with an increased severity of PTSD.

Adults

The onset of type 1 diabetes during adulthood ought to produce similar adjustment disorders within several months of diagnosis in both the individual and partners or close family members. A German study used structured interviews that provided diagnoses according to DSM-IV in a sample of adults (aged 17–40 years) with newly diagnosed type 1 diabetes and compared them with a large reference group, comprising a representative population of 2046 persons of a similar age. People with type 1 diabetes had a rate of major depressive episodes twice that of the reference group (5.8% vs 2.7%) [18]. A more careful analysis showed that these differences were statistically significant only for women with type 1 diabetes (9.3% vs 3.2% in the reference group), with no differences in men (3.6% vs 2.2%) nor for other psychiatric disorders [22]. Studies of adults with type 2 diabetes report mixed findings regarding psychological morbidity in the first year following diagnosis. Interestingly, in the Anglo-Danish-Dutch study of intensive treatment in people with screen detected diabetes in primary care (ADDITION), screening for type 2 diabetes and a subsequent diagnosis of type 2 diabetes had limited psychological impact on newly diagnosed individuals compared to those without diabetes [23]. A meta-analysis demonstrated the prevalence of depression to be higher in adults with diagnosed type 2 diabetes compared to those with undiagnosed type 2 diabetes, impaired glucose metabolism, or normal glucose metabolism [24]. The recent LifeLines study was a large epidemiological study of 90 686 participants who underwent diagnostic psychiatric interviews and had fasting glucose levels measured [25]. In contrast with the earlier meta-analysis [19], LifeLines showed that depression was independently associated with type 2 diabetes, both diagnosed (OR 1.4 [95% CI 1.1 to 1.8]; p = 0.006) and undiagnosed (OR 1.8 [95% CI 1.3 to 2.6]; p = 0.001), while anxiety is independently associated with diagnosed type 2 diabetes (OR 1.4 [95% CI 1.2 to 1.7]; p < 0.001) but not undiagnosed type 2 diabetes [25]. A smaller clinical study of 71 participants reported that >50% expressed no emotional reaction to the diagnosis and felt that they could cope [26].

Psychological reactions emerging in the course of diabetes

Living with and managing diabetes are a complex endeavour. People with type 1 diabetes or insulin-treated type 2 diabetes must take responsibility for administering insulin doses and checking glucose levels (often several times per day), carefully monitoring food intake and physical activity, and then readjusting insulin, food, and/or exercise in response to high or low glucose values or during acute illness. For those with type 2 diabetes not using insulin, the treatment regimen can be less onerous, but adopting and

sustaining healthy lifestyle behaviours can also be burdensome, and having to adjust diet and physical activity to improve outcomes can be frustrating and demoralizing. In either instance, people with diabetes and their families assume primary responsibility for these self-care behaviours, all of which are directed at achieving or maintaining optimal glycaemic levels and quality of life.

Psychological impact among children and adolescents with diabetes

Most children and adolescents with type 1 diabetes function well psychologically as the diabetes progresses, although there may be small increases in depressive and anxiety symptomatology and internalizing behaviours, such as somatic complaints, social withdrawal, and sleep disturbance. In school-aged children [27] this is evident after two to three years of type 1 diabetes, yet the magnitude of these changes does not reach clinically significant psychopathology. Somewhat higher rates of externalizing, or aggressive, behaviours have also been reported, with this phenomenon especially pronounced in boys [27], and strongly associated with persistent hyperglycaemia [28].

Children who report more difficulties in managing their type 1 diabetes also show more symptoms of psychological distress. Levels of psychological distress shortly after type 1 diabetes onset are often a good predictor of psychological problems later [29]. This suggests that it is helpful to assess psychological well-being shortly after diabetes onset and to monitor this routinely thereafter; the utility of monitoring psychological well-being in adolescents with diabetes, for example with the MIND Youth Questionnaire (MY-Q), was confirmed in a randomized controlled trial (RCT) [30, 31]. The frequency of assessments can be adjusted to the needs of the young person with diabetes, and intensified where indicated to guide further clinical actions and initiate stepped care [32].

Disordered eating is a common and clinically relevant problem in young people with diabetes. In a national survey among Danish adolescents with type 1 diabetes, approximately one-third of participants had overeating or binge eating symptoms [33]. Symptoms of binge eating were associated with elevated depression, lower quality of life, higher anxiety, and worse clinical outcomes. Disordered eating and insulin omission are common problems in diabetes, which are frequently overlooked and associated with less optimal glycated haemoglobin (HbA_{1c}) [34].

Marked elevations were found in rates of psychiatric disorder when assessed by a structured psychiatric interview. Not only were girls more often affected than boys [35, 36], but their risk for recurrence of depression was greater. In a cohort of Australian children with newly diagnosed type 1 diabetes assessed over a 10-year period, 37% had at least one DSM-IV diagnosis [35]; of those, 60% met criteria for two or more disorders and 55% met criteria for three or more disorders [35]. Each of mood, anxiety, and eating disorders was present in 17% of the sample and nearly 20% manifested a behavioural disorder. Those adolescents who met criteria for a DSM-IV psychiatric disorder were also more likely to have manifested significant externalizing problems shortly after diagnosis, which were likely to have preceded diagnosis. Maternal psychopathology is a potent predictor of subsequent psychiatric disorder and increased depressive symptomatology in children and adults with type 1 diabetes [37].

Elevated rates of suicidal ideation have been reported for adolescents with type 1 diabetes, with lifetime prevalence rates of ~26% compared to 9–12% for adolescents without diabetes [38]. Although the rate of actual suicide attempts is low among young people with

diabetes (4%), suicidal ideation was associated with greatly increased rates of disengagement from medical treatment.

Relatively little is known about diabetes-specific distress in children and adolescents. Largely this is due to the dearth of appropriate measures for this age group and lack of recognition, until recently, of the potentially important role of diabetes-specific distress. A recent systematic review [39] highlights that only three measures have been developed specifically for adolescents and the prevalence of clinically relevant diabetes-specific distress is estimated to affect around one-third of adolescents. Diabetes distress appears to be associated with higher HbA_{1c} (particularly when age-appropriate measures of diabetes distress are used), although associations with self-care behaviours were mixed [39]. While parental emotional support appears to be associated with lower rates of diabetes-specific distress, neither age nor gender appears predictive of diabetes-specific distress [39]. Importantly, diabetes-specific distress is strongly associated with depressive symptoms [39], suggesting that these constructs are inter-related and perhaps that interventions to reduce diabetes-specific distress may improve the general well-being of adolescents with diabetes.

The International Society for Pediatric and Adolescent diabetes (ISPAD) consensus guidelines [40] emphasize that ‘Mental health professionals should be available to interact not only with patients and families at clinic visits to conduct screening and more complete assessments of psychosocial functioning, but also to support the diabetes team in the recognition and management of mental health and behavior problems. There should also be easy access to consulting psychiatrists for cases involving severe psychopathology and the potential need for psychotropic medications. All mental and behavioral health specialists should have training in diabetes and its management.’

Psychological impact among adults with diabetes

The process of psychological adaptation to the diagnosis of diabetes in adulthood remains incompletely understood, largely because few longitudinal studies have been conducted with adults. The Diabetes Control and Complications Trial (DCCT) [41], the largest prospective study of adults with type 1 diabetes, found no change in self-reported psychological symptomatology over a follow-up period of 6–9 years, and found no relationship between type of treatment (conventional or intensive insulin therapy) and levels of psychological distress [42]. In an early systematic review, rates of clinically significant depression were higher in both treatment groups (25%) compared with rates of depressive symptoms (measured by self-report questionnaire) in the general population (14%) [43].

Cross-sectional studies of adults with either type 1 diabetes or type 2 diabetes have demonstrated repeatedly that rates of psychological distress, particularly depressive symptoms and anxiety, tend to be higher than in the general population, but are usually comparable to those reported in individuals with other chronic conditions [44–46]. Using self-report measures of psychological symptoms, Peyrot and Rubin found greatly elevated rates of both depressive (41%) and anxiety symptomatology (49%), with 38% of their entire sample showing elevations in both domains; however, repeated reassessment of these individuals over a six-month period indicated that these effects are quite unstable [47]. Across all three assessments, only 13% of the sample was persistently disturbed. The strongest predictors of ongoing distress included being female, having less than a high school education, being middle-aged, and having more than two diabetes-related biomedical complications [48]. A longitudinal study in individuals with type 2 diabetes

treated in primary care with three-year follow-up found that 26% met the criterion for depression at one or more assessments [49]. Incident depression was present at follow-up in 14% of those without depression at baseline, and 66% reported recurrent or persistent depression during follow-up. The results also clearly showed that the best predictor of future depressive symptoms is a history of depression [49]. A systematic review of 26 studies, mostly involving adults with type 2 diabetes, concluded that there is a bidirectional longitudinal association between depressive symptoms and HbA_{1c}, with small effect sizes [50].

The concept of diabetes-specific distress emerged in the adult diabetes literature over 25 years ago, with the publication of the Problem Areas In Diabetes (PAID) scale [51]. There was no significant difference in diabetes distress scores among those with type 1 diabetes or insulin-treated type 2 diabetes, and scores were only weakly associated with age and diabetes duration [52]. 60% of study participants reported at least one diabetes-related problem as *serious*, with the top five most frequently endorsed serious problems being:

- Worries about the future and the possibility of serious complications.
- Feeling guilty or anxious when you get off track with your diabetes management.
- Feeling scared when you think about living with diabetes.
- Feeling discouraged with your diabetes regimen.
- Feeling depressed when you think about living with diabetes.

This seminal study also found that diabetes-specific distress was associated negatively with self-care (after adjustment for age, diabetes duration, and general emotional distress) and correlated positively with HbA_{1c}. Various more recent and international studies corroborate these findings [52–54], though it should be noted that few such studies exist in low- to middle-income countries. Elevated diabetes-specific distress is experienced by 20–30% of adults with type 1 diabetes, and is more likely in women and in those with longer type 1 diabetes duration, severe hypoglycaemia, and younger age [55]. While many of the key emotional problems may not discriminate by diabetes type [51], the diabetes distress experienced by adults with type 1 diabetes tends to relate to ‘worries about low blood sugar reactions’ and ‘feeling burned out by the constant effort to manage diabetes’, while that experienced by adults with type 2 diabetes relates more to ‘not having clear and concrete goals for your diabetes care’ and ‘feeling constantly concerned about food and eating’ [55].

Many studies have focused on diabetes distress, but longitudinal studies remain scarce. For example, we do not know whether elevated diabetes distress is associated with an increased risk of developing long-term diabetes-related complications, and little is known about how diabetes distress develops [56]. It is increasingly apparent that the communication style and (unrealistic) expectations of healthcare professionals may increase the diabetes distress experienced by those with diabetes and contribute to its development [56]. Thus, considerable advocacy efforts now focus on the language (words) used in diabetes to ensure appropriate and realistic communication with and about people with diabetes [57, 58].

Psychosocial impact of diabetes-related complications

Psychological reactions to acute biomedical complications

Acute complications of diabetes include diabetic ketoacidosis (DKA; Chapter 41) and severe hypoglycaemia (Chapter 40), both

of which may be rare or recurrent events for an individual, and be influenced by the individual’s personal and treatment characteristics.

The frequency of DKA peaks in adolescence, and recurrent DKA remains an issue among only a minority of adults with type 1 diabetes, largely predicted by intentional insulin omission or disordered eating behaviours. Skinner notes that this is because of feelings of depression, resentment, denial, and rebellion against diabetes [59]. Many interventions have potential depending on the person’s circumstances: changing insulin regimens (including nurse-led injections, insulin pump), cognitive behavioural therapy (CBT), and family therapy are all options. A recent case-control study confirmed that people with type 1 diabetes and recurrent DKA had higher levels of anxiety or diabetes distress, more difficulties with emotion regulation and higher levels of personality dysfunction [60]. An important step in resolving recurrent DKA is a multi-disciplinary approach, with knowledge of the person with diabetes from a psychosocial perspective and, perhaps most importantly, not losing contact with the person experiencing recurrent DKA [59].

Acute hypoglycaemic episodes are often uncomfortable and unpredictable. They are accompanied by autonomic arousal characterized by aversive symptoms such as trembling, sweating, light-headedness, pounding heart, nervousness, feelings of agitation, and worries that this episode could lead to a seizure, coma, or death if not treated promptly. Thus, the development of fear of hypoglycaemia, and the corresponding effort to avoid any situation that may lead to a recurrence of a hypoglycaemic event, is unsurprising and an adaptive psychological reaction. In the second Diabetes Attitudes, Wishes and Needs (DAWN2) study, conducted in 17 countries, 56% of participants with diabetes reported being worried about hypoglycaemic events [61]. Fear of hypoglycaemia is indiscriminate, occurring in children [62] and adults with diabetes [63, 64], but especially in parents [62] and spouses [65], who can be more fearful than the individual, as they are often more acutely aware of its impact, while the person is unconscious with little recall of the event. In the DAWN2 study, 61% of family members of people with diabetes reported being worried about hypoglycaemia [66].

Adults with type 1 diabetes who experience recurrent hypoglycaemia, or even a single episode of severe hypoglycaemia when accompanied by seizure or coma, have greater fear of hypoglycaemia [67]. This can be accompanied by broader diabetes-specific distress and impaired generic emotional well-being [68]. This is likely to be a consequence of several factors, including pre-existing personality traits, particularly neuroticism or trait anxiety, and current level of psychological distress [69]. Recent work has begun to explore the relationship between fear of hypoglycaemia and risk of severe hypoglycaemia, identifying four subgroups (e.g. low fear/low risk; high fear/high risk; low fear/high risk; high fear/low risk), demonstrating the complexity of such fear and the importance of understanding the nature of the fear for determining suitable clinical interventions [70].

A systematic review including 27 studies in adolescents with type 1 diabetes concluded that severe hypoglycaemia was associated with more worries about hypoglycaemia, but was not clearly associated with diabetes distress, depressive symptoms, anxiety symptoms, or disordered eating or post-traumatic stress disorder [71]. More recent, more frequent, and also more severe episodes of hypoglycaemia were associated with adverse psychological outcomes [71]. Another systematic review of 30 studies in adults with type 1 diabetes reported that there was no association between

hypoglycaemia and diabetes-specific quality of life, but also that severe hypoglycaemia was linked to increased fear of hypoglycaemia and higher levels of diabetes distress, and lower general emotional well-being [72]. No associations with depression, anxiety, or health status were found. Self-treated hypoglycaemia was positively associated with fear of hypoglycaemia. Importantly, none of the included studies had investigated the impact of hypoglycaemia on general quality of life [72]. A recent systematic review of longitudinal studies concluded that (recurrent) hypoglycaemia has a negative impact on quality of life in people with type 2 diabetes [73]. Hypoglycaemia is associated with more depressive and anxiety symptoms, and also with impairments of the ability to drive, work, and function in ways that are important for quality of life [74].

In addition to being associated with higher levels of generalized psychological distress, fear of hypoglycaemia may lead people with diabetes, and parents of children with diabetes, to avoid hypoglycaemia by treating falling blood glucose prematurely and hence maintaining blood glucose at higher than optimal levels [75]. Other, much rarer, diabetes-specific fears include fear of injecting or self-testing [76, 77]; the prevalence of a phobia to needles or blood and injury remains controversial, but is likely between 1% and 10% [76, 77].

Psychological reactions to long-term biomedical complications

Several international studies have now demonstrated that worries about the future and the possibility of serious complications are the foremost *problem areas* for people with diabetes [51–54]. This is unsurprising given that long-term complications (such as retinopathy, neuropathy, nephropathy) can have a devastating impact on the individual's health [78]. Due to the emphasis placed on the importance of managing diabetes optimally to prevent complications, their development may also be viewed by people with diabetes, their families, healthcare providers, and others as a sign that they have *failed* to self-manage the condition adequately. Thus, it is reasonable to consider that the onset of complications leads to psychological distress, due to the emotional impact and significance of a new health status, but also to a change in self-perception or identity and to self-blame and guilt. This conjecture has not been tested empirically and it is unknown how adults react psychologically immediately after a complication appears. A systematic review of 22 longitudinal studies concluded that the relationship between depression and diabetes complications is bidirectional [79]. Depression was a stronger predictor of diabetes complications than vice versa. To date, results from meta-analyses [79] have shown that baseline depression was associated with a higher risk of incident macrovascular (HR 1.38; 95% CI 1.30 to 1.47) and microvascular complications (HR 1.33; 95% CI 1.25 to 1.41). Having diabetes complications was associated with an increased risk of developing depressive disorder (HR 1.14; 95% CI 1.07 to 1.21) [79].

People who develop retinopathy, and with it varying degrees of vision loss, experience a range of adverse social impacts (including social isolation, increasing dependence on others, and disruption to family functioning) as well as an array of emotional impacts (including loss of confidence, fear, vulnerability, anger, stress, and depression) [80]. However, the degree of psychological distress secondary to visual loss may not be unique to people with diabetes; at least one study of older adults has reported no significant difference in psychological adjustment between those with and without diabetes, either at the onset of visual loss or when re-evaluated 12 months later [81].

Social stigma and discrimination

Social stigma is a negative social judgement that can lead to perceived or experienced blame, stereotyping, rejection, exclusion of, or discrimination against, a person or group based on a particular feature. The International Diabetes Federation's (IDF) Global Diabetes Plan 2011–2021 advocates that we must 'challenge social stigma and discrimination in the context of diabetes' [82]. In 2013, the first narrative review focused on this topic [83] showed diabetes stigma to be an underexamined but potentially important issue. In-depth exploratory interview studies focused on diabetes stigma among adults [84, 85] showed that more than 80% of respondents reported (without prompting) that they have experienced some form of diabetes stigma and/or discrimination. This led to the development of two novel diabetes stigma assessment scales (DSAS-1 and DSAS-2) to enable studies to quantify the extent and impact of diabetes stigma [86, 87]. These have shown that 25–67% of respondents have been 'blamed and shamed' for developing diabetes and/or its complications – by family, community, media, and health professionals; 77% of adults with type 1 diabetes and 37% of adults with type 2 diabetes indicate that other people judge them for their food choices; and 26% of adults with type 1 diabetes 'feel embarrassed about what people might think' if they need help with a hypoglycaemic episode, while 31% of adults with type 2 diabetes blame themselves for having type 2 diabetes (self-stigma). Comprehensive assessments of correlates and moderators show that diabetes stigma has diverse negative associations with psychological well-being, diabetes self-management, social support, and seeking healthcare support [88–91].

Collectively, this work shows that stigma adds substantially to the burden of living with diabetes. However, further research is needed urgently to identify effective interventions to reduce diabetes stigma, and to advance our understanding of diabetes stigma among culturally and linguistically diverse populations.

Quality of life

Psychological distress has so far been the primary focus of this chapter, but the extent to which diabetes affects an individual's perceived quality of life is also important. Defining and measuring quality of life remains controversial, although it is generally agreed that it is multidimensional (including physical, psychological, and social domains), subjective (domains will vary in importance and relevance for each individual), and dynamic (changing over time) [92]. A useful way to gain insight about this is to ask a person with diabetes 'What aspects of life are important for your quality of life?' and then 'How does your diabetes affect these?' [93].

Generic, health-related quality of life

Most attempts to assess quality of life actually assess health status, or what is commonly (and perhaps confusingly) referred to as *health-related quality of life*, with the two most frequently used measures being the Medical Outcomes Study Short-form 36 (SF-36) and the EuroQol EQ-5D [92]. In people with diabetes, such measures are typically more sensitive to differences between those with and without macrovascular complications or other non-diabetes-related comorbidities [94], or following major procedures such as pancreas transplant [95], than to differences between those with and without microvascular complications or using intensive versus conventional treatment regimens [96]. Large-scale studies comparing the health-related quality of life of people with various chronic conditions have typically found little evidence that it is differentially disrupted in adults with diabetes. For example, when

health-related quality of life was assessed in a large cohort of adults with diabetes using the Medical Outcome Study (MOS-36) questionnaire, people with diabetes reported more problems in physical and social functioning than those without chronic conditions, but tended to function better than people with cardiovascular, pulmonary, or gastrointestinal disorders [97]. For individuals with type 1 diabetes, poorer health-related quality of life is associated with being older, having biomedical complications, being female, being less physically active, and having a lower income [98]. Similarly, among individuals with type 2 diabetes, impaired health-related quality of life was associated with being female, the presence of diabetes-related complications, other non-diabetes-related comorbidities, and duration of diabetes [99].

Nieuwsteeg et al. [100] reviewed 17 studies that compared generic quality of life of children and adolescents with type 1 diabetes with that of their healthy peers. The authors concluded that the weighted effect sizes across all studies indicated no substantial differences in quality-of-life domains between children and adolescents with type 1 diabetes and healthy controls. On the other hand, disease-specific problems were certainly present.

Diabetes-specific quality of life

Diabetes-specific quality-of-life instruments do not enable comparisons between conditions, but they are more likely to be sensitive in measuring the impact of diabetes, and are also more responsive in assessing the consequences of treatment changes than generic or health-related measures [92, 93]. This is because they include domains that are particularly relevant to diabetes, for example dietary freedom, and exclude other domains of less relevance, such as mobility.

The Diabetes Quality of Life (DQOL) measure was the first questionnaire to be developed specifically to assess the impact of diabetes on quality of life [101]. It was designed for use in the DCCT to examine explicitly factors such as satisfaction, impact of diabetes, social and vocational worry, and diabetes-related worry. The DCCT findings suggested that quality of life is unimpaired by type of treatment (conventional or intensive insulin therapy) [102]. The apparently benign experience of being in the intensive-treatment arm of the DCCT (despite more injections, more blood glucose monitoring, and a threefold increase in severe hypoglycaemia) may be a consequence of the greater level of psychological and medical support provided in such clinical trials. Alternately, it may reflect the relative insensitivity of the DQOL measure, which is capable of detecting the impact of major treatments (e.g. pancreatic transplantation) but is less sensitive to the more subtle differences between types of insulin regimen [92, 93].

Another widely used tool to assess diabetes-specific quality of life is the Audit of Diabetes Dependent Quality of Life (ADDQoL) [103]. While healthy adults with type 1 diabetes or type 2 diabetes typically report a good overall present quality of life, they also indicate that the impact of diabetes on their quality of life is negative [103, 104]. In particular, the aspect of life most negatively impaired by diabetes is 'the freedom to eat as I wish', an item that captures eating what, when, how much, or how little the person prefers and, importantly, not having to eat when they do not wish to do so [104, 105]. Diabetes-specific quality of life is typically more negatively impaired for those using insulin compared with other medications, and for those living with one or more long-term complications [103]. However, several randomized trials demonstrate that more flexible and convenient treatment regimens (even when insulin is required) improve diabetes-specific quality of life

compared with treatment regimens that impose more rigidity in terms of timing of medications and meals [105, 106].

The DAWN2 study shed light on the impact of diabetes on quality of life of 1368 adults with type 1 diabetes and 7228 adults with type 2 diabetes from 17 countries [61]. Overall, the impact of diabetes on various dimensions of quality of life was negative, with only 28% reporting a positive impact on at least one of the six life dimensions. A negative impact of diabetes on physical health was reported by 62% of respondents, followed by emotional well-being (by 46%), financial situation (by 44%), leisure activities (by 38%), work or studies (by 35%), and relationships with family and friends (by 21%). Around 40% of respondents reported that their medication routine interferes with their ability to live a normal life [61]. The measure used in the DAWN2 study (the DAWN Impact of Diabetes Profile) has since been validated, and is a brief, reliable, valid, and highly acceptable measure of the impact of type 1 diabetes and type 2 diabetes on quality of life [107]. It was also rated favourably in a study comparing five diabetes-specific measures of quality of life completed by adults with type 1 diabetes in the UK and Australia [108].

De Wit et al. have reviewed the instruments used to assess quality of life in young people with diabetes, identifying five diabetes-specific instruments, each with limited evidence regarding psychometric properties and various issues limiting their application in clinical practice [109]. The Pediatric Quality of Life Inventory (PedsQL) and the KINLD-R appear to be the most suitable instruments, but further research is needed to seek standardization of measurement in adolescents and to establish cross-cultural validity. Boys with type 1 diabetes report better diabetes-specific quality of life than the girls with type 1 diabetes [100]. More recent studies evaluating changes in quality of life associated with the use of continuous subcutaneous insulin infusion (CSII) have been mixed, with some indicating no benefit, while others suggested modest benefit [110], particularly among children and their parents [111]. Optimal metabolic management has sometimes [112], but not invariably [113], been found to be associated with better diabetes-specific quality of life in adolescents.

Age at onset of diabetes may also affect certain aspects of life quality. An early survey found that adults diagnosed with type 1 diabetes before 9 years of age were more satisfied with their marriage, and were more likely to have children than those diagnosed later [114]. The authors suggest that individuals diagnosed earlier in development may be more adept at integrating the condition as part of their lifestyle, and thus find less disruption from diabetes later in life. More recent work also suggests that the linkages between marital satisfaction, higher levels of diabetes-related satisfaction, and better glycaemic levels may reflect better psychosocial adaptation to a variety of illness-related and marital role stresses and strains [115]. Among older adults (mean age 81 years), the aspects of life most negatively impaired by diabetes are independence and dietary freedom [116].

Impact of psychosocial factors on diabetes self-management

The relentless need for self-care, lack of immediate reward, unpredictability of blood glucose levels, and the feelings of guilt, anxiety, and failure that a person can experience when blood glucose levels are suboptimal (or unexplainable) can cause diabetes-specific distress, and may adversely affect general mood and

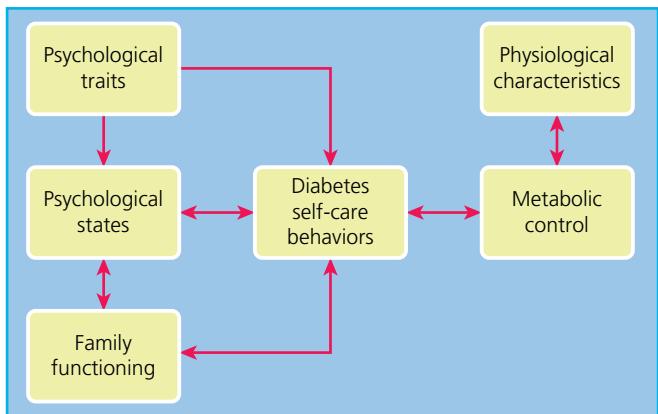

Figure 63.1 A systems model of the relationships between psychological, social, behavioural, and glycaemic factors.

emotional well-being. Conversely, certain personality traits or coping styles that are intrinsic to an individual's psychological make-up may modulate the person's ability to manage diabetes self-care activities, as may environmental and psychosocial factors, such as peer pressure to engage in certain 'forbidden' activities, disruptive interpersonal conflicts, and the normal stresses and strains of everyday life. Overall, an individual's *psychology* may influence, and be influenced by, the process of diabetes management.

According to a systems model of health, there is no simple direct relationship between any single psychological variable and glycaemia [117]. Rather, health outcomes are determined by a system of reciprocal relationships among multiple psychological, behavioural, and physiological variables. Figure 63.1 shows one such model of this process. Psychological *traits* are relatively enduring characteristics that include personality, temperament, and coping style. These may have an indirect impact on glycaemic levels, via their impact on self-care behaviours and emotional state. Psychological *states*, such as stress, are more transitory, reflecting emotions at a given point in time. These may influence glycaemic levels directly via the autonomic nervous system, or indirectly by affecting the individual's self-care behaviours. Both family interactions and self-care behaviours may affect, and be affected by, the individual's mood or level of stress. Family functioning, including conflicts and degree of family cohesiveness, can affect psychological state (and vice versa), but can also influence self-care behaviours. Self-care behaviours include medication use, diet, exercise, and monitoring, and these behaviours serve as the primary final common pathway to glycaemic levels.

Psychological traits and glycaemic state

Early psychological research in diabetes focused on the influence of personality traits, and found that glycaemia is more likely to be optimal in individuals with certain personality characteristics such as a strong need for achievement and a high level of responsiveness to social demands [118]. By contrast, glycaemia tends to be worse in those who are opportunistic and alienated [119], or who have poor impulse control, a propensity for self-destructive behaviours, and difficulty maintaining interpersonal relationships [120]. A systematic review described that, in addition to genetic factors, several psychological constructs such as depression, lethargy, distress, disordered eating, anxiety, and family conflict were associated with

higher HbA_{1c} in people with type 1 diabetes [121]. In adults with type 2 diabetes, higher neuroticism levels are associated with better glycaemic levels, suggesting that moderate levels of worry may be needed to motivate these older adults to manage their diabetes [122]. Furthermore, adults with type 2 diabetes and type D personality, defined as high negative affect coupled with high social inhibition, report more barriers to medication use and are less likely to eat healthily or to consult health professionals when problems with diabetes management occur [123].

Coping styles, broadly categorized as emotion focused and problem focused [124], serve to modulate the individual's response to stressful situations. Emotion-focused or cognitive coping attempts to reduce threats from the environment by reinterpreting or reappraising the situation ('Stay calm, it really cannot hurt you'). Problem-focused coping, in contrast, seeks to change the environment and thereby eliminate the threat. Within each of these categories, specific behavioural strategies may be differentially effective. Some may actually exacerbate stress (e.g. emotion-arousing strategies that include anger, impatience, or anxiety), while others (e.g. stoicism) may reduce or *buffer* the effects of stress [125]. In adolescents with type 1 diabetes, an emotion-focused coping style (e.g. behavioural and mental disengagement; aggressive coping) is associated with suboptimal glycaemic levels and reduced diabetes-specific quality of life, whereas active coping strategies (directed at approaching and making a direct effort to change the situation causing psychological distress) are linked to better glycaemic levels [126]. A meta-analysis of 21 studies has shown that the use of approach coping is associated with both better overall psychological adjustment and with somewhat better glycaemia [127].

Two recent reviews indicate that positive psychological characteristics (e.g. optimism, self-efficacy, and resilience) from childhood through to adulthood are consistently associated with optimal glycaemic levels, fewer diabetes-related complications, and reduced mortality rates [128, 129]. The mechanisms mediating these associations may include behavioural factors (e.g. medication taking, healthy eating) as well as reduced inflammation, and improved neuroendocrine and autonomic functioning.

Psychological states and glycaemic state

Another psychological state worthy of consideration is emotional stress. Stress stimulates the release of several stress hormones to mobilize energy to enable the *fight-or-flight* response. However, in people with little or no endogenous insulin production, stress-induced increases in blood glucose cannot be metabolized properly. Thus, environmental stress and the individual's emotional reaction have impacts on glucose management. A review by Buchberger et al. demonstrated a positive relationship between anxiety and HbA_{1c} in adolescents with type 1 diabetes [130].

The complexities of demonstrating the relationship between stress and glycaemia are exacerbated by the many variables that influence the generalizability of findings [131, 132]. Studies have been conducted in children, adolescents, and adults with type 1 diabetes or type 2 diabetes. Stressful experiences have been documented in self-report studies using simple checklists, validated questionnaires, or in-depth interviews, or in experimental studies with exposure to an array of stressors (mathematical problems, video games). The duration of exposure may be influential and the major limitation of such studies is that they do not necessarily reflect real-life stressors. Real-world stress can be caused by trauma, threat, major life events (e.g. bereavement or losing a job), chronic stressors (e.g. long-term unemployment or carer responsibilities),

or other day-to-day *hassles* (e.g. work, finances, relationships, exams, noise, illness, surgery). Furthermore, individuals perceive stressors in different ways, either as negative (e.g. death, financial problems) or positive (e.g. birth of a child, marriage). Exactly how stress affects glycaemia remains controversial and few empirical studies have been conducted [131, 132]. A five-year prospective study of 132 adolescents, using longitudinal growth curve modelling, found that stressful life events (reported annually) predicted greater psychological distress, and suboptimal self-care and glycaemic levels [133]. The effect was stronger in older adolescents and that the effect of stress on glycaemia was likely mediated by self-care behaviours.

Family characteristics, interactions, and glycaemia

Diabetes can dramatically disrupt the entire family, particularly when the individual with diabetes is a child or adolescent [134]. Children, especially younger ones, are more likely to have optimal glycaemic levels when their parents take an active role in managing their diabetes, whereas for adolescents, shared management responsibilities with parents typically results in more favourable outcomes [135–137]. A systematic review showed that family conflict is associated with higher HbA_{1c} [138], while a higher level of social support from family and friends was predictive of better dietary self-care [139]. Conversely, suboptimal glycaemic levels in children and adolescents is predicted by higher maternal trait anxiety levels [140], lower parental intelligence [141], greater levels of family stress, more family conflict and less family cohesion [142], and sociodemographic variables (e.g. single-parent households) [143]. In adults with diabetes, better marital satisfaction is associated with better diabetes-related quality of life [115, 144] and less diabetes-specific distress [115].

The relationship between family characteristics and glycaemia in children is most likely mediated via a behavioural pathway whereby family conflicts disrupt planning and performance of diabetes management activities; this pattern has been supported by a large prospective study [142]. A web-based portal has been developed that supports parents of children with type 1 diabetes, with online parent–professional communication, peer support, and information about diabetes [145]. The intervention did not reduce parenting stress [145].

Impact of behaviour on diabetes management

Historically, the terms *concordance*, *adherence*, and *compliance* have been used interchangeably to refer to the extent to which an individual simply follows their diabetes management regimen or plan, so-called *doctor's orders*. This model is now referred to as the *acute care model*. In recent years there has been a shift from the acute care model to chronic care models, and in terminology from *adherence* to *engagement* in self-care [146]. Chronic care models acknowledge the following:

- Almost 100% of diabetes care is self-care by the person with diabetes; only a few hours per year are spent with health professionals.
- Diabetes self-care is behaviourally complex. It can be helpful for healthcare professionals to consider diabetes self-care (e.g. taking insulin or other medications, glucose monitoring, eating healthily, counting carbohydrates, and maintaining physical activity) as a series of balls that need to be juggled, while balancing on a beam

that represents life and all its competing demands (e.g. work, family, social life). If, from time to time, one or more balls are dropped, it is not something to be criticized or viewed as a character flaw, but rather it is because juggling all day, every day is challenging, tedious, and ultimately exhausting.

- Clinicians can offer advice, but optimal outcomes are dependent on the person with diabetes being fully engaged in adopting and sustaining the self-care behaviours. Only the person themselves is in a position to know what self-care activities are appropriate, possible, and sustainable in their unique living situation [147].
- The degree to which one *follows* a diabetes regimen cannot be determined easily, because there is no standard against which the person's actual behaviour can be compared. For example:
 - Few clinicians provide a written management plan that specifies all aspects of diabetes care.
 - Recommendations often differ between clinicians, and the extent to which the clinician has communicated clearly in the consultation or the extent to which the person agrees with the regimen discussed is often unclear [148].
 - As it is the person with diabetes, and not the healthcare professional, who is responsible for nearly all diabetes care, increasingly these outdated terms (concordance, adherence, compliance) and gross oversimplifications of the realities of living with and managing diabetes are being replaced with the question of the extent to which a person with diabetes *engages* in various self-care behaviours [146].
- Not all self-care activities are equal in value in terms of their relative effectiveness for optimizing glycaemia. Furthermore, certain self-care behaviours are far more likely to be maintained than others:
 - The international DAWN2 study demonstrated that taking medications as recommended and having a healthy diet are more common than self-monitoring of blood glucose and physical activity, and that engagement in these activities varies across countries [61].
 - Specific self-care behaviours are sometimes [149], but not invariably [150], related to glycaemic outcomes.

Behavioural factors: self-monitoring of blood glucose

Self-monitoring of blood glucose ought to be a particularly salient self-care activity. A large medical registry study of 24 312 adults with diabetes found that those with type 1 diabetes who self-monitored ≥3 times daily subsequently had HbA_{1c} values that were 1% (11 mmol/mol) lower than those who monitored less frequently [151]. For adults with type 2 diabetes using oral medication or insulin, monitoring at least daily was associated with a statistically and clinically significant reduction in HbA_{1c} (0.6% [7 mmol/mol]) [151]. For adults with type 2 diabetes not using medications (for whom there was no clear recommendation regarding glucose monitoring frequency), there was a statistically significant HbA_{1c} reduction (0.4% [4 mmol/mol]) compared with those not monitoring at all [151].

Other studies have provided less positive results. For example, a clinical trial comparing continuous glucose monitoring (CGM) with blood glucose monitoring found a difference in HbA_{1c} (0.5% [6 mmol/mol]) at 26 weeks favouring CGM in adults aged 25 years or older, but no difference among those aged 15–24 years or 8–14 years [152]. Use of CGM averaging six or more days per week was 83% in the adult group, 30% in the young adult group, and 50% in the paediatric group. These data indicate that active use of the

CGM device is crucial in achieving improved glycaemia, and that further work is needed to determine barriers to effective use.

In adults with type 2 diabetes not using insulin, the value of blood glucose monitoring is more controversial. A systematic review and a meta-analysis concluded there is little clinical benefit from blood glucose monitoring in this group [153, 154]. However, these reviews combined studies with considerable variation in trial design and implementation of blood glucose monitoring (education, frequency, and follow-up action) and it is unsurprising that little benefit was found *on average* [153–156]. Simply monitoring blood glucose values, and not using that information to adjust insulin or oral medications frequently and systematically, has little meaningful impact on long-term glycaemia; however, the reviews also suggest that there is considerable benefit to be derived by individuals who are motivated to monitor [155, 156]. A more recent clinical trial in adults with non-insulin-treated type 2 diabetes demonstrated that a structured approach to monitoring (incorporating these steps) indicates that blood glucose monitoring offers both clinical benefits (i.e. reduced HbA_{1c}, particularly in those following the protocol as intended) [157] as well as improved emotional well-being and confidence in diabetes self-care [157, 158].

It is noteworthy that blood glucose monitoring has no dose-response and is not an active agent (i.e. the mere act of checking blood glucose levels cannot reduce HbA_{1c}). Indeed, while blood glucose monitoring is often considered as a single self-care activity among many others, it is actually just one aspect of a complex intervention with multiple facets, including the following:

- Agreement on glucose targets between the person and their health professional.
- Discussion of people's motivations and associated beliefs about the necessity of but also their concerns regarding blood glucose monitoring.
- Timing and frequency of blood glucose monitoring.
- A supportive health professional trained in interpretation of glucose monitoring patterns.
- Appropriate training and feedback for the person with type 2 diabetes.
- Collaborative review of glucose monitoring patterns to identify areas for improvement and what may have contributed to the readings.
- A plan for how to change diet, physical activity levels, or medication.
- Behavioural change: modifying diet, increasing physical activity, or changing medication regimen.

Methodological issues in self-care assessment

The generally weak relationship between self-care behaviours and glycaemia remains problematic for any model purporting to predict successful diabetes management. This could reflect the possibility that HbA_{1c} is not the most appropriate glycaemic measure, but it is more likely that the unexplained variance in glycaemia reflects unspecified physiological or situational characteristics, as well as the difficulties inherent in measuring various self-care behaviours [159]. A review of 23 studies found that better medication taking was associated with lower HbA_{1c}, and this was a stronger relationship when medication taking was characterized in terms of prescription refills (78%; 7 of 9 studies) than when self-report (subjective) measures were used [160]. As self-care is typically assessed by asking people to describe their behaviour, rather than by direct observation, it is possible that self-reports may exaggerate or otherwise misrepresent the extent to which the

person with diabetes performed a particular self-care behaviour [159]. Furthermore, self-care questionnaires typically ask the person to report on their average behaviour over the past week (or few weeks), whereas HbA_{1c} reflects average blood glucose over the past 8–12 weeks. Thus, *average* behaviours may be too crude and the two time periods are likely incompatible with a strong relationship. Finally, other factors such as stress, dietary behaviours, physical activity levels, hormonal changes, and other medications can affect blood glucose such that they may have an (unmeasured) influence on HbA_{1c}.

Interventions to reduce psychological distress and improve self-management, glycaemic outcomes, and quality of life

Reducing depression and diabetes distress

The treatment of depression among people with diabetes is both necessary and effective. A systematic review and meta-analysis of 14 RCTs involving 1724 adults with type 1 diabetes or type 2 diabetes demonstrated that treatment (psychotherapy, pharmacotherapy, or collaborative care) is effective in reducing depressive symptoms [161]; of the various treatment options available, the effect was greatest for psychotherapeutic interventions (Cohen's $d = 0.58$). CBT appears to be particularly promising in reducing the severity of depressive symptomatology. CBT trains individuals to use problem-solving strategies to reduce stressful situations and to use cognitive techniques to *think away* their distorted beliefs, and replace them with more accurate and adaptive thoughts. Van Bastelaar et al. tested a web-based, diabetes-specific treatment of depression that was based on the principles of CBT, showing that this intervention reduced both depression and diabetes-specific distress [162]. A meta-analytical review of 13 RCTs on the efficacy of eHealth interventions in supporting the psychological and physical well-being of adults with type 1 diabetes or type 2 diabetes showed benefits for HbA_{1c} and depressive symptoms, although the effect on HbA_{1c} was not maintained [163].

Another effective treatment approach is mindfulness-based cognitive therapy (MBCT). MBCT is an eight-week protocolized therapy programme that can be delivered in groups or individually. MBCT combines meditation exercises with elements of cognitive therapy. The main goal of this intervention is the cultivation of mindfulness, which is the self-regulation of one's attention focusing on direct experience, while adopting an open, curious, and accepting attitude towards these experiences, especially one's psychological processes, such as thoughts and feelings. A systematic review of nine RCTs concluded that mindfulness-based interventions are effective in reducing depression, anxiety, and HbA_{1c} in people with diabetes [164]. Few studies have focused specifically on reducing diabetes-specific distress, though many intervention trials have included diabetes distress as a secondary outcome [56]. A systematic review of 41 such trials involving 6650 adults with type 1 diabetes or type 2 diabetes demonstrated no overall effect of intervention on diabetes distress [165]. Where diabetes distress was reduced, this was most likely to occur when the intervention was psychoeducational in nature, involving at least six sessions, over at least three months' duration, and delivered by a generalist rather than a mental health professional [165]. Further intervention studies focused specifically on the reduction of diabetes-specific distress are needed.

Importantly, people with diabetes do not necessarily want more access to specialist mental health services, but rather they prefer to discuss the impact of diabetes on their emotional and mental health with their diabetes healthcare professionals [166, 167]. Thus, in recent years an evidence-based practical guide was developed in Australia to enable healthcare professionals to develop their skills and confidence to have such conversations [168]. Adaptations have been made freely available for UK and US health professionals by Diabetes UK and the American Diabetes Association [169, 170], and the diabetes distress chapter is available in Danish from the Steno Diabetes Center Copenhagen.

Empowerment-based approaches

The *empowerment* approach encourages clinicians to understand what living with diabetes is like from an individual's perspective and to enable people with diabetes to take personal responsibility for their health, making self-selected choices about self-management [147, 171]. Embracing empowerment requires a paradigm shift on the part of clinicians to a position where they acknowledge that the person with diabetes is in control of, responsible for, and ultimately lives with the consequences of their own diabetes care. Knowledge is the cornerstone of empowerment. Empowerment programmes also aim to improve the person's ability to identify and set realistic goals, apply problem-solving strategies to overcome barriers to those goals, develop more effective coping strategies in general, manage stress more effectively, increase social support, and improve self-motivation. Empowerment occurs when the healthcare professional's objective is to enable the person with diabetes to make autonomous, informed decisions, and when the person with diabetes is doing so [171].

The theoretical argument is compelling and a review of qualitative studies describes positive experiences in using the empowerment approach [172]. However, surprisingly few trials have been conducted. Results from an early RCT demonstrated that when following a six-week empowerment programme, adults with diabetes showed a significant decline in HbA_{1c} as well as an increased ability to set goals, manage stress, obtain external support, and make decisions about diabetes management [173]. The limitations of this study include the short-term follow-up (six weeks post-intervention) and small sample ($n = 64$), which was highly educated (77% college education, 84% diabetes education). Other trials of person-centred consultation approaches have had less positive outcomes overall. For example, in a randomized trial involving 250 adults with newly diagnosed type 2 diabetes, in which clinicians in the intervention arm received 1.5 days' theoretical and practical training in person-centred consulting skills, the intervention group reported significantly better communication with the doctor, greater treatment satisfaction, and better psychological well-being than the control group [174]. However, there was no impact on glycaemic levels and cardiovascular risk increased, prompting the authors to urge caution that 'Professionals committed to achieving the benefits of patient-centred consulting should take care not to lose focus on disease while paying attention to the unique experience of illness of each patient' [174].

However, there is growing evidence and recognition of the role that language plays in how people think and feel about their diabetes [175]. The words we use to describe diabetes, people with diabetes, and the way in which it is managed have the power to motivate, elevate, and support or, conversely, to upset, demotivate, and harm. It is incumbent on all of us, as healthcare professionals, researchers, or policy makers, to ensure our language is neutral, non-judgmental,

fact based, and free from stigma. It is important to use respectful, inclusive language that is person centred and strengths based (i.e. focused on positive attributes and what a person can do, rather than what they cannot do or have not done). In the past decade, numerous diabetes associations, health organizations, and groups of people with diabetes around the world have published position statements to demonstrate that #LanguageMatters. These include statements from Diabetes Australia, the International Diabetes Federation, the American Diabetes Association and Association of Diabetes Care and Education Specialists, NHS England, and Diabetes Canada, as well as from France, Italy, India, and Brazil.

Structured training and educational approaches

The education of people with diabetes has evolved from didactic information-giving ('obedience training to follow dietary prescriptions' [176]) one to one or in large groups, to theoretically driven, evidence-based, structured training in small groups, in which people with diabetes are able to talk with diabetes educators (nurses/dieticians) and their peers about their diabetes and problems with self-care, and learn the knowledge and skills they need for a life with diabetes (Chapter 26). This approach began in Germany in the 1980s, with the structured diabetes teaching and treatment programme developed by Michael Berger and Ingrid Mühlhauser, where several trials demonstrated the effectiveness of flexible, intensive insulin therapy for improving glycaemia in people with type 1 diabetes without increasing severe hypoglycaemia [176] (unlike the intensive treatment approach adopted in the DCCT [41]). In the UK, this approach was adopted as the Dose Adjustment For Normal Eating (DAFNE) programme, where an RCT demonstrated for the first time the unique combination of benefits for both biomedical and psychological outcomes [105]. Several studies have demonstrated sustainability of outcomes over the long term [177] and successful implementation in the real world [178, 179], while qualitative research has highlighted where the programme can be improved [180], and this is now the focus of further research (DAFNEplus) in the UK. The DESMOND programme offers a range of structured training sessions for people with newly diagnosed or ongoing type 2 diabetes, with RCTs demonstrating greater improvements in weight loss, smoking cessation, and beliefs about illness, although no benefit for glycaemia up to 12 months after diagnosis [181]. Three years later HbA_{1c} had improved in both groups, but no differences were observed between those receiving DESMOND or control intervention in any biomedical or psychological outcomes [182]. Importantly, improvements in four out of five health beliefs were sustained [182], and these were predictive of psychological distress at three years, indicating the importance of early formative experiences around diagnosis, and in terms of education provision and health provider support [183].

Programs have also been developed that teach those using insulin to recognize and anticipate blood glucose fluctuations to enable them to prevent extreme high and low levels, and reduce their fear of hypoglycaemia. A review demonstrated that the benefits of the face-to-face Blood Glucose Awareness Training (BGAT) programme, developed in the USA, can be substantial. There was a 57–92% reduction in severe hypoglycaemic events, a 65–86% reduction in driving mishaps, a 10–51% improvement in hypoglycaemia awareness, and a 6–21% reduction in fear of hypoglycaemia [184]. Several studies have been limited by small sample sizes, and by a focus on skills acquisition (estimation of blood glucose) rather than clinically important outcomes, such as severe hypoglycaemia. The German

face-to-face programme HyPOS has also demonstrated improved awareness of hypoglycaemia and reduced frequency of severe hypoglycaemia in a fully powered RCT [185]. The results of a new trial where BGAT is compared to a new intervention that addresses cognitive barriers to hypoglycaemia avoidance were published in 2019 [186]. The study was conducted in adults with type 1 diabetes and problematic hypoglycaemia, and outcomes include severe hypoglycaemia rates, hypoglycaemia awareness status, overall diabetes management, and quality of life [186].

Technological approaches

Advanced technologies for insulin delivery (e.g. predictive low glucose suspend pumps) and real-time continuous glucose monitoring (RT-CGM) have improved dramatically in recent years, and have the potential to reduce HbA_{1c} and fear of hypoglycaemia, and to improve quality of life [187]. In the first large-scale trial of sensor-augmented pump therapy in 485 adults and children with type 1 diabetes, over a 12-month follow-up sensor-augmented pump therapy offered significant advantages in terms of reducing fear of hypoglycaemia in adults and parents of children, as well as improving treatment satisfaction in adults, children, and parents [188]. However, such devices are expensive and require uninterrupted use, which many users find too burdensome. A 12-month observational study of sensor-augmented pump therapy in 15 countries in Europe and Israel found that improvement in HbA_{1c} was associated with more frequent sensor use [189]; average sensor use over 12 months was 30% (range 0–94%) and sensor use decreased with time (37% over the first three months, 27% over the final three months). For those with recurrent severe hypoglycaemia and its debilitating impact on quality of life, the adoption of technology into everyday management seems an obvious option. However, a clinical trial demonstrated that insulin pumps and RT-CGM offered no added benefit over multiple daily injections and standard finger-prick blood glucose monitoring for reducing severe hypoglycaemia, time spent in hypoglycaemia, or fear of hypoglycaemia, with the insulin pumps offering an advantage in terms of greater treatment satisfaction [190].

Most recently, the impact of *closed-loop* (artificial pancreas) technology has been investigated overnight in the home setting. Semi-structured interviews with 15 adolescents with type 1 diabetes using the technology and 13 parents demonstrated several perceived benefits (e.g. reassurance/peace of mind, confidence, time off from diabetes demands, safety, and improved glycaemic control) as well as disadvantages (e.g. difficulties with calibration, alarms, and size of the devices, and mixed effects were found on fear of hypoglycaemia) [191]. Semi-structured interviews with 24 adults using the technology have demonstrated similar positive and negative themes [192]. Although diabetes technologies have advanced considerably in the past decades, routine psychosocial assessment has not kept up with these new technologies. Although there is evidence supporting the use of CSII and CGM and, to a lesser degree, automated insulin delivery in terms of psychosocial outcomes, little is known about the barriers and facilitating factors regarding diabetes technology uptake [193].

Cognitive behavioural approaches to improve outcomes

Several meta-analyses have reported that psychological or psychotherapeutic interventions have modest effects in reducing psychological distress and improving glycaemia [194–196]. Traditional individualized and group therapy provides emotional support for

both children and adults with diabetes, and may be particularly beneficial for those who are confronting the development of complications. When a time-limited, problem-oriented individualized treatment was compared with standard insulin treatment counselling in adults with type 1 diabetes, those receiving psychotherapy showed greater reductions in both problem severity and HbA_{1c} [197].

Coping skills training programmes are effective in improving the diabetes management skills of adolescents treated with intensive insulin therapy [198]. Based on a cognitive behavioural skills-building model, coping skills training presents participants with a series of social situations that are particularly problematic for adolescents, and asks them to demonstrate how they would resolve that situation (e.g. manage food choices with friends). As implemented by Grey et al. [198], groups of two to three adolescents role-play each scenario with a highly trained group leader who provides correction and models appropriate coping behaviour. Six weekly sessions lasting 60–90 minutes followed by monthly visits are typical for a training programme. Over a 12-month follow-up period, adolescents randomized to coping skills training plus intensive diabetes management had significantly lower HbA_{1c} (7.5% vs 8.5% [58 vs 69 mmol/mol]) and reported better self-efficacy as well as less difficulty in coping with diabetes and less depression when compared with adolescents who received intensive diabetes management alone [136].

Peyrot and Rubin [199] discuss the utility of including both problem-focused and emotion-focused interventions as part of an integrated behaviour change support programme. According to their model, interventions must occur in a particular sequence of five steps:

1. Specify the person's problem.
2. Translate the person's intentions to change into concrete, attainable goals.
3. Collaborate with the person to identify barriers to reach those goals and formulate effective strategies.
4. Establish a *contract* with the person to meet, or approach, those goals.
5. Provide continuing support.

This framework makes much sense from a clinical perspective. The extent to which such an approach is successful in initiating lasting clinically significant changes in mood, behaviour, and glycaemic control is likely to be dependent on the problem, the person, and the relationship with health professionals, but it is certainly an approach worth evaluating in formal clinical trials. Arguably, this was the basis of the Comparison of Optimised MDI versus Pumps with or without Sensors in Severe Hypoglycaemia (HypoCOMPASS) study, which demonstrated prevention of severe hypoglycaemia and reduced fear of hypoglycaemia in a six-month RCT [190]. A systematic review and meta-analysis of 12 RCTs concluded that CBT improved short- and medium-term HbA_{1c}, but no significant effect was found in the long term [200]. CBT also decreased anxiety and depression (short and medium term) and long-term depression, while conflicting results were reported for diabetes-specific distress and quality of life [200].

Psychotherapeutic and family-focused approaches

Several behavioural and psychological interventions have been developed to improve engagement in self-care among people with diabetes [199, 201]. These differ from more traditional group therapy programmes in so far as they use several sessions to target one or more self-care behaviours and the psychological factors that may

interfere with optimal self-care. A typical self-management programme may meet once or twice monthly for seven or more sessions, discuss specific self-care strategies (e.g. glucose monitoring, physical activity), role-play appropriate behaviours, use homework assignments to practise what has been learned, and resolve problems or barriers encountered during diabetes management. Variations on this basic theme include the use of 6- or 12-monthly *booster* sessions after the end of the programme, which are designed to review and reinforce previously learned material. Interventions developed initially for people without diabetes with high levels of psychological distress are increasingly being applied to persons with diabetes, and both CBT and *motivational interviewing* [202, 203] or *motivational enhancement therapy* [179] programmes have led to modest improvements in HbA_{1c} and in self-reported quality of life.

Family-focused behavioural interventions are particularly successful in improving diabetes management in children. In one of the largest studies of its kind, Wysocki et al. randomized 119 families of adolescents to either 10 sessions of behavioural family systems group therapy, 10 sessions of an education and support group, or standard diabetes therapy (with minimal psychological support) [204]. Behavioural family systems therapy included four modules:

- Problem-solving training, which focused on conflict resolution.
- Communication skills training.
- Cognitive restructuring to identify and change those attitudes and beliefs that impede effective communication.
- Specialized family therapy interventions.

In the 12 months following treatment, adolescents who participated in behavioural family systems therapy showed long-term improvement in relationships with their parents compared with adolescents in the other two treatment groups, and also manifested improved adherence to their diabetes management regimen,

although these behavioural and psychological changes were not associated with improvements in metabolic control [205]. Similar interventional approaches have also been applied to older adults with type 2 diabetes and, as is the case with children and adults with type 1 diabetes, there are reductions in psychological distress and occasionally, but not invariably, small improvements in long-term glycaemia [206].

Conclusion

Diabetes is a behaviourally, psychologically, and cognitively demanding chronic condition. One of the greatest problems facing people with diabetes is the failure, or inability, of many clinicians to empathize with how challenging it is to live with the daily self-care demands of a condition like diabetes, to identify those experiencing psychological distress quickly, and to provide appropriate support. From this chapter, it is clear that people with diabetes have a remarkable level of psychological resilience but, like anyone else, they may experience psychological distress, made more likely by having to cope daily with the demands of living with a chronic condition. It is evident that the behavioural changes needed for optimal self-management are unlikely if the person lacks the prerequisite information, motivation, and/or behavioural skills. Furthermore, such changes are unsustainable if they cannot be incorporated into the person's lifestyle, if they compromise their quality of life, and/or if they are not supported by family/friends and healthcare professionals. It is incumbent on all members of the healthcare team to recognize the complex psychosocial impacts of diabetes and to continue to develop better ways of delivering healthcare and support in order to alleviate distress, improving both biomedical health outcomes and quality of life.

Role of Cognitive Function in Managing People with Diabetes

Tamsin Santos, Chelsea Baird, Sally Eastwood, Kerrie Shiell, and Joseph E. Ibrahim

Queen Elizabeth Centre, Ballarat Health Service and Department of Forensic Medicine, Monash University, Melbourne, Australia

Key points

- Cognition refers to a range of mental processes or thinking skills, which help us to acquire knowledge and understanding through thought, experience, and sensation.
- Adults with type 1 diabetes may have impairments in multiple cognitive domains, including attention (visual and sustained), visual perception, processing speed, and executive function (concept formation, cognitive flexibility, and anticipation). The cognitive domain of memory as well as learning can be spared.
- Type 2 diabetes is associated with declines in the cognitive domains of executive function, processing speed, memory, and language (verbal fluency).
- Clinicians should screen older individuals with diabetes for cognitive impairment using a standardized test.
- A formal diagnosis of dementia is needed to develop a tailored management plan.
- It is important to consider and evaluate mood for comorbid depression.
- People with diabetes and declining cognitive function are at greater risk of both hyperglycaemia and hypoglycaemia due to difficulties with learning and retaining new knowledge and an inability to recognize the importance of self-care.
- The presence of dementia must be integrated into decisions and care planning; however, it should not detract from seeking to achieve optimal management.
- Re-evaluating glycaemic management plans should occur at least annually. This should be a comprehensive assessment, taking into account cognitive screening performance and lived experience.
- Polypharmacy is common in older adults and increases risks for drug interactions, medication errors and omissions, falls, and cognitive impairment. Medication management including regular review and appropriate de-prescribing is essential for optimal care in people as they grow older and have chronic disease and dementia.
- Social isolation is a risk factor for cognitive decline and dementia. Social support for individuals with diabetes and dementia is important. Education and support for carers are needed.

The role of cognition and the impact of cognitive impairment in sustaining self-care in people with diabetes are both under-recognized and underappreciated. Physicians often fail to identify cognitive impairment in as many as 56% of individuals [1]. As a result, these people do not receive adjustments in their treatment plan to compensate for their cognitive abilities. With an ageing society and the increasing prevalence of multimorbidity, it is crucial for clinicians to understand the nature and impact of cognitive impairment to manage their chronic health conditions successfully.

Type 1 diabetes accounts for about 5–10% of all people with diabetes [2] and although life expectancy is still shorter than those without diabetes, people with type 1 diabetes now live much longer than they did three decades ago. This prolonged lifespan puts them at risk of developing dementia [3]. The risk ratio for dementia in inpatients with type 1 diabetes is 1.65 times more than in people without diabetes [4] and people with type 2 diabetes are almost twice as likely to develop dementia [5].

This chapter begins by describing and defining cognition function, then addresses the nature of dementia and the associations

between diabetes and dementia. The second half of the chapter presents four case studies to demonstrate the application of this new knowledge of theory and principles into clinical practice.

Cognition

To fully appreciate cognitive impairment in its many forms, the clinician must first develop an understanding of cognition.

Definition of cognition function

In broad terms, cognition refers to a range of mental processes or thinking skills, which help us to acquire knowledge and understanding through thought, experience, and sensation [6]. These skills have been characterized in various ways, but commonly fall into six cognitive processes or domains:

- Attention
- Processing speed
- Visual perception

- Memory
- Language
- Executive function [7].

Attention involves the brain's ability to allocate cognitive resources to focus or switch one's focus between competing information or stimuli. Imagine the golfer who must ignore all extraneous distractions to successfully complete the putt. In contrast, *processing speed* relates to the time a person requires to understand and respond to information. Clinically, people with reduced processing speed take longer to formulate an answer and respond to questions. The next process, *visual perception*, involves our ability to interpret and understand stimuli in the real world and to understand the physical relationship between self and the environment. Examples include being able to correctly thread buttons through buttonholes, coordinate tools and utensils, and even find your way. *Memory* refers to the processes necessary for the acquisition, storage, retention, and retrieval of information for future use. This is a necessary precursor for successful self-care, as one needs to remember appointment times, manage medication, and track blood glucose levels.

In contrast, when examining *language*, the clinician will need to consider the person's ability to comprehend speech and express themselves through language. Disorders in this domain may be quite isolating for the individual, as they are unable to express their needs or understand instructions and information being conveyed by others. The final cognitive process, known as *executive function*, is an umbrella term used to describe a set of complex cognitive processes required for mental control and self-regulation of behaviour and emotion. These processes oversee and coordinate other aspects of our thinking, emotion, and behaviour. These include such things as planning, judgement, abstract reasoning, emotional regulation, self-monitoring, initiation, and inhibition. Impairments in these areas can have substantial implications for a person's ability to monitor their health and seek support when necessary. Executive dysfunction is often overlooked, and people with these deficits are commonly labelled as *non-compliant* and/or *difficult patients*.

Assessing and measuring cognitive function

Several widely available validated cognitive screens are commonly used to detect cognitive impairment. The standardized Mini Mental Status Examination (sMMSE) is a 30-item test, which assesses orientation, attention, language, memory, and perception in older adults. If an individual scores below 24 correct items on the test, this is usually considered indicative of cognitive impairment [8].

Unfortunately, the sMMSE does not formally assess executive function, which is a crucial cognitive domain for self-care in general and specifically for self-managing chronic disease such as diabetes. Another commonly utilized screen is the Montreal Cognitive Assessment (MoCA) [9]. This is also a 30-item measure, which is more sensitive to identifying cognitive impairment, and it assesses a broader range of cognitive processes, including executive function. Both measures are quick to administer and provide the clinician with some understanding of the person's cognition.

There are many other cognitive screening tools developed for specific populations or subgroups. For example, the Rowland Universal Dementia Assessment Scale (RUDAS), which was developed in Australia, is another routine cognitive screen designed for people from diverse cultural, educational, and linguistic backgrounds. This relatively brief screen assesses orientation, praxis, judgement, language, and memory, which enables the clinician to develop an understanding of cognition, while controlling for a range of demographic variables that could otherwise deflate the performance.

Assessing cognitive function using these standardized tests provides an indication of the severity and extent of the individual's cognitive function. It is important to remember that the tests are not a diagnostic tool for any specific neurocognitive condition, but act as a screening facility.

Comprehensive neuropsychological assessment remains the gold standard and requires an in-depth examination of the six cognitive processes already described, together with a consideration of the impact of mood and behaviour. These investigations are combined with observations from the clinician, the clinical history, and reports from significant others to ensure that the psychometric data is understood in context.

These rigorous clinical assessments along with laboratory and neuro-imaging studies are used to formulate a diagnosis of the underlying cause of a person's cognitive impairment.

Cognitive impairment and dementia

Cognitive impairment is diagnosed when an individual's performance, on at least one of the domains, is significantly below their premorbid level of function. An understanding of premorbid function is commonly derived through discussions with the individual or family about levels of occupational and educational attainment, or via measures resistant to the effects of brain insult [10].

Cognitive impairment may be associated with a range of congenital or developmental conditions. However, in later life, cognitive impairment is often associated with a traumatic event or disease process affecting normal brain function.

Dementia is one of the most common conditions influencing cognitive function in older people [11]. Dementia itself is an umbrella term, used to describe a range of devastating, pervasive, neurodegenerative processes, which progressively render a person uncommunicative, bed-bound, and fully dependent on others for all personal care. In the most recent revision of the Diagnostic and Statistical Manual (DSM-5) [12], dementia has been termed *major neurocognitive disorder*. By definition, a major neurocognitive disorder is diagnosed when there is significant change in at least one cognitive domain, coupled with significant deterioration in the individual's ability to independently manage activities of daily living. These changes are not primarily attributed to another mental disorder, nor do they occur exclusively in the context of a delirium [7]. A minor neurodegenerative condition (or mild cognitive impairment) is diagnosed when the extent of cognitive and/or functional impairment is comparatively modest.

These illnesses are caused by pathological changes to the brain. Each condition is differentiated by the type and location of its pathology, and the resulting changes to thinking skills, personality, and behaviour. For example, abnormal protein deposits in the medial temporal lobe are widely believed to explain the memory dysfunction seen in Alzheimer's disease.

The World Health Organization (WHO) estimates that around 50 million people are currently living with dementia, with rates expected to rise to 82 million by 2030, and 152 million by 2050 [11].

Dementia and diabetes

Impact of dementia as a comorbidity in a person with diabetes

Suboptimal self-care in people with diabetes and cognitive impairment or dementia increase the risk of poor clinical outcomes, with

higher frequencies of hyperglycaemia, hypoglycaemia, and diabetes-related complications [13].

The presence of cognitive impairment or other comorbidities may inappropriately influence management plans, leading to setting or accepting more lenient glycated haemoglobin (HbA_{1c}) targets, as well as fewer investigations and reduced engagement with specialist services [14]. In addition to chronic hyperglycaemia ($\text{HbA}_{1c} > 9\% [75 \text{ mmol/mol}]$), hypoglycaemic episodes are also more prevalent in those with cognitive impairment or dementia. Subsequently, these episodes may worsen a person's cognition, impair performance on the sMMSE, and reduce medication taking and self-care in this cohort [15].

With the rise in prevalence of both dementia and diabetes worldwide, it is important for healthcare professionals to be aware of the coexistence of these conditions in individuals with diabetes to understand how these cognitive changes affect management [16]. Additionally, identifying which cognitive and self-management domain(s) is/are impaired in a person with diabetes allows clinicians to implement self-care strategies better suited to the strengths of the individual [16, 17]. Optimizing an individual's self-care functions enhances glycaemic management and possibly prevents or slows the progression of the multitude of damaging diabetes-related complications.

Differences in cognitive function between type 1 diabetes and type 2 diabetes

Both type 1 diabetes and type 2 diabetes have been associated with the development of dementia [18]. Adults with type 1 diabetes can have impairments in multiple cognitive domains, including attention (visual and sustained), visual perception, processing speed [19], and executive function (concept formation, cognitive flexibility, and anticipation) [20]. The cognitive domain of memory as well as learning can be spared [19]. Acute hyperglycaemia ($> 15 \text{ mmol/l; } 270 \text{ mg/dL}$) in adults with type 1 diabetes affects performance on psychomotor tasks and mental subtraction speed, as well as increasing subtraction errors in the processing speed cognitive domain [21]. Acute hypoglycaemia impairs the cognitive domains of visual perception (spatial ability) [22], attention (flexibility), and processing speed [23].

In type 2 diabetes, many longitudinal studies suggest an association with declines in the cognitive domains of executive function, processing speed, memory [24], and language (verbal fluency) [25].

Pathogenic mechanisms linking diabetes with dementia

Type 1 diabetes

The mechanisms underlying cognitive impairment in type 1 diabetes are complex. These can be influenced by the age of onset of diabetes, duration of diabetes, occurrence and severity of hypoglycaemia and hyperglycaemia, presence of cerebral white-matter changes, cerebral atrophy, and vascular disease. The discussed mechanisms can lead to the development and progression of both vascular and Alzheimer's dementia subtypes [26]. We explore three of these variables in more detail.

Onset of diabetes

Early-onset type 1 diabetes – that is, in children younger than 7 years of age – is an important factor influencing cognitive function in adulthood, as the younger developing brain may be more vulnerable to the effects of hypo- and hyperglycaemia [27].

Disease duration

Disease duration in adults with type 1 diabetes is inversely associated with cognitive performance and is a strong predictor for impaired cognitive function in memory (delayed recall) [28], psychomotor speed [29], processing speed, attention, language (verbal ability), and executive function [30].

Hyperglycaemia

The incidence of cognitive impairment in people with diabetes and chronic hyperglycaemia is 28% compared to 5% in the general population [31]. Chronic hyperglycaemia may trigger mechanisms that promote neuronal damage and endothelial dysfunction, resulting in the development of cognitive impairment over time [32]. Furthermore, chronic hyperglycaemia dramatically increases the risk of microvascular disease typically attributed to diabetes (retinopathy, nephropathy, and neuropathy), which is also associated with cognitive impairment [26].

Type 2 diabetes

Type 2 diabetes is associated with lower total brain volume [33], grey-white-matter volume, more cerebral infarcts, and white-matter hyperintensity volume, which all mediate cognitive impairment [34]. Type 2 diabetes, particularly when treated with insulin, is associated with both vascular and Alzheimer's dementia [35].

Although the association with vascular and Alzheimer's dementia is not only explained by an increased prevalence of clinical strokes, it also remains possible that silent infarctions are due to type 2 diabetes pathology [35]. Furthermore, in the subgroup of people with type 2 diabetes treated with insulin, the association with both dementia subtypes is independent of education level, smoking, body mass index, presence of atherosclerosis, systolic blood pressure, and antihypertensive medication use [35].

Vascular dementia and type 2 diabetes

Like cerebrovascular events (also referred to as *stroke*), risks factors for vascular dementia include hypertension, diabetes, advanced age, male sex, smoking, and cardiac diseases [36].

Alzheimer's dementia and diabetes

The correlation between type 2 diabetes and Alzheimer's dementia is strongest in people treated with insulin. This may represent more serious and long-standing diabetes, but also that exogenous insulin itself or hypoglycaemic episodes (which frequently complicate insulin therapy [37]) increase the risk of Alzheimer's dementia. A direct correlation has been reported between increased endogenous insulin levels and impaired cognitive function [38].

The common finding of cerebral infarctions and subcortical white-matter lesions in Alzheimer's dementia suggests that underlying vascular factors may also be important in late-onset Alzheimer's dementia [36]. Some studies suggest that in addition to vascular disease, alterations in glucose, insulin, and amyloid metabolism underlie the pathophysiology of Alzheimer's dementia [18].

Some other mechanisms such as glycation of proteins and advanced glycation end-products may also be involved in the aetiology of diabetes complications, as these can be found in the plaques and tangles of individuals with Alzheimer's dementia [39]. Advanced glycation end-product epitopes have even been detected in the earliest states of Alzheimer brain lesions and promote known plaque and tangle properties. Progressive glycation augments the deposition of proteins by crosslinking, and it induces macrophages to secrete acute-phase reactants, thereby stimulating an

immune-cell response, possibly contributing to nerve-cell death by the formation of free radicals [40].

Type 2 diabetes also directly affects neurotransmitter metabolism, which can contribute to Alzheimer's dementia. Decline in blood-brain barrier transport of choline (precursor of acetylcholine) [41], decreased acetylcholine synthesis by brain glucose utilization/insulin-induced hypoglycaemic episodes, blockade of acetylcholine muscarinic receptors, and loss of cholinergic activity can all disrupt higher cognitive functions and affect the severity of Alzheimer's dementia [42].

Clinical management of people with cognitive impairment and diabetes

Self-management

Optimal management of chronic disease such as diabetes requires effective self-management to maintain independence [43] and reduce morbidity and mortality [44]. As self-management is a strong predictor of morbidity, a better understanding of how to improve cognitive, emotional, and physical abilities to manage disease is essential [45]. Self-management improves glycaemic levels [46] and can reduce mortality by a hazard ratio of 2.21 [47]. The five domains of self-management (Box 64.1) are:

- Problem solving.
- Decision making.
- Finding and utilizing appropriate services.

- Working with healthcare professionals to make decisions about treatment.

- Taking action [17].

Some key self-management behaviours in diabetes include following complex medication regimens (applying to both oral and injectable drugs), appropriate timing of insulin doses, performing and interpreting blood glucose testing, healthy eating plans, adequate exercise, satisfactory foot care, and attending screening examinations and tests for potential end-organ complications [48].

Self-management and dementia

Self-management is particularly challenging in older people with diabetes and comorbid cognitive impairment [14]. The impact of dementia on a person's ability to self-manage their diabetes depends on which cognitive domain(s) are affected, the severity of impairment in the domain(s), and then the complexity of the required self-management tasks [17].

It is crucial for clinicians to recognize and assess older people with cognitive impairment and then consider the impact this impairment may have on self-management domains (Box 64.1) [16, 17]. This knowledge will assist clinicians in developing management plans tailored to the individual and work to circumvent any barriers imposed by the cognitive impairment.

Individuals with diabetes and cognitive deficits associated with dementia may experience impairments in all the domains relevant for successful chronic disease self-care [16]. An abnormal sMMSE

Box 64.1 Self-care domains, tasks involved, and implicated cognitive domains

Self-care of the individual		Cognitive domain implicated	Impact of impairment, possible presentations
Problem solving: identifying problems and generating solutions	Acquiring information	A, LM	Repetitive questioning or disengagement; unable to recall information; rapid forgetting
	Understanding information	E	Unable to acknowledge extent of health issues; dismissive of solutions
	Generating solutions	E	Unable to generate simple solutions
Decision making: acting in response to changes in disease condition	Appropriate solution choice	E, LM	Concrete responses; poor understanding of management
	Medical device use	P, V, La	Failure to take medication and follow lifestyle regimen
Finding and utilizing appropriate resources	Attending clinical appointments	E, V	Failure to attend appointments; gets lost; unable to access transport
	Negotiating goals of care	E	Unable to agree on goals of care and may appear stubborn
	Communicating with services and others	La	Unable to describe symptoms; delay in seeking help; argumentative
Working with healthcare professionals to make decisions about treatment	Psychological and emotional adjustment	E	Overwhelmed at changes in care regimen; frustration or aggression
	Monitoring, medication taking, and lifestyle change	E, LM, Mo	Impulsivity; unable to override ingrained behaviour patterns; poor medication taking; low mood
Taking action			

A, attention and information processing; E, executive function; La, language; LM, learning and memory; Mo, mood and motivation; P, praxis; V, visuospatial and constructional.

Source: Modified from Ibrahim et al. 2017 [17].

score (<24) corresponds with decreased self-care, diabetes monitoring, independence in activities of daily living, and a need for increased personal care assistance and more hospitalizations [14].

Collaborative approach

Clinicians should work in collaboration with people with diabetes and caregivers to assess an individual's current capabilities, identify potential barriers to successful self-management, and make efforts to adjust the provision of information according to the person's skill set [17].

Cautionary tales

Mistaken assumption of clinical futility

Often a pre-existing diagnosis of dementia may take precedence in the clinical approach to managing a person with diabetes. When this occurs, treatment options may be discounted based on a misguided notion that there is global cognitive impairment. This potentially leads to suboptimal treatment and avoidable morbidity and mortality [49].

Life expectancy for people with Alzheimer's dementia may range from 3 to 10 years, largely dependent on the initial age of diagnosis [50]. However, from the initial cognitive symptoms, life expectancy may be as long as 20 years [51], a significant period over which to limit complications of diabetes and empower the self-management abilities of the individual.

Misattribution of 'failures in adherence'

Labelling individuals as resistive and deliberately non-compliant may also occur as a person's cognitive decline progresses. As cognitive function becomes more impaired, individuals may be unable to take appropriate action to prevent or treat hypoglycaemic episodes [14, 52].

Clinicians may mistakenly assume that the individual is disinterested, unmotivated, or even recalcitrant. However, hypoglycaemia in the setting of pre-existing dementia could be secondary to a poor response to the prescribed regimens [15], along with a reduced understanding of diabetes management [52].

Carer involvement

Educating carers about diabetes management is important. It is also beneficial for self-care tasks to be bolstered by social supports, even though this may not necessarily improve glycaemic levels (HbA_{1c}) [52].

Balancing improvements in self-management tasks versus glycaemic levels is important for people with dementia as tight glycaemic targets may have their own disadvantages, such as falls, in this vulnerable population. Hypoglycaemia may result from poor cognition [13] as well as setting overly intensive glycaemic targets [53].

Targeted management plans

Developing targeted management plans requires clinicians to consider the variability in severity and types of cognitive impairment. Healthcare professionals must challenge the assumptions that cognitive impairments in dementia are global and similar between individuals, and refute that treating people with dementia is futile [16].

Glycaemic targets in individuals with diabetes and comorbid dementia must be correlated with a person's level of cognitive impairment, cognitive domains affected, underlying prognosis, likelihood of distressing symptoms, and the person's health and

lifestyle wishes. There are numerous suggested guidelines from medical and clinical experts around the world and these are notable, as they highlight the importance of tailoring treatment for each individual [54].

Tailored management plans should focus on the individual's diabetes management knowledge, motivation, perceptual problems, and effects of the condition on eating and drinking appropriately [55]. To add to this complexity, clinicians must also understand how cognitive processes and self-management challenges vary depending on the nature and severity of the person's comorbid neurodegenerative process.

Depending on the dementia subtype, any of the cognitive domains (attention and information processing, language, visuospatial ability and praxis, learning and memory, and executive function) may be impaired. Impairment in one or more of these cognitive domains can affect the five key processes of chronic disease self-management [17] (Box 64.1).

Case studies

This section provides four case studies demonstrating different presentations and aspects of clinical management.

Case Study 64.1 Mild cognitive impairment and delirium

Mrs A was a 91-year-old female retired school teacher, who lived alone and was proud of self-managing type 2 diabetes. She was treated at an acute hospital following a fall and fractured hip, complicated by a urinary tract infection and hyperglycaemia. Two weeks after returning home, Mrs A became unwell and appeared more confused when family members spoke with her. A visit to the emergency department revealed the presence of hyperglycaemia, hyperosmolar non-ketotic coma, a urinary tract infection, and rapid atrial fibrillation.

The case study 64.1 of Mrs A highlights the importance of recognizing the impact of both immediate and longer-term impairments on a person's ability to manage their own healthcare needs. People with diabetes must have a certain level of both physical and cognitive prowess to monitor and maintain blood glucose levels and adapt treatment regimens. Unfortunately, Mrs A's medical history (age, living alone, diabetes, urinary tract infection, pain from fracture, and surgery) not only makes her more susceptible to delirium, but also puts her at greater risk for developing a major neurocognitive disorder.

Short-term impairment: delirium

Acute changes in cognition are often accompanied by associated changes in function. For Mrs A, the confusion resulting from her delirium would compromise her ability to monitor her blood glucose levels and make the necessary adaptations to her treatment regimen.

The presence of infection and reduced mobility significantly increases her risk of delirium [56], a serious condition that can lead to persistent cognitive changes, functional decline, and premature institutionalization [57]. This acute medical condition affects a person's ability to maintain their attention and level of awareness.

It develops quickly, usually within hours to days, and may present with cognitive fluctuations in memory, orientation, language function, or perception [12]. While the condition often resolves over time, many people still experience a degree of permanent cognitive impairment or a sudden worsening of subtle pre-existing deficits.

Long-term impairment: dementia

In Mrs A's case, her increasing age and the presence of type 2 diabetes heighten her risk of both Alzheimer's disease and vascular dementia. However, the implications for Mrs A are substantial, with changes commonly seen in memory, attention, and executive dysfunction in vascular dementia, and additional perceptual and language changes in Alzheimer's disease [7]. These cognitive deficits will compromise Mrs A's ability to manage her chronic health condition.

Mrs A would need reasonable *attention* to sustain her focus while discussing her treatment regimen with health practitioners. Attention is a necessary first step for all cognitive processes. Without attention, Mrs A would be unable to register or retain information about changes in her treatment or learn to utilize treatment aids.

Similarly, impaired *processing speed* may have a significant impact, particularly in circumstances where Mrs A is receiving lengthy verbal descriptions about changes in treatment. A person with slowed processing will struggle to integrate this information.

The implications of cognitive impairment are often under-recognised and frequently underappreciated. Consider the impact of *language* or *visual perceptual* deficits in Mrs A's case, with poor perceptual abilities hampering her ability to manipulate the equipment necessary to monitor and treat her diabetes. If her language is compromised, she will struggle to comprehend changes in her treatment plan, or express concerns about her care.

All too often, the orthopaedic injury becomes the focus of care, with little consideration given to the interplay of risk factors affecting short- and long-term cognitive impairments and how these impairments influence the person's health outcomes.

Key learning points

Mrs A's acute orthopaedic hospitalization represents a good opportunity to review her cognition, diabetes care, and self-management abilities. During the hospital admission, every opportunity should be utilized to assess a person's cognition and function. This includes formal testing as well as questions and observations required as part of the care of the individual. For example, when considering memory:

- Can Mrs A recall her postoperative instructions for hip precautions?
- Does her level of recall match her actions?
- Does she appear to remember you on successive visits?
When considering processing speed:
- Is there a considerable delay in the speed of her response to questions?
- Does she appear confused by lengthy instructions?
When considering attention:
- Does she maintain eye contact with you during conversation?
- Is she distracted by extraneous noise and people walking by?

Delirium is very common in hospitalized individuals. Delirium is an acute alteration in attention and cognition. It is a medical emergency and may be the initial presenting symptom for a myriad of medical problems, prompting a search for the underlying precipitant.

Home assessments may assist the team with discharge planning to ensure that the home environment is well set up for Mrs A's needs

and to further review her cognition within her home environment. Cognitive function needs to be reassessed once the delirium has resolved; this may take several weeks or months.

Case Study 64.2 Multidisciplinary management of diabetes and dementia

Mrs B was a 75-year-old woman who lived at home with her husband. Past medical history included being a cigarette smoker with chronic obstructive pulmonary disease (COPD), dementia, type 2 diabetes, depression, osteoarthritis, and oesophageal ulceration.

Mrs B had a fall, sustaining a fracture of the left ankle, and remained in hospital for almost nine weeks. Mrs B's mobility had declined and she was no longer able to ambulate independently. Her unstable diabetes could only be managed with the introduction of twice-daily insulin to her medication regimen. Her husband (and carer) was worried about administering insulin. Despite this, Mrs B and her husband wished to return home. Hospital staff were concerned that Mrs B's care needs were now too high to be met in the community.

A medical assessment determined that Mrs B lacked the capacity for decision making. This led to an application being filed for a guardian to make medical, accommodation, and lifestyle decisions. An independent guardian was appointed for 12 months. Following an investigation, the guardian supported Mrs B and her husband's decision to return home.

After returning home, Mrs B's diabetes management was coordinated through her usual local medical officer and visiting community nurses. However, Mrs B's husband found it increasingly difficult to access the community and their visits to their local general practitioner became less frequent. Mr B then cancelled community nursing visits, citing that Mrs B no longer wanted to continue to engage with the service and that he would continue to manage his wife's diabetes.

One afternoon, Mr B called an ambulance as he found his wife unresponsive in her armchair. On arrival, Mrs B's blood glucose level was 2.6 mmol/l. She was transported to the emergency department where she was found to have aspiration pneumonia.

The case study 64.2 of Mrs B highlights the complexities that arise from ageing, disability, dementia, multiple comorbidities, and psychosocial circumstances.

The context of care and understanding the other health professionals who can contribute is important information for medical practitioners providing care to people with diabetes. While the expectation is that a medical practitioner will focus their time and energy on clinical requirements, for example ensuring glycaemic levels, the role must be much greater.

Multidisciplinary team

The involvement of a multidisciplinary team is essential for the successful transition of a person with diabetes and cognitive impairment from hospital to community-based care. Ideally, a multidisciplinary team assessment would enhance the person's independence and promote interventions for sustainable management in the community.

When a multidisciplinary team assesses and provides intervention to individuals with diabetes, it provides a holistic approach to the care needs of the person. This approach is also driven by the primary aetiology and chronology of diagnoses:

- Does the person have pre-existing diabetes and has subsequently developed a cognitive impairment?
- Does the person have a pre-existing cognitive impairment and subsequently developed diabetes?

The answers to these questions will shape how the multidisciplinary team approaches the person's care needs and the interventions they will provide. If the person had pre-existing diabetes, then they may retain that pre-existing knowledge and embedded skills required for managing this condition. Any new changes to management may be difficult to retain and the person may revert to their previous well-established practice or habits. In the other situation, if a person has a pre-existing cognitive impairment, then acquiring any new knowledge and skills required to self-manage diabetes will be challenging for the individual with diabetes.

Key issues

Let us now consider some of the other possible issues for Mrs B in this situation and the role of the multidisciplinary team. Key issues include assessment of cognition and degree of impairment to determine the capacity for decision making in a person with unstable diabetes. For example, when considering memory:

- When you provided Mrs B with information about her changed treatment regimen, did she retain the instructions later in the session?
- Did she recall the information at your next visit?
- Did her memory improve if she received the information a number of times?
- Was her memory improved with visual aids (e.g. written material or simple visual diagrams)?

When considering her executive function:

- Does Mrs B understand the implications of maintaining her community supports?
- Can she voice the risks and benefits of continuing these supports and appreciate the ramifications of relinquishing these supports in the community?

Other factors that will inform the care plan:

- Assessment and management of carer stress.
- Consideration of the trade-offs between optimal management of diabetes in a supervised setting in comparison to what is possible at home in the community.
- Understanding the importance of establishing and specifying clear goals for glycaemic management, which has to be balanced with what would be the acceptable upper and lower blood glucose levels in this situation.
- Determination of strategies that address high-demand clinical tasks in a person with substantial cognitive impairment and threshold for entry into long-term care.

Members and roles of individuals within the multidisciplinary team

Fortunately, multidisciplinary team members include a broad range of healthcare professionals, such as medical staff, nursing staff, pharmacists, physiotherapists, occupational therapists, neuropsychologists, social workers, dietitians, and speech therapists. This is not a complete list of disciplines, as the composition of the team depends on the individual's demographics and clinical conditions being managed. For example, a multidisciplinary team for people

with diabetes would include a diabetes educator and dietitian, who provide education and advice on using diet and insulin dosing. The broader the skill base of the team, the more holistic the provided treatment will be, resulting in better personalized care. In the case of Mrs B, we will examine the roles of the physiotherapist, occupational therapist, and neuropsychologist.

Physiotherapist

The physiotherapist would monitor and treat Mrs B for the fractured ankle, seeking to improve her transfers and mobility, with the aim of reaching independence (with or without a mobility aid).

This level of independence reduces the care burden in the community and assists with promoting regular physical activity as part of the management of her diabetes. If Mrs B is unable to become independent, the role of the physiotherapist is to provide education and training to her caregiver on how to safely support Mrs B to transfer to and mobilize at home. Ongoing physiotherapy review within the home environment is valuable to promote independence and address the home environment changes needed to accommodate a new mobility aid. Home-based physiotherapy would also encourage and establish a regular schedule of exercise to maintain mobility and prevent decline.

Occupational therapist

An occupational therapist's role is to determine the person's pre-morbid level of function and routines, which include the level of support and assistance in care. This knowledge assists in determining realistic goals for discharge.

An occupational therapist will thoroughly assess the person's function, through standardized and functional assessments in different care settings. A functional assessment provides a wealth of information about the person's physical capabilities, as well as their cognitive abilities within a routine task; for example, the task of making breakfast, which requires planning and execution of multiple different tasks.

Due to her poor mobility, Mrs B was unable to safely complete her personal or domestic activities of living and would require the assistance of her husband and formal carers to complete these tasks at home.

Mrs B's ability to self-manage her diabetes requires identifying the multiple and separate physical tasks and cognitive functions. For example, does Mrs. B have the physical capability to

- Use the blood glucose meter?
 - Read the result?
 - Draw up insulin?
- Does she have the cognitive capability to:
- Recognize the blood glucose meter?
 - Interpret the blood glucose level?
 - Determine how much insulin to administer?

These tasks and assessments of capability and reliability are often shared between the occupational therapist and nursing staff, who are able to monitor whether Mrs B is retaining the information from one day to the next.

The primary intention is to determine if the person is able to carry out these tasks independently. If this is not possible, due to physical (hand dexterity or visual impairment) or cognitive (poor problem solving or memory) deficits, the team would then look to family or carers to determine if they could complete the tasks.

The process is carried out with the family member in the same way, to ensure they have the physical and cognitive capacity to complete the tasks. With Mrs B, her husband was worried about

administering insulin correctly and requested this be completed by a community nurse. Occupational therapists would also work with the person in the community to ensure their environment is well set up to meet the person's safety requirements, but also provide cognitive assessment and intervention. This could include providing visual prompts or alert systems to remind the person to check their blood glucose levels and administer insulin.

Neuropsychologist

To assist the multidisciplinary team to better understand the strengths and deficits of a person's cognition, a referral should be made to a neuropsychologist. Neuropsychologists are clinical experts in determining a person's premorbid level of cognition and what degree of decline has occurred in the different cognitive domains.

Neuropsychologists assess all areas of cognitive function, to provide information to the multidisciplinary team as to what areas of strength a person still possesses and where there has been the greatest decline. This assists the multidisciplinary team in identifying and using a person's strength to continue to function as independently as possible. With Mrs B, a neuropsychology assessment provided clear evidence of substantial cognitive decline in multiple domains, which supported the guardianship application.

Key learning points

It is important to recognize early in the hospital admission if a person has complex medical and care needs. This enables referral to appropriate community programmes to support the person's transition from hospital to home. An optimal community programme is one that has a holistic approach with a broad range of medical, nursing, and allied health professionals.

- Mrs B has a complex diabetes treatment regimen and significant care needs. For long-term care in the community to be sustainable, engagement and support for her caregiver are essential. It is vital to explore what barriers have led to disengagement by a carer and consider how to overcome these.
- Transition to the community is a good opportunity for medical practitioners to review the appropriateness of glycaemic targets. The goals of treatment may need revising, especially in context of Mrs B's goal of remaining at home.
- It can be invaluable to have carers attend the hospital to practise the care routines required for when a person returns home. This ensures the team is aware of the person and carer's capabilities as well as the dynamic between them. For example, Mr B could be provided with education including prompt sheets on how to manage Mrs B's blood glucose levels and symptom management. This would be reviewed once again when Mrs B returns home.

Case Study 64.3 Promoting self-care

Mr C was a 71-year-old man who lived at home, supported by his son and daughter who lived nearby and visited twice daily. Past medical history included dementia, previous stroke, a heavy smoker of up to 30 cigarettes a day, and a heavy drinker of alcohol, complicated by pancreatitis and diabetes, for which he was treated with twice-daily insulin.

Over the past few years, Mr C's mobility and manual dexterity had declined to a level where he was house-bound and

was no longer able to visit the local bar for a drink. Complicating the situation further, Mr C also suffered stiffness and paralysis in one arm and difficulties using his other hand.

Mr C had given up cigarette smoking, but wanted to continue drinking alcohol as he claimed this was the only activity in life he enjoyed. Mr C wanted to drink more than health guidelines recommend and required his children to purchase the alcohol. His children supplied meals and assistance with shopping; however, Mr C's intake was erratic and there was often spoiled food in the fridge.

Community nursing supported Mr C with administering insulin morning and night, although Mr C did not monitor his blood glucose levels. Nurses also assisted with personal care and noted that Mr C had small pressure injuries on his sacrum and was malnourished, having lost 7 kg in the past 12 months. Visiting nurses noted increasing occasions of Mr C declining to take medication, food, or fluids.

Individuals with chronic diseases often have difficulty with self-managing their condition, and this inability increases their burden of care and hospitalization [16]. As described earlier, self-management includes problem solving, decision making, resource utilization, interacting with healthcare providers, and taking action [58]. It also requires the person to actively participate in their day-to-day treatment and management [58].

In this case study 64.3 of Mr C, we again confront the chronology of his past medical history. Which came first: the diabetes or the dementia? As we can see, diabetes may arise from pancreatitis due to chronic alcohol overuse, which also causes cognitive impairment. We also see that different aetiologies for cognitive impairment may occur in the same person.

Although Alzheimer's disease is the most common form of dementia and typically is associated with older age, dementia in a younger person may be due to vascular disease related to cigarette smoking, and cognitive impairment exacerbated by alcohol overuse.

Key issues

Let us now consider some key issues for Mr C in this situation:

- Mr C has stated that he wants to continue drinking alcohol, as he considers this as enhancing his quality of life.
- Alcohol is detrimental to his cognitive and physical function and creates a tension for clinical staff around how to address their duty of care.
- The presence of dementia may affect his ability to make decisions and so there is a need to assess the nature and extent of cognitive impairment. Given the extent of vascular risk factors, Mr C's executive function is likely to be compromised. Deficits in this domain are frequently under-recognized.

When considering executive function:

- Consider a formal cognitive screening tool, such as the MoCA.
- Is executive dysfunction hampering his ability to appreciate the impact of his life choices on his health?
- Could self-monitoring deficits, commonly seen in executive dysfunction, affect his ability to manage his blood glucose levels?

Given that Mr. C has already had a stroke, what other domains are affected?

- His manual dexterity may be compounded by changes in visual spatial function.
- What about his language function?

When considering language function:

- Has he understood the instructions provided to check his blood glucose levels?

When considering his visual spatial function:

- Did he have the necessary visual spatial ability to utilize the equipment required to monitor his blood glucose levels?

Other issues include:

- There is evidence of self-neglect, in that Mr C is declining to take medication, food, or fluids and is losing weight.
- There is an ongoing need for community supports and the potential for resistive or antisocial behaviour if Mr C is inebriated when nursing staff attend.
- There is suboptimal management of Mr C's diabetes and the development of pressure injuries.

Once again, the multidisciplinary team would complete standardized and functional assessments to determine Mr C's areas of cognitive strength and spend time with him to determine his health and lifestyle goals.

Clinical dilemmas

The key clinical dilemmas in brief include a choice between the following:

- Respecting Mr C's lifestyle choices and desire to live at home, which are likely to lead to suboptimal clinical outcomes with unstable diabetes and ongoing decline in his health status.
- Seeking to implement feasible but suboptimal clinical interventions at home, which Mr C may choose to ignore and potentially cause a breakdown in the therapeutic relationship.
- Seeking a guardian to enforce Mr C relocating to a long-term care facility with its highly controlled environment that could implement optimal clinical interventions, but conflicts with Mr C's lifestyle wishes.

Clinical approach

The key starting point for the multidisciplinary team is to assess and utilize Mr C's cognitive strengths to assist him to reach his goals. This also requires determining if he understands the consequence of continuing to drink alcohol in excess, as this will likely cause deterioration in cognitive function, increase his risk of falls, worsen glycaemic levels, and potentially create an antisocial environment for community health staff.

In this situation, assessment of his cognitive function, mental state, and premorbid personality by a medical practitioner and neuropsychologist would be beneficial to inform the decision-making process. In addition, a trial period at home would assist in separating the perceived from the real risks to Mr C's situation. This is important, as healthcare professionals may be paternalistic and defensive in their approach to decision making because of legal concerns about breaching their duty of care.

The next step is to consider the existing and any new interventions that would provide a comprehensive approach to assist Mr C to achieve his goals. As stated, Mr C was receiving assistance from visiting nurses for personal care tasks and to administer insulin. Family members were also visiting twice daily, helping with domestic and community tasks. This use of formal services is consistent with a self-management model, as it encompasses resource utilization and interaction with healthcare providers.

The neuropsychologist within the multidisciplinary team along with the community nurses could develop strategies to

compensate for any deficits in Mr C's cognitive function. This may include:

- Referrals to a dietician to optimize nutritional intake.
- Developing a system to ensure Mr C is eating adequately, such as having 'meals on wheels' delivering a hot midday meal to encourage Mr C to eat during the day.
- Visual aids and a diary to remind Mr C of his appointments.
- Technology aids to assist with medication taking.
- Ensuring Mr C's family are aware of his cognitive changes and how these may affect his day-to-day care.
- Surveillance of Mr C's health status, given he appears to lack insight into the significance of the sacral pressure injury.

The aim of a multidisciplinary team is to maintain the person's independence and their ability to remain at home safely if this is their wish. To do this, it is pertinent that the multidisciplinary team fully understands the person's cognitive profile. This serves three functions. First, it allows the formulation of strategies to assist the person in proactively participating in their own self-care; second, it identifies deficits that need to be addressed through other services; and third, it assists in developing appropriate contingency plans.

When chronic diseases such as diabetes are self-managed appropriately, it slows the cognitive decline and therefore people maintain their independence within the community.

Key learning points

- It is important to consider and evaluate mood for comorbid depression. Mr C has several risk factors (including chronic disease, previous strokes, alcohol dependence, and social isolation) and depression may be complicating his current presentation.
- There are various risk factors for cognitive impairment. Mr C has previous strokes, diabetes, and ongoing alcohol dependence. An understanding of his cognitive strengths and deficits will help guide treatment plans and discussions with him about his long-term goals.
- Completing a home assessment with an occupational therapist prior to returning home would allow an opportunity to enhance the environment to support a person's independence; for example, utilizing small hand aids to compensate for the reduction in manual dexterity.
- Collaboration of the occupational therapist with the community nurse to monitor and actively treat the pressure injuries would include assessing for appropriate equipment for Mr C's seating and mattress. The team should ensure the equipment complements Mr C's cognitive abilities and lifestyle choices.

Case Study 64.4 Prevention of cognitive decline

Ms D was an 83-year-old woman who lived in a nursing home and required assistance with activities of daily living (including administration of medication). She had a past medical history of Parkinson's disease, depression, ischaemic heart disease, a cardiac pacemaker, and type 2 diabetes.

Her medications include co-beneldopa (benserazide hydrochloride and levodopa), long-acting insulin, aspirin, metoprolol, atorvastatin, amitriptyline, and gliclazide MR.

One day at approximately 11 a.m., a junior nurse entered Ms D's bedroom to find her unconscious with a blood glucose reading that was profoundly hypoglycaemic. Ms D was admitted to hospital for further treatment and investigation, where aspiration pneumonia was diagnosed.

In this case study 64.4 of Ms D, we consider the challenges of preventing further cognitive decline, the role and the importance of appropriate glycaemic targets, and avoiding hypoglycaemia.

Key issues

Let us consider some key issues for Ms D in this situation:

- What comorbidities could affect Ms D's cognitive function?
- What is the impact of medication on the management of underlying conditions?
- What glycaemic goals might be appropriate for Ms D?

Comorbidities

Ms D has Parkinson's disease, multiple vascular risk factors including diabetes, and is prescribed multiple medications, which could all contribute to progressive decline in cognitive function. Identifying reversible factors is essential to optimize care and long-term function. One prevalent and potentially reversible comorbid condition is depression.

Depressive symptoms are highly prevalent in older adults with diabetes and are significantly correlated with poorer cognition [59]. People with comorbid depression and diabetes are 3.5-fold more likely to develop dementia compared with those with either condition alone [60]. Regular screening and evaluation for mood symptoms using validated tools (such as the Geriatric Depression Scale) are recommended.

Cardiovascular risk factors

The pathogenesis of cognitive decline in diabetes is multifactorial, and preventive measures need to address more than just glycaemic goals. Older people with diabetes are at increased risk of cardiovascular disease and stroke.

Management of lipid and blood pressure to individualized targets is recommended, as is lifestyle management, including optimal nutrition, smoking cessation, moderate alcohol intake, and exercise [61]. However, it is important to recognize that behavioural change may be difficult to implement in the setting of cognitive impairment (especially executive dysfunction) and that making small changes or enlisting help from caregivers can be useful strategies [62].

Aspirin therapy (while not recommended for the prevention of cognitive decline) may be appropriate for primary or secondary prevention of other cardiovascular diseases.

Medication

Medication errors

Although this information about medication and polypharmacy will be familiar, it is worth restating:

- Individuals with diabetes co-beneldopa require frequent monitoring of blood glucose levels and possible dose adjustment of anti-diabetes agents.
- As the medication regimen becomes more complex, the risk of the person becoming hypoglycaemic increases.
- The risk of medication errors increases with the number of medications prescribed.
- Cognitive impairment alters Ms D's ability to identify herself to staff, increasing the risk of errors due to misidentification. Also, she is no longer able to check what is being administered.

Anti-diabetes agents and cognitive health

No specific anti-diabetes agents have been shown to reduce the risk of dementia in diabetes [63]. However, treatment goals may influence the choice of pharmacotherapy. Agents with a lower risk of hypoglycaemia are preferred in older adults.

Cholinesterase inhibitors and N-methyl D-aspartate antagonists

Cholinesterase inhibitors (rivastigmine, donepezil, and galantamine) and N-methyl D-aspartate (NMDA) antagonists (memantine) are the only currently recommended medications for the treatment of Alzheimer's dementia. These agents may result in modest improvements in cognition and function in mild to moderate Alzheimer's dementia, although their use can be limited by gastrointestinal side effects and headaches [64]. Cholinesterase inhibitors are underprescribed in older people with diabetes and dementia, even though their use reduces mortality in this cohort [65]. Use of these cognitive enhancers in people with diabetes could help in the self-management of diabetes, preventing further cognitive decline.

Glycaemic goals and maintaining cognitive health

Strict glycaemic targets are fundamental to preventing end-organ damage in diabetes, but a more considered approach is required when it comes to preventing dementia. Chronic hyperglycaemia (HbA_{1c} levels $>7\%$ [53 mmol/mol]) has been associated with an increased risk of cognitive impairment and further decline in older adults with diabetes [66]. However, the older person's brain is also vulnerable to the effects of neuroglycopenia.

Episodes of severe hypoglycaemia are associated with an increased risk of developing dementia, independent of HbA_{1c} [67]. The American Diabetes Association has suggested individualized treatment targets in older adults with diabetes. Practice guidelines [61] recommend a glycaemic goal of:

- HbA_{1c} of $<7.5\%$ (58 mmol/mol) in those with few medical comorbidities and intact cognitive and functional status.
- HbA_{1c} of $<8\text{--}8.5\%$ (64–69 mmol/mol) in frailer older adults, with multiple chronic diseases, cognitive impairment, or functional dependence.

To identify the appropriate treatment strategy, regular cognitive screening is vital. Established cognitive impairment is a risk factor for reduced self-care and severe hypoglycaemic episodes [16, 68] and thus further cognitive decline. Recognizing the correct glycaemic targets and supported self-management to achieve these goals is crucial for maintaining cognitive health, functional independence, and self-care.

Key learning points

- Re-evaluating glycaemic management plans should occur at least annually. This should be a comprehensive assessment, taking into account cognitive screening performance and lived experience.
- Polypharmacy is common in older adults and increases risks of drug interactions, medication errors and omissions, falls, and cognitive impairment.
- Social isolation is a risk factor for cognitive decline and dementia. Residents in nursing homes may still experience social isolation. A healthcare professional should spend time with Ms D to determine her interests and abilities to enhance social interaction and activity.
- Often there is an assumption that a nursing home is designed and equipped for the needs of residents. This is not always the case. It is important that residents are assessed to ensure their environment meets their needs. This is especially true for residents with cognitive impairment, who may not be able to voice their concerns or needs. This may include review of their seating, overall set-up and access, and ability to use a call bell. It is important, given Ms D's diagnosis of Parkinson's disease, that she is able to use the bell, to alert staff if she is feeling unwell and facilitate a timely response.

Conclusion

People with declining cognitive function and diabetes are at a greater risk of chronic hyperglycaemia because they have difficulties with learning and retaining new knowledge, the inability to recognize the importance of self-care, which involves planning and organizing daily tasks to optimize control, and may lack the motivation to adhere to care plans.

Clinicians need to be aware of the onset, presence of, and impact of dementia in persons with diabetes. Rather than a classic presentation of *forgetfulness*, the onset of dementia may manifest in the person not retaining information relevant to diabetes, having an inability to learn insulin adjustment skills or perform insulin injections, and missing clinical appointments.

The presence of dementia as a comorbid condition must be integrated into decisions and care planning. However, it should not detract from seeking to achieve optimal management.

Key points

- The interactions between diabetes and mental disorders are bidirectional and complex: diabetes raises the risk of mental disorders, but mental illness and its treatment with certain psychotropic medications also increase the risk of diabetes.
- The prevalence of diabetes is increased two- to threefold among those with mental disorders, including in depression, anxiety, and psychotic illnesses.
- The mechanisms underlying the association between diabetes and mental illness are multifactorial and include genetic and environmental factors, as well as effects of the disorders and their treatments.
- The presence of comorbid diabetes and mental illness worsens outcomes for both conditions. The rates of microvascular and macrovascular complications, acute metabolic dysregulation, and diabetes-related deaths are all higher in people with mental illness; and the severity of and recovery from mental disorders are adversely affected in the presence of diabetes.
- Since mental health problems are more common among people with diabetes, heightened levels of awareness and knowledge about

mental disorders are vital for the healthcare professionals who work with them.

- Screening for mental health problems should form part of the holistic care of people with diabetes; the availability of mental health expertise in the settings where people with diabetes are treated is generally poor and should be improved.
- Weight management in people with psychotic illnesses is essential to tackle overweight and obesity related to these conditions and help reduce the incidence of diabetes. Tailored lifestyle interventions have been shown to reduce body weight in selected people with psychosis. Several drug therapies promote weight reduction in people taking antipsychotic drugs. These interventions should be offered to people with psychotic disorders.
- Effective diabetes management, incorporating primary care, diabetes services, and mental health teams working together, is essential to reduce the poorer health outcomes and current inequity experienced by people with mental illness and diabetes.

The greatest challenge facing medicine in the twenty-first century is multimorbidity, defined as any combination of chronic disease with at least one other disease (acute or chronic) or biopsychosocial factor (associated or not) or somatic risk factor in the same individual [1]. While diabetes healthcare professionals are used to managing this increasingly common challenge, given the effects of diabetes on many body systems, the comorbidity of diabetes and mental illness is less well appreciated, despite being common and worsening the outcomes of both conditions [2]. Mental illness may hinder an individual's ability to undertake the diabetes self-management that is central to the maintenance of health and prevention of complications and premature mortality. Therefore, an understanding of the complex interaction between physical and mental health is crucial to the management and outcome of people with diabetes.

Both diabetes and mental disorders are common conditions, and therefore a degree of co-occurrence would be expected purely by chance. There is considerable evidence, however, that diabetes is

associated more frequently than expected with a range of mental disorders. In particular, it appears that people with common mental disorders, including depression, anxiety and eating disorders, and psychotic disorders such as schizophrenia and bipolar affective disorder, are at increased risk of developing diabetes [3, 4]. Furthermore, those with diabetes go on to develop a range of psychological problems at increased rates compared to those without diabetes [4]. This was noted over a century ago; in his celebrated textbook *Pathology of Mind*, Henry Maudsley wrote: 'Diabetes is a disease which often shows itself in families in which insanity prevails. Whether one disease predisposes in any way to the other or not, or whether they are independent outcomes of a common neurosis, they are certainly found to run side by side, or alternately with one another more often than can be accounted for by accidental coincidence or sequence' [5].

Unfortunately, in most countries healthcare services are poorly equipped and organized to deliver high-quality care for both

physical and psychological needs in the same setting [6]. Clinicians need to be aware of the increased risks of comorbidity and the need for screening. Diabetes healthcare professionals should be able to provide *first-response* management for mental health problems, and recognize the needs of those with more complex problems for whom specialist management is essential. The topic of multimorbidity has attracted interest from researchers, and considerable progress has been made in understanding the epidemiology and psychosocial and biological mechanisms involved. Efforts targeting mental health and primary care providers have increased awareness of diabetes and metabolic problems in general, and have led to initiatives to increase routine screening and referrals for diabetes specialty care for people with mental disorders, with varying degrees of success [7].

This chapter will provide an overview of the relationship between diabetes and mental illness, in particular focusing on the association with depression, anxiety, eating disorders, and psychotic illness (schizophrenia and bipolar illness). Within each section, the epidemiology of the comorbidity, mechanisms underlying the association, and clinical implications will be considered.

Depression

The association between diabetes and depression has been recognized for many years. In the seventeenth century, Thomas Willis described how ‘diabetes is a consequence of prolonged sorrow’ [8]. Nevertheless, depression is a frequently ignored component of holistic diabetes care. Until the last decade, any discussion of mood disorders and diabetes would have concentrated solely on the increased rates of depression in people with diabetes, and is likely to have viewed such comorbidity as an ‘understandable’ reaction to the difficulties resulting from living with a demanding and life-limiting chronic physical illness. We now understand that the relationship between the two conditions is more complex than this:

- At least in the case of type 2 diabetes, the relationship between diabetes and depression is bidirectional, as depression is a risk factor for the development of diabetes [9–11].
- Biological aspects of diabetes may contribute to the development of depression and vice versa.
- Other antecedent factors, such as the early nutritional environment or neighbourhood, may contribute to the risks of both conditions [4].

Given the large numbers of people with diabetes and depression, ~10% and 4.4% of the total world’s population, respectively, and the twofold higher rates of depression in people with diabetes [12], the comorbidity of these two conditions presents a major clinical challenge as the outcomes of both are worsened by the presence of the other. Quality of life is worse, diabetes self-management is impaired, the incidence of complications is increased, and life expectancy is reduced [4]. The costs of treatment increase significantly both for individuals with the comorbidity and for health economies, but these costs do not necessarily result in significant improvements in disease or quality-of-life outcomes [13].

Case definition

Depressive symptoms exist on a continuum of severity. Standard definitions of *clinical depression* are based on symptom count and duration; the most widely used diagnostic criteria in current practice are those of the American Psychiatric Association Diagnostic

Table 65.1 DSM-5 criteria for a major depressive episode.

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood, or (2) loss of interest or pleasure.
1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g. feels sad or empty) or observation made by others (e.g. appears tearful).
 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).
 3. Significant weight loss when not dieting or weight gain (e.g. a change of >5% of body weight in a month), or decrease or increase in appetite nearly every day.
 4. Insomnia or hypersomnia nearly every day.
 5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
 6. Fatigue or loss of energy nearly every day.
 7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
 8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
 9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.
- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The symptoms are not due to the direct physiological effects of a substance (e.g. a drug of abuse, a medication) or a general medical condition (e.g. hypothyroidism).

Source: American Psychiatric Association 2013 [14].

and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) major depression (Table 65.1) [14]. This definition approximates to a level of symptomatology that is associated with significant disability and dysfunction, but it is important to note that depressive symptoms of lesser severity may still compromise self-care and outcomes in people with diabetes.

The clinical category of mood disorders includes both unipolar depression and bipolar (previously known as *manic-depressive*) illness. This section will focus on unipolar depression; bipolar illness will be included in the section on psychotic disorders.

Epidemiology

Depression is common, affecting between 3% and 5% of the general population at any time. Between 1990 and 2017 globally, its incidence increased by 50% to 3.25 per 1000 (age-standardized rate) [15]. Depressive disorders are now ranked as the single largest contributor to non-fatal health loss (7.5% of all years lost to disability) [16].

Considerable variability in measurement and use of terminology has contributed to heterogeneity and inconsistency in studies examining diabetes and depression [4]. The meaning of the term *depression* spans relatively minor, occasional negative mood states (which should more accurately be termed *depressive symptoms*) to incapacitating and treatment-resistant disorders that fulfil all diagnostic criteria for clinical depression. Many self-rating scales do not acknowledge the overlap between symptoms of diabetes and

those of depression (e.g. fatigue, weight loss), potentially leading to overestimates of the prevalence of depression in those with diabetes [17]. The gold standard for ascertainment of case status is a research diagnostic interview; at most, rating scales can only give a probabilistic estimate of caseness. A further confounding factor is the construct of *diabetes-related distress*, which captures the emotional distress associated with living with diabetes [18]. Diabetes-related distress correlates modestly with depressive symptoms with ~30% overlapping variance, but remains distinct from depression in its association with self-management and glycaemic levels.

Studies have tended to ignore the heterogeneity of diabetes, studying mixed populations of different forms of diabetes (e.g. type 1 diabetes and type 2 diabetes). It is important to distinguish between these groups for several reasons:

- People with type 2 diabetes are generally older and depression prevalence varies with age.
- Pathological mechanisms may differ.
- The rates of diabetes-related complications and other comorbid conditions such as obesity and heart disease differ.
- Management demands are different.

Studies have often been based on *convenience* samples, usually drawn from specialist diabetes clinics, where referral patterns and the effect of other biases in sample composition, such as ethnicity, were unknown. Finally, studies often have low or unknown response rates, and since the presence of depressive symptoms may reduce the likelihood of responding in such studies, this biases

prevalence estimates further. More recent studies using better methods, and meta-analyses, have tended to report lower estimates of prevalence.

In a meta-analysis of 44 studies, the prevalence of depression was more than doubled in people with type 1 diabetes compared with the general population (22% vs 13%), while for people with type 2 diabetes the rates were increased by 55% (19% vs 11%) [19]. The prevalence of depression in people with diabetes was higher in studies carried out in specialist care (36%) than in those in community or primary care (12%). The same meta-analysis also reported higher rates of depression in low- and middle-income countries compared to countries with high-income economies [19], a finding that was also reported in another meta-analysis of 248 observational studies including over 8 million people with type 2 diabetes. The pooled prevalence of depression across the world was 28%, but this varied across regions; studies from Asia and Australia reported the highest rates while those from Europe reported the lowest values [20]. Despite these regional differences, the association between diabetes and depression appears to be a significant issue across many countries; in a study including 231 797 adults from 47 countries, people with diabetes were more than twice as likely to have experienced an episode of depressive symptoms than those without (Figure 65.1) [21]. Similar to what is observed in the general population, the prevalence of depression is higher among women with diabetes compared with men with diabetes (34% vs 23%) and among those under 65 years [20].

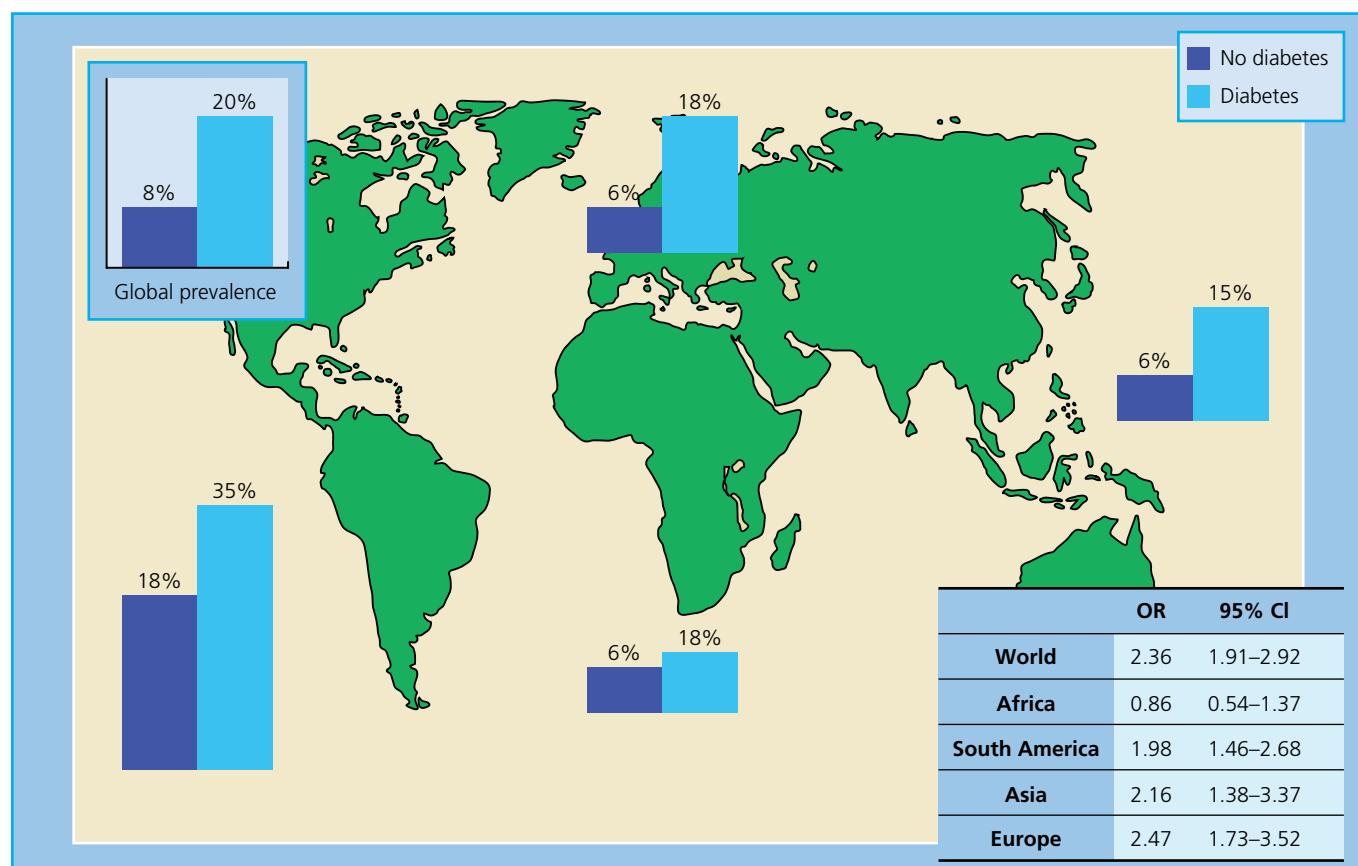

Figure 65.1 Depressive episodes in people with and without diabetes. Odds ratios (OR) of an episode of depressive symptoms according to diabetes presence with 95% confidence intervals (CIs). Source: Data from Mommersteeg et al. 2013 [21].

The course of depression has been studied in 2460 people with type 2 diabetes in a primary care setting [22]. Over a three-year period, 26% met the criterion for depression on at least one occasion, with incident depression present in 14%. Recurrence or persistence of depression was evident in 66% of those with baseline depression. Depression was more common in women and those with low education, non-cardiovascular chronic diseases, stressful life events, or a self-reported history of depression. A meta-analysis of 11 cohort studies including ~50 000 people with type 2 diabetes but without depression at baseline indicated that the incidence of depression is 24% higher in people with diabetes [10], while another meta-analysis of 13 studies found that incident depression was increased by 15% in people with diabetes at baseline [11]. The discrepancy between prevalence and incidence rates may be explained by the greater persistence of depression and higher relapse rates in people with diabetes.

The prevalence of depression is also increased in children and adolescents with type 1 diabetes or type 2 diabetes. A meta-analysis of 109 studies involving 52 493 children with diabetes found that the prevalence of depression was 22.2% among children with type 1 diabetes and 22.7% in children with type 2 diabetes [23]. Consistent with studies in adults, the prevalence of depression was higher among girls (29.7%) than boys (19.7%) and in low- to middle-income countries (29.3%).

Depressive disorders as a risk factor for diabetes

A meta-analysis of nine cohort studies found that adults with depression had a 37% increased risk of developing type 2 diabetes [9] after accounting for factors common to both disorders, including sex and body mass index (BMI). There is heterogeneity across studies, which in part could be ascribed to ascertainment bias. It is also worth noting that people with depression may be more likely to be screened for diabetes than those without, so studies relying on routinely collected healthcare data may overestimate the difference in diabetes risk between people with depression and the general population.

Which people with diabetes are likely to develop depression?

Risk factors for depression in otherwise healthy individuals, including female sex, marital status, childhood adversity, and social deprivation, operate equally in people with diabetes and much depression in people with diabetes may be *independent* of the presence of the disease. However, there are both treatment- and diabetes-specific risk factors associated with depression. The use of insulin in type 2 diabetes is associated with higher rates of depression compared to non-insulin medications or dietary and lifestyle interventions alone; a meta-analysis of 28 studies reported an overall 59% high risker of developing depression in people taking insulin, or a 42% higher risk when compared with other oral anti-diabetes agents [24]. It seems unlikely that insulin causes depressive symptoms *per se*, but insulin is associated with increased treatment demands and is generally used in people with more advanced disease. The intensive self-monitoring of blood glucose required with insulin therapy may also adversely affect depressive symptoms [25]. Recurrent hypoglycaemia and elevated glycated haemoglobin (HbA_{1c}) are both risk factors for depression and insulin therapy is usually associated with greater glycaemic variability than other treatments. Again we can see evidence of the bidirectional relationship between diabetes and depression: in a 10-year study

of 3742 people with type 1 diabetes requiring emergency room visit or hospitalization, those admitted with a hyperglycaemic or hypoglycaemic event were 1.4-fold and 74% more likely to develop depression, respectively. Conversely, the 20% with depression at baseline had a 2.5-fold increased risk of hospitalization for a severe hyperglycaemic episode and an 89% increased risk of severe hypoglycaemia [26].

There is a well-recognized association between cardiovascular disease and depression [27], but the development of microvascular complications, particularly sexual dysfunction and painful peripheral neuropathy, are also associated with depression [28, 29]. In a specialized outpatient clinic, the presence of two or more complications more than doubled the risk of depression in people with type 2 diabetes, with neuropathy and nephropathy showing the strongest association [30].

Proposed mechanisms linking depression and diabetes

Several psychological, sociological, and biological models have been proposed to explain the association between diabetes and depression. While there may be specific reasons why one condition predisposes to the other, recent research has also considered common antecedents to both (Figure 65.2) [4].

Common antecedents

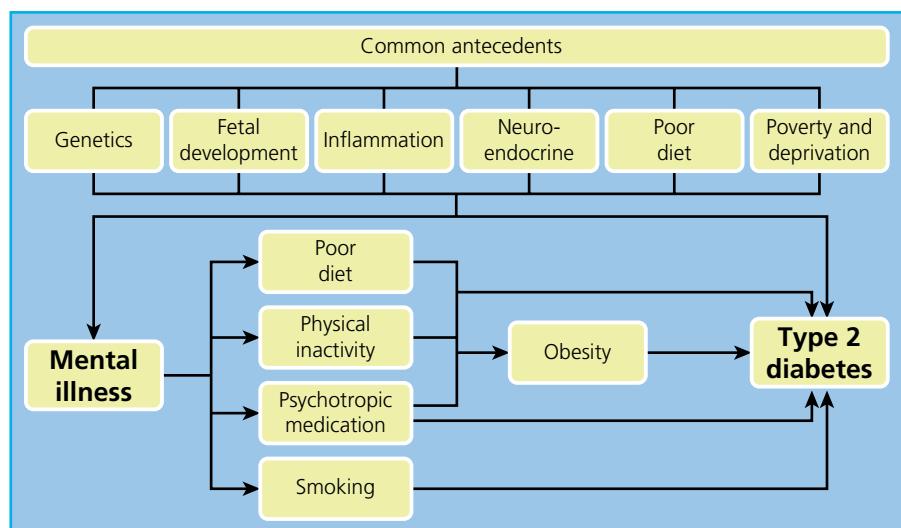

An adverse intra-uterine environment may predispose individuals to both type 2 diabetes and depression. There is a J-shaped relationship between birth weight and plasma glucose, insulin concentrations, and type 2 diabetes, while some but not all studies have shown that fetal undernutrition is associated with adult depression [4]. One possible mechanism is programming of the hypothalamic–pituitary adrenal (HPA) axis, as both depression and diabetes are associated with HPA dysfunction [31]. Adverse environmental factors in postnatal life, ranging from childhood adversity to neighbourhood environment and poverty, may also influence the predisposition to depression and diabetes.

Why diabetes may increase the risk of depression

The traditional view holds that depression is an understandable reaction to the challenges of living with a demanding chronic physical illness that is associated with disabling complications and premature mortality. This was supported by an early meta-analysis that found no increase in depression rates among those with undiagnosed diabetes or impaired glucose metabolism [32]. A more recent meta-analysis of 20 studies, however, found that compared with individuals with normal glucose metabolism, the prevalence of depression was moderately increased in those with undiagnosed type 2 diabetes (odds ratio [OR] 1.27, 95% confidence interval [CI] 1.02 to 1.59), but more markedly increased in those with previously diagnosed type 2 diabetes (OR 1.80, 95% CI 1.40 to 2.31) [33]. As the prevalence of depression is higher following a diagnosis of diabetes, this suggests that the knowledge of the diagnosis and the burden of managing the condition and its complications are important in the aetiology of depressive symptoms, but are not the only factors; nevertheless, healthcare professionals need to convey the diagnosis of diabetes sensitively and provide psychosocial support to mitigate against this effect.

Other factors could include biological mechanisms, as it is well recognized that both hypoglycaemia and hyperglycaemia affect brain function in the areas involved in cognition and mood [34].

Figure 65.2 Mechanisms that explain why mental illness may predispose to type 2 diabetes and vice versa. There are a number of common antecedents that increase the risk of both conditions. Once an individual develops mental illness, other health behaviours may occur, which together with the effects of psychotropic medication may further increase the risk of diabetes, either directly or indirectly through the development of obesity. Animal studies of diabetes have shown loss of hippocampal integrity and neurogenesis, which may contribute to mood symptoms, while in humans, MRI studies have shown hippocampal atrophy. Prefrontal glutamate-glutamine- γ -aminobutyric acid levels are increased in people with type 1 diabetes in a way that correlates with mild depressive symptoms [35].

Why depression may lead to diabetes

People with depression tend to be more sedentary and eat diets that contain more saturated fats and refined sugars and less fruit and vegetables than the general population [36, 37]. Other self-care behaviours may also be relevant; a meta-analysis found that people with depression were significantly less likely to follow diabetes treatment recommendations including missed medical appointments, medication use, glucose monitoring, and foot care [38]. This could lead to a vicious cycle whereby poorer self-care management leads to hyperglycaemia, which in turn worsens depressive symptoms and consequently contributes to less effective diabetes self-care. Depression is associated with disrupted sleep patterns [39], which may increase insulin resistance and risk of type 2 diabetes [40].

Pharmacological treatment of depression has also been implicated in the development of diabetes; some antidepressants may cause significant weight gain, which may worsen insulin resistance [41]. Case reports and observational studies have shown a consistent association between the use of antidepressants and diabetes, while randomized controlled trials (RCTs) have reported both hyperglycaemic and hypoglycaemic effects [42]. It is uncertain, however, whether any or all antidepressants cause diabetes, as their use may be a marker of individuals at high risk of diabetes.

Consequences of depression in diabetes

Comorbid depression adversely affects diabetes outcomes and decreases quality of life [43–45]. This is not explained by hyperglycaemia as, rather surprisingly and in contrast to diabetes-related distress, no consistent association between depressive symptoms and HbA_{1c} has been found [46–48]. Nevertheless, treatment studies suggest that improving glucose levels may accompany a reduction of depressive symptoms [49].

Depression is associated with worsened severity and incidence of many diabetes complications. Again we see a bidirectional relationship, as not only are those with diabetes complications at increased risk of diabetes, but people with diabetes and depression are at increased risk of developing both microvascular and macrovascular complications [28, 29]. A recent meta-analysis of nine studies involving over one million people with type 1 diabetes or type 2 diabetes reported that depression was associated with a 38% increased risk of incident macrovascular disease and 33% increased risk of microvascular complications [29].

In one 10-year cohort study of individuals with childhood-onset diabetes, retinopathy severity was predicted by increasing duration of diabetes, with length of time spent in hyperglycaemia and with overall proportion of time depressed [50]. Similar results have been seen in people with type 2 diabetes; in one longitudinal study, those with high depression scores at both baseline and six-year follow-up were more likely to progress to diabetic retinopathy and to proliferative diabetic retinopathy than those with low depression scores [51].

One complication that may be particularly associated with depression is painful peripheral neuropathy. Recent studies suggest that not only is chronic pain a risk factor for depression, the presence of depression may itself worsen the experience of pain [52].

Depression, even if mild, is also associated with premature overall and cardiovascular mortality. A meta-analysis of 16 studies found that depression was associated with a 46% and 39% increased risk of all-cause and cardiovascular mortality, respectively [53]. In one study the annual mortality rate for those with diabetes and depression was 8%, 2.5-fold higher than those without either condition alone [54].

Management of people with diabetes and depression

The main aims of treatment are to reduce depressive symptoms and to improve self-care, glycaemic levels, and diabetes outcomes. A major difficulty for most clinics is the lack of readily available specialist mental health input, and this has been a disincentive for services to engage actively in tackling this important clinical problem [55]. By contrast, guidelines for the management of diabetes

now include support for psychological well-being [56, 57]. Most clinics should be able to provide first-response management for simple depressive disorders, although specialist help will still be required for more complex cases, where there is diagnostic uncertainty, lack of response to initial treatment, or suicide risk.

Screening and diagnosis of depression

The first step to the effective management of depression is its recognition and diagnosis. At present, screening and case finding are not part of the routine management of people with diabetes; however, given the high prevalence of comorbid depression in people with diabetes, this seems worthwhile and healthcare professionals should ensure they have appropriate skills to diagnose mood disorders.

A formal diagnosis of depression requires a time-consuming validated interview and so quick and cheaper screening methods are needed for primary and secondary care settings [58]. Although there are many short questionnaires that screen for depressive symptoms, it is important to use one that has been evaluated adequately in people with diabetes because of the overlap of symptoms between diabetes and depression, such as lethargy, irritability, or weight change [17]. Questionnaires that rely heavily on these symptoms tend to overestimate the likelihood of depression.

The most widely used and validated questionnaire in type 2 diabetes is the Patient Health Question-9 (PHQ-9) [59, 60]. It is also the shortest, containing nine questions, and can be easily completed by the person with diabetes alone. The cut-off for major depression is ≥ 10 points in primary care populations, but it has been suggested that use of a higher cut-off of ≥ 12 points in people with diabetes may improve the discrimination between diabetes-related symptoms and depressive symptoms [61]. Other well-validated questionnaires for people with diabetes include the Beck Depression Inventory, the Center for Epidemiologic Studies Depression Scale, and the Hospital Anxiety and Depression Scale (HADS) [51]. These questionnaires should not be used to diagnose depression, but rather to identify those who should undergo a diagnostic interview by a clinician.

Another straightforward approach that can be used by diabetes healthcare professionals is to ask two simple questions:

- During the past month, have you been bothered by having little interest or pleasure in doing things?
- During the past month, have you been bothered by feeling down, depressed, or hopeless?

If the answer to either is yes, the healthcare professional should ask if the person with diabetes want helps with this problem. If the answer to this is also yes, then the healthcare professional should undertake a diagnostic interview and offer appropriate referral and treatment.

While screening is a necessary first step, it alone is insufficient to improve clinical outcomes [58]. A Cochrane meta-analysis reported that depression screening in the general population had little or no impact on the detection and management of depression if used alone, and recommended that screening strategies could not be justified without organizational changes to ensure appropriate treatment if needed [62]. The importance of this for diabetes was demonstrated in a Dutch RCT that investigated the benefits of depression screening [63]. Following screening, although written feedback was provided to both participant and doctor, neither utilization of mental health services nor depression scores improved. Furthermore, without links to treatment, screening could lead to harm, including the stigma associated with depression, the risk of

labelling transient distress as illness, and societal discrimination by insurance companies [49]. Several reasons might explain the observed low effectiveness of screening for depression in people with diabetes, including a low acceptance of screening and subsequent referral to further care by people with diabetes, failure to screen those at highest risk of depression, reluctance by healthcare professionals, and the generally poor quality of depression care in primary care systems [49].

Treatment of depression in people with diabetes

Knowledge of psychological interventions and appropriate drug therapy is important for diabetes healthcare professionals, as well as an awareness of the need for prompt referral to specialists when psychological difficulties continue to interfere significantly with well-being or diabetes self-management.

Previously people with diabetes were specifically excluded from trials of depression treatment and so consequently there were relatively few studies examining antidepressant and psychological treatment of depression in this population until recently. Nevertheless, more recent studies have clearly indicated that treating depression in diabetes with either psychological therapies or antidepressant medication is effective [64].

Psychological treatment

A variety of psychological treatments, including cognitive behavioural therapy (CBT), problem-solving, and psychodynamic techniques, have been used to treat depression in people with diabetes. These have been delivered in various settings in both primary and secondary care by different members of the healthcare team [64]. Others have used web-based and telephone contacts [65]. The trials have a preponderance of people with type 2 diabetes and no trials have been conducted with only people with type 1 diabetes. A meta-analysis of psychological treatments, including group-based and online therapies, reported they were effective for the treatment of depression with large effect sizes [64]. There is more debate about the effect on glycaemic levels [49], with one systematic review reporting a reduction in HbA_{1c} of $\sim 0.6\%$ (6 mmol/mol) [66] while another reported a less pronounced and overall non-significant improvement in glycaemic management (standardized mean differences [SMDs] from 0.40 to -1.40) [67]. Four trials on psychological interventions found improved glucose levels (SMD -0.25 to -0.68) [49]. The most recent systematic review found a small to moderate effect size (0.607 ; 95% CI 0.15 to 1.1) of psychotherapy interventions on glycaemic levels in people with depression and diabetes [64].

Pharmacotherapy

Effective and well-tolerated antidepressants are widely available and affordable and form an integral component of management for many people with depression. People with diabetes respond to antidepressants as well as the general population, with amelioration of depressive symptoms. Formal efficacy trials in people with diabetes are limited to a relatively small group of antidepressants, including nortriptyline, fluoxetine, bupropion, sertraline, paroxetine, and citalopram [49], leaving substantial gaps in the evidence for effectiveness (for both depression and glycaemic management) and safety for many commonly prescribed antidepressants. All antidepressants studied appear to have similar efficacy in terms of depression outcomes as long as adequate doses are used, with effect sizes of -0.61 SMD [67], but no trials have reported the medium- and long-term sustainability of pharmacological interventions for depression in diabetes after treatment cessation.

The treatment of choice depends largely on the side-effect profile, individual preference, and response. Selective serotonin reuptake inhibitors (SSRIs) are less cardiotoxic than tricyclic antidepressants, are safer in overdose, and consequently are widely used as first-choice agents. There are important drug–drug interactions with some members of this class and oral anti-diabetes agents through inhibition of the cytochrome P450 3A4 and 2C9 isoenzyme. For example, the use of fluoxetine may potentiate the effect of sulfonylureas, precipitating hypoglycaemia [68]. Some antidepressants, including mirtazapine, paroxetine, and some tricyclic antidepressants, may cause undesirable weight gain [41]. By contrast, bupropion, which is available in the USA, is associated with weight loss. Furthermore, unlike SSRIs, it does not appear to worsen sexual function and therefore may have advantages for people with diabetes [69]. Several new antidepressant medications have been approved, including vilazodone, vortioxetine, and levomilnacipran [70]. Differentiating these from most of those already available is a more benign weight gain profile for all three, fewer problems related to sexual functioning for vilazodone and vortioxetine, and potential relief of the cognitive dysfunction that can be associated with depression, as demonstrated with vortioxetine. None of these drugs, however, has been tested specifically in people with diabetes.

The clinical trials demonstrate a modest improvement in glycaemic levels with SSRIs (SMD -0.38) [49]. However, older studies have shown a mixed effect on glycaemic levels, ranging from hyperglycaemic effects with tricyclic antidepressant medications to euglycaemic or slightly hypoglycaemic effects with SSRIs and serotonin-noradrenaline reuptake inhibitors. Consequently, the findings of improved glycaemia with certain antidepressants should not be extrapolated to other untried antidepressants [49].

Most guidelines recommend that treatment should aim for complete remission of depressive symptoms. To achieve this, treatment must be sustained at an adequate dose for at least 4–6 months after remission has been attained to consolidate recovery and reduce the risk of relapse and recurrence. In addition to possible direct pharmacological effects, it should be remembered that treating depression may lead to a change in the individual's behaviour and routine, which may require adjustment of diabetes self-management. For example, if appetite improves, insulin requirements may increase, or if the person becomes more active, they may decrease.

Models of care

In most healthcare systems, depression is managed mostly within primary care and many diabetes healthcare professionals feel ill-equipped to manage depression. In the USA, a case management model known as *collaborative care* has been developed, whereby a multidisciplinary team works together to identify and treat depression within primary care settings. The model incorporates identification of high-risk cases, problem-solving therapy delivered by trained nurse case managers, and pharmacological treatments using a stepped-care approach. The first study to evaluate this approach was the Pathways study, which showed improvements in depression symptoms but no change in glycaemia [71]. Subsequently, greater attention was paid to intervention strategies for diabetes, resulting in improved glycaemic and blood pressure management as well as improved depressive symptoms [72]. In a meta-analysis of five studies from the USA, collaborative care was effective for treatment of depression, with a moderate effect size for depression outcomes and a small effect size for glycaemic

levels [64]. As well as being clinically effective, these models of care are also highly cost-effective [73].

Anxiety disorders

The global prevalence of anxiety disorders in the general population is even higher than depression at 7.3%, and is continuing to increase in all regions of the world. Anxiety disorders are ranked as the sixth largest contributor to non-fatal health loss globally and appear in the top 10 causes of years lived with disability in all World Health Organization (WHO) regions [16]. Despite this high global burden, and the recognized stress associated with receiving a diagnosis of diabetes and then living with the condition, there has been relatively limited research on the relationship between anxiety and diabetes. Most studies have considered anxiety symptoms only as part of a depressive disorder, or have combined depressive and anxiety disorders in overarching terminologies of *common mental disorder* or *psychological symptoms*. There is, however, emerging evidence of an important bidirectional association between diabetes and anxiety disorders, related to adverse outcomes for both, independently of depression.

Case definition

Anxiety disorders comprise a group of mental disorders characterized by excessive worries or fears, somatic symptoms, and behavioural disturbances. Many of these symptoms and behaviours are commonly experienced in everyday life. However, in an anxiety *disorder*, they differ from *normal* experiences in terms of severity, course, and impact on functioning. The DSM-5 classification includes the following conditions under anxiety disorders [14]:

- Generalized anxiety disorder
- Panic disorder
- Separation anxiety disorder
- Selective mutism
- Specific phobia
- Social phobia
- Agoraphobia.

Previously, post-traumatic stress disorder (PTSD) and obsessive compulsive disorder were also included in this group. Although there are important differences in presentation, diagnostic criteria, epidemiology, and clinical management, specific anxiety disorders are often not differentiated in research, and at times even in clinical practice. By far the most common disorder is generalized anxiety disorder. DSM-5 diagnostic criteria for generalized anxiety disorder are given in Table 65.2 [14].

Epidemiology

Anxiety disorders are the most common of all mental disorders, and affect almost 30% of the adult population at some point in their life [74]. As is the case for depression, anxiety disorders are more common in women than men, and are associated with lower socio-economic status and chronic diseases. All age groups can be affected, with a trend towards a lower prevalence in older age groups. Anxiety disorders contribute a considerable burden of disease; in 2016, they were responsible for 357 disability-adjusted life years lost per 100 000 globally, second only to depression [75].

Most studies of anxiety and diabetes have been conducted in clinical, typically hospital, settings rather than in community populations. Studies have often not distinguished between the various types of anxiety disorders, or even between anxiety *symptoms* and anxiety *disorder*. Where specific disorders have been investigated,

Table 65.2 DSM-5 diagnostic criteria for generalized anxiety disorder.

- A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
- B. The individual finds it difficult to control the worry.
- C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):
 - Note: Only one item required in children.
 - 1. Restlessness, feeling keyed up or on edge.
 - 2. Being easily fatigued.
 - 3. Difficulty concentrating or mind going blank.
 - 4. Irritability.
 - 5. Muscle tension.
 - 6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).
- D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- E. The disturbance is not attributable to the physiological effects of a substance (e.g. a drug of abuse, a medication) or another medical condition (e.g. hyperthyroidism).
- F. The disturbance is not better explained by another medical disorder (e.g. anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

not only detect generalized anxiety disorder, but also panic disorder, social anxiety disorder, and PTSD [83]. It cannot, however, be used to distinguish between these conditions. Although none of these instruments has been validated for use in diabetes, they are widely used in practice to screen or assess anxiety in chronic conditions.

A systematic review of 18 studies including 2584 adults with diabetes reported that generalized anxiety disorder was the most common type of disorder, with a current prevalence of 13.5% and lifetime prevalence of 20.5% [84]. Current and lifetime prevalences for panic disorder and PTSD were much lower (1.3% and 1.9%; and 1.2% and 3.7%, respectively). The prevalence of elevated symptoms of anxiety was 40%, higher in women than men, but similar for both type 1 diabetes and type 2 diabetes. A later meta-analysis of 12 studies with 12 626 people with diabetes reported a 25% increased risk of having an anxiety disorder or anxiety symptoms in people with diabetes compared to those without diabetes. The risk was increased by 20% for anxiety disorder (seven studies) and by 48% for anxiety symptoms (five studies) [85].

There have been wide variations in prevalence of anxiety reported across countries, which may be due to differing approaches to case ascertainment, heterogeneous study populations, and inconsistent distinction between anxiety disorders and symptoms. A recent study used the Mini-International Neuropsychiatric Interview to diagnose anxiety in 3170 adults with type 2 diabetes attending outpatient clinics in 15 countries [86]. The overall prevalence of anxiety disorders was 18%; 8.5% had generalized anxiety disorder and 5.1% had a lifetime diagnosis of panic disorder. Despite using a standardized approach for case ascertainment, there was huge variation in prevalence estimates between countries, ranging from 0% in Bangladesh to 72% in Ukraine. The authors suggest these differences may be driven in part by cultural differences in presentation and reporting of symptoms.

There have been a few longitudinal studies investigating the incidence of diabetes in anxiety and vice versa. A systematic review and meta-analysis of 15 studies and ~1.8 million participants reported that incident diabetes was increased by ~50% in those with baseline anxiety, confirming that both anxiety symptoms and anxiety disorders are risk factors for diabetes [87]. PTSD was also associated with an increased diabetes risk (OR 1.5; 95% CI 1.1 to 2.1). The review included only two studies of the incidence of anxiety in people with diabetes (one in a multiple sclerosis population), both showing no association [88, 89]. However, significant methodological limitations of these studies preclude any definitive conclusions. Several other studies, not eligible for this review, have indicated that diabetes is likely a risk factor for anxiety. For example, a study using data for around one million people from a Taiwanese insurance database reported a higher annual incidence of anxiety disorder over five years in people with diabetes [90]. Further research is needed to better understand this relationship.

Studies in children and adolescents have also shown an association between diabetes and anxiety, with one study reporting a 2.5-fold increased risk of developing incident anxiety over 26 years in young people with type 1 diabetes [91]. A systematic review of symptoms of depression and anxiety in young people with type 1 diabetes found 13.4% and 17% of participants with state and trait anxiety scores, respectively [92]. A recent systematic review of anxiety in children and adolescents with chronic conditions, including three studies with 336 young people with type 1 diabetes, reported prevalence ranging from 15.5% to 32.1% compared with 0% to 8% in the control groups [93].

studies have mostly reported on generalized anxiety disorder and PTSD. A further limitation of research in this area is that, unlike for depression, scales used to detect and measure anxiety have not been validated in diabetes populations. This is an important consideration, since a key challenge in diabetes is distinguishing between symptoms of anxiety and symptoms associated with hypoglycaemia. Symptoms common to both include adrenergic (e.g. tachycardia, sweating, pallor), mood, and cognitive disturbances. The presence of these symptoms in the absence of hypoglycaemia (or hyperglycaemia) would indicate that they are driven by anxiety.

Another challenge is distinguishing between an anxiety disorder and the understandable distress and fears commonly associated with living with and managing diabetes. A number of scales have been developed to assess diabetes-specific anxieties. The Hypoglycaemia Fear Survey [76] and the Fear of Complications Questionnaire [77] measure fears among people with type 1 diabetes. There is also the common fear of various invasive procedures (injecting insulin, blood glucose testing), which can be assessed using the Diabetes Fear of Injecting and Self-Testing Questionnaire [78] and the Measure of Invasiveness and Skipping Self-Monitoring [79].

The gold standard for making a diagnosis of an anxiety disorder is clinical interview, using recognized diagnostic criteria. The most common instruments used in research are the Beck Anxiety Inventory [80], the Hospital and Anxiety Depression Scale (HADS) [81], and the Generalized Anxiety Disorder Scale-7 (GAD-7) [82]. Despite its name suggesting otherwise, the GAD-7 does

Who is likely to develop an anxiety disorder?

The risk factors for developing an anxiety disorder in the general population are also relevant in diabetes, with women, younger people, and those with chronic medical conditions at highest risk [85, 86, 94, 95]. Depression is also a risk factor for anxiety, although the latter disorder is often overlooked in the presence of depressive symptoms. Factors specific to diabetes include longer duration of diabetes, fear of hypoglycaemia, and insulin use. The risk of an anxiety disorder, however, seems to be similar for type 1 diabetes and type 2 diabetes [87].

In one study of people with type 1 diabetes, 25% of participants met criteria for PTSD using self-reported symptoms, with PTSD related to hypoglycaemia [96]. In another study, 9% of people with diabetes using insulin reported anxiety symptoms related to self-administration of insulin [97], while an earlier study reported that 28% of people using insulin experienced anxiety related to self-injection [98].

Anxiety disorders as a risk factor for diabetes

Anxiety disorders are associated with an increased risk of diabetes [87]. Although this association may in part be mediated by the coexistence of depression, there is emerging evidence that anxiety is an independent predictor of incident diabetes. In 2156 adults initially free of diabetes, a positive anxiety screen predicted a diabetes diagnosis over a 10-year follow-up period [99]. The evidence for an association is strongest for PTSD, with several prospective studies reporting that PTSD increases odds of incident diabetes during follow-up (OR ranging from 1.3 to 2.1) [100–102].

Proposed mechanisms linking anxiety and diabetes

Although direct evidence is limited, several plausible biological and psychological mechanisms may help explain the link between anxiety and diabetes.

Biological mechanisms

Several biological pathways may mediate this association; one possible mechanism is via the HPA axis [103]. Anxiety may initiate activation of the HPA axis, triggering release of counter-regulatory hormones, such as glucagon, adrenaline, noradrenaline, cortisol, and growth hormone. Cortisol also stimulates the sympathetic nervous system, which is associated with symptoms of anxiety. Chronic anxiety may lead to insulin resistance, visceral adiposity, dyslipidaemia, and hypertension and an increased risk of type 2 diabetes [104, 105].

A related proposed mechanism to explain the relationship between anxiety and diabetes, which also implicates the HPA axis, is the concept of allostatic load [106]. This refers to the dynamic process of adaptation to environmental challenges via changes in multiple biological pathways, including the HPA axis, autonomic nervous system, and metabolic and immune systems. The purpose of these adjustments is to maintain homeostasis, but sustained stimulation may lead to *allostatic load*, which manifests as chemical imbalances, changes in diurnal rhythm of hormones, and even atrophy of brain structures. A study of allostatic load compared people with type 2 diabetes with matched people without diabetes; post-stress recovery in blood pressure, heart rate, and cholesterol were impaired in the group with diabetes [107]. Among other changes, cortisol and interleukin (IL)-6 concentrations were elevated, while people with diabetes reported greater stress experience than those without diabetes.

Studies in PTSD-discordant twins lend support to these putative mechanisms and suggest common biological and behavioural factors for both PTSD and diabetes [102]. PTSD is often associated with disruption of HPA axis regulation and the other mechanisms already described [108, 109]. However, the evidence is by no means unequivocal, as no consistent pattern of HPA alteration has been found [109]. PTSD is also associated with chronic hyperarousal of the sympathetic nervous system and renin-angiotensin-aldosterone system, which in turn is associated with neurometabolic changes, inflammation, and oxidative stress [110]. PTSD has been associated too with abnormalities in limbic-neuronal structure and function that contribute to central regulation of body weight.

Psychological mechanisms

People with diabetes may experience heightened anxiety related to many aspects of diabetes. Receiving a diagnosis of diabetes is often viewed as life-changing, bringing with it anxieties about undesirable changes to lifestyles, and fears of complications and even of shortened life expectancy [95, 103]. There may also be anxieties related to treatment, particularly with insulin, including fear of hypoglycaemia, glucose self-monitoring, and self-administration of insulin. Around 60% people with diabetes report anxiety about managing their type 2 diabetes; and this anxiety is associated with less effective self-management, persistent hyperglycaemia, and higher levels of diabetes complications.

Additionally, in common with other chronic disorders, the demands of self-care and increased need to access healthcare can be stressful and may have a significant impact on day-to-day life activities, including employment. Diabetes may be associated with adverse economic consequences by affecting earnings and employment, particularly in the presence of diabetes complications, contributing a further source of stress [111]. These multiple stressors are likely to mediate the increased risk of anxiety disorders seen in diabetes [95].

Consequences of anxiety in diabetes

Although it might be anticipated that anxiety would improve motivation to carry out self-management behaviours, and therefore lead to better glycaemic management, the evidence on outcomes of comorbid diabetes and anxiety disorders is mixed. A systematic review and meta-analysis of 12 studies found anxiety was not associated with glycaemic levels, but when limiting the analysis to studies using diagnostic interviews anxiety was associated with hyperglycaemia [112]. Several later studies have reported stress and anxiety to be associated with less effective diabetes self-management [113–116]. High levels of self-reported anxiety have also been associated with poor perceived glycaemic management, a greater number of diabetes complications, and poorer quality of life [117, 118]. In a recent multicountry study, presence of generalized anxiety disorder and current panic disorder as well as lifetime panic disorder were all significantly associated with persistent hyperglycaemia [86], but this was not replicated in another study from Portugal [119]. The discrepant results may be explained by a number of methodological limitations, including conflating anxiety symptoms with anxiety disorder, use of self-report measures for case finding, and cross-sectional design. A longitudinal study from the Fremantle Diabetes Study Phase II found no direct effect of generalized anxiety disorder on BMI, HbA_{1c}, smoking status, and blood glucose self-monitoring, although lifetime anxiety disorder was independently associated with increased risk of subsequent severity of depressive symptoms [120]. A four-year follow-up to this study found that a significant proportion

of individuals (13%) continued to report elevated anxiety symptoms, but they were not associated with health-related outcomes over time [121]. Another longitudinal study reported a ~20% increased mortality risk in men with diabetes in the presence of anxiety symptoms, but not in women [122].

In children and young people with diabetes, a systematic review identified eight studies (six cross-sectional and two longitudinal) investigating the association between anxiety and disease management and glycaemia [93]. Again, there were mixed findings: three studies reported an association between higher anxiety and sub-optimal diabetes management; one study found no association; and one found a relationship between high anxiety scores and both reduced HbA_{1c} and improved medication taking. A study investigating the association between social anxiety and diabetes-related outcomes found a positive association with self-reported moderately prudent (as opposed to either poor or good) diet, and with restricted food and drink intake.

In summary, there is inconsistent and contradictory evidence of an association between anxiety, self-management behaviours, glycaemia, and adverse outcomes in diabetes.

Management of people with diabetes and anxiety disorders

Although evidence for the effects of coexisting anxiety and diabetes on outcomes is equivocal, it is nevertheless clear that this comorbidity places a considerable burden on a significant proportion of people with diabetes. However, evidence-based guidance on the detection and management of anxiety disorders in diabetes is limited, often addressing anxiety symptoms only in the context of depression. The National Institute for Health and Care Excellence (NICE) guidelines on the management of type 2 diabetes [123], for example, do not mention anxiety disorders, and the Canadian Diabetes Association Clinical Practice Guidelines combine recommendations for depression and anxiety [124].

Screening and diagnosis of anxiety disorders

Recognition and diagnosis of anxiety in diabetes are a critical first step for effective management. Although there has been no evaluation of routine screening for anxiety in people with diabetes (and future research should address this evidence gap), given the considerable evidence that it is prevalent, persistent, and distressing, and the availability of effective treatments, regular screening for anxiety is recommended. The American Diabetes Association Position Statement recommends screening at diagnosis, at periodic intervals, and when there is a change in disease, treatment, or life circumstance; including caregivers and family members in this assessment is recommended [56].

When assessing for anxiety in diabetes, care needs to be taken to distinguish symptoms of anxiety from those of hypoglycaemia. Monitoring blood glucose while symptomatic can help make the distinction. Screening and diagnostic measures for anxiety have not been validated specifically in people with diabetes, while the gold standard is a clinical diagnostic interview conducted by a trained clinician. This may not be practicable in non-mental health settings. Screening tools such as GAD-7 [83] and HADS [81] can be used by non-specialists, with onward referral for confirmation of diagnosis and treatment as needed.

Treatment of anxiety in people with diabetes

Knowledge of treatment options and services for anxiety is important for healthcare professionals working in diabetes services.

Although evidence for effective treatments specifically in diabetes is sparse, there is a well-established evidence base for the management of anxiety disorders in the general population.

Psychological treatment

Psychological treatments either alone or in combination with pharmacotherapy, using a stepped care approach, are the mainstay in the management of anxiety disorders. Early identification and communication of the diagnosis, with psychoeducation, are the first steps, and may be sufficient to help alleviate mild symptoms of anxiety without further intervention. A range of low-intensity psychological interventions, including self-help resources, guided self-help, or psychoeducational groups, are the first-line management for those with ongoing symptoms following a period of monitoring. For those with marked functional impairment, or not responsive to low-intensity treatments, individual high-intensity psychotherapy (CBT) should be offered [125].

Trials of psychological therapies in people with diabetes have typically not targeted anxiety disorders, but rather symptoms of anxiety either as part of a depressive disorder or undifferentiated *common mental disorder*. A systematic review of the effectiveness of CBT on glycaemic levels and psychological outcomes in adults with diabetes identified 4 studies examining anxiety as an outcome and 11 measuring HbA_{1c} [126]. CBT was effective for reduction of anxiety symptoms at 3 and 6 months but not at 12 months, and for a significant short- and medium-term reduction in HbA_{1c}. These studies did not target individuals with a diagnosed anxiety disorder or elevated anxiety symptoms.

Pharmacotherapy

Effective pharmacological treatments for anxiety include SSRIs and tricyclic antidepressants [127]. These may be used instead of, or in combination with, psychotherapy in people with significant anxiety symptoms, depending on individual preference [125]. They should be reserved for individuals who have not responded to low-intensity interventions, or who have debilitating symptoms with significant functional impairment. As these drugs may affect glycaemic levels, closer blood glucose monitoring is recommended.

Models of care

There is a need for healthcare professionals with specific training in the detection and management of anxiety disorders working within diabetes services. Studies have shown that people are more likely to follow through and access mental healthcare that is co-located [128]. Few healthcare systems have mental health expertise embedded within physical health services and resource constraints limit the wider roll-out of such models of care. Collaborative care models [129], which have been found to be effective for the management of depression and diabetes, could also offer a feasible approach for delivering evidence-based management of anxiety in primary care or diabetes services [103].

Eating disorders

Eating disorders are the second most common mental illness in people with type 1 diabetes [95]. Eating disorders and disordered eating in diabetes encompass a broad spectrum of conditions, ranging from well-defined eating disorders like anorexia or bulimia nervosa to harmful diabetes self-care behaviours driven by fear of weight gain, with direct and indirect insulin restriction being the most common [130]. People with type 1 diabetes and

eating disorders have described their dual condition as a vicious cycle between having diabetes and disordered eating cognitions reinforcing each other [131, 132].

Because eating disorders are commonest in adolescents and young adults, there has been more research on the co-occurrence of eating disorders and type 1 diabetes [133]; far less is known about such problems in the larger population with type 2 diabetes [134–138]. Nevertheless, binge eating disorder and bulimia nervosa are seen as risk factors for type 2 diabetes and are associated with insulin resistance [139, 140].

Comorbid eating disorders significantly increase mortality [141, 142] and incidence of acute [143, 144] and late diabetes complications [145–147]. Currently, there is no evidence-based treatment that also improves glycaemia-related clinical outcomes [148].

Case definitions

The DSM-5 [14] and WHO International Classification of Diseases, 11th edition (ICD-11) [149] define three common eating disorders:

- Anorexia nervosa
- Bulimia nervosa
- Binge eating disorder.

Neither publication, however, acknowledges the specifics of eating disorders as a comorbidity to diabetes; in particular, there is no consideration of the relation to acute metabolic complications such as diabetic ketoacidosis, and chronic microvascular or macrovascular complications, as well as diabetes-specific cognitions such as the fear of insulin as promoting weight gain and behaviours including insulin restriction.

Clinicians with experience of working with people with diabetes and eating disorders have voiced the need for clarity in definition and for clinical diagnostic criteria for the spectrum of this dual condition. The coexistence of the two disorders goes beyond the current definition of *classical eating disorder*, because a large proportion of presenting clinical cases do not fit the established categories of eating disorders in spite of their significant clinical risk [150]. There is currently no clear international consensus on the definition of the wider spectrum of disordered eating in type 1 diabetes that accounts for the unique feature of insulin omission or restriction to control or reduce weight. This is an area of intense clinical research [151], with new clinical definitions emerging, such as *type 1 diabetes with disordered eating* (T1DE) and *diabulimia* [131, 134, 150]. However, these terms have not yet been included in the diagnostic catalogues.

With the exception of the Diabetes Eating Problem Survey-Revised (DEPS-R) [152] and the modified Sick, Control, One, Fat, Food tool (mSCOFF) [153], commonly used eating disorder or disordered eating self-report questionnaires, diagnostic interviews, and diagnostic criteria do not include questions on diabetes-specific disordered eating cognitions or diabetes self-care behaviours arising from these, nor are they validated for people with type 1 diabetes.

Eating disorders exist on a continuum of severity, and there is a lack of good evidence on which to establish a formal boundary or cut-off for *clinical* significance. When an eating disorder co-occurs with a chronic condition such as diabetes, its significance is increased by the potential for harm resulting from impaired self-care and acute and chronic hyperglycaemia. Thus eating disorders, which may be seen as *mild* in an otherwise healthy individual, may be moderate to severe in terms of risk for adverse clinical outcomes in a person with diabetes. The clinical red flags for severity in people with diabetes are persistently high HbA_{1c} (>86 mmol/mol, 10%), and recurrent hospital admissions in hyperglycaemia or diabetes ketoacidosis or with severe hypoglycaemia.

Table 65.3 DSM-5 diagnostic criteria for anorexia nervosa, bulimia nervosa, and binge eating disorder, and clinical features of type 1 diabetes disordered eating (T1DE).

Anorexia nervosa

- Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. Significantly low weight is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected.
- Intense fear of gaining weight or becoming fat, even though underweight.
- Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.

Bulimia nervosa

- Recurrent episodes of binge eating. An episode of binge eating is characterized by (1) eating, in a discrete period of time (e.g. within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances; and (2) a sense of lack of control over eating during the episode.
- Recurrent inappropriate compensatory behaviour to prevent weight gain, such as: self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting or excessive exercise.
- The binge eating and inappropriate compensatory behaviours both occur, on average, at least once a week for 3 months.
- Self-evaluation is unduly influenced by body shape and weight.
- The disturbance does not occur exclusively during episodes of anorexia nervosa.

Binge eating disorder

- Recurrent episodes of binge eating. An episode of binge eating is characterized by (1) eating, in a discrete period of time (e.g. within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances; and (2) a sense of lack of control over eating during the episode.
- The binge eating episodes are associated with three (or more) of the following: (1) Eating much more rapidly than normal. (2) Eating until feeling uncomfortably full. (3) Eating large amounts of food when not feeling physically hungry. (4) Eating alone because of feeling embarrassed by how much one is eating. (5) Feeling disgusted with oneself, depressed, or very guilty afterward.
- Marked distress regarding binge eating is present.
- The binge eating occurs, on average, at least once a week for 3 months.
- The binge eating is not associated with the recurrent use of inappropriate compensatory behaviour as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa.

T1DE (type 1 diabetes disordered eating) and diabulimia (not part of DSM-5 criteria)

- Established diagnosis of type 1 diabetes.
- Restriction or omission of insulin with the intention to control body weight.
- Persisting hyperglycaemia, or problematic hyperglycaemia and/or high glycaemic variability.
- Recurrent admissions in diabetic ketoacidosis; recurrent problematic hypoglycaemia.

Source: American Psychiatric Association 2013 [14].

The diagnostic criteria for the common forms of eating disorder and clinical features of T1DE are given in Table 65.3.

Epidemiology

Binge eating disorder is the commonest eating disorder, with an estimated lifetime prevalence of 2.6% among US adults, more than the prevalence for bulimia nervosa and anorexia nervosa

combined, with a gender ratio that is far less skewed [154, 155]. In contrast, ~1 in 250 females and 1 in 1000 males will experience anorexia nervosa, usually during adolescence or early adult life. Bulimia nervosa is more common, affecting 0.5–1% of young women in community studies. Longitudinal studies have shown that eating disorder diagnoses are often unstable over time, and cross-sectional studies underestimate the proportion of the population affected in the long term. Incidence rates in adolescent and young adults are higher than previously estimated.

Eating disorders are twice as common in people with type 1 diabetes than in the general population [156], with prevalence rates ranging between 0.9% in clinical databases [144], to 27% in females and 8.6% in males in population-based studies [157] and up to 36% in screening studies [158–160], depending on age group, gender, and case definition. This reflects the poor classification of the spectrum of T1DE, resulting in these broad prevalence estimates and possibly a high number of cases remain undetected. Insulin restriction in type 1 diabetes, which is seen to varying degrees in eating disorders, is associated with threefold increased mortality compared to those who do not restrict insulin [146]. Intentional insulin omission occurs remarkably frequently, increasing from 2% among girls aged 9–13 years, to 11% among girls aged 12–19 years, to 34–40% among young women aged 16–30 years [161]. Mortality is driven by accelerated onset of late diabetes complications secondary to persistent hyperglycaemia [146, 162] and by acute metabolic complications due to insulin omission or overdose.

For type 2 diabetes the epidemiological data are even scarcer, with prevalence estimates for binge eating disorder ranging from 1.4% to 29% and night eating syndrome 3.8% [133, 135, 163].

Diabetes as a risk factor for the development of an eating disorder

The diagnosis of diabetes can trigger the onset of an eating disorder in a person with pre-existing vulnerability factors, like early life events, important transitions, past psychiatric history, or personality factors (perfectionism). For example, for someone putting body weight and image at the centre of their self-evaluation, the experience of drastic weight loss in the run-up to the diagnosis of type 1 diabetes with following weight regain due to rehydration and re-insulinization, as well as the focus on carbohydrate content and food intake mandated by diabetes self-management, may drive the development of an eating disorder [132]. Predisposing traits of perfectionism, low self- and body esteem, and interpersonal and emotion regulation difficulties [158, 164] increase vulnerability to disordered eating in those with type 1 diabetes, once they interact with the necessary focus on eating in type 1 diabetes, a mechanism also discussed in an earlier conceptualization of type 1 diabetes and disordered eating [141]. This provokes unhelpful behaviours, such as strict dieting, restricting insulin, and binge eating, leading to neuroadaptive changes driven by loss of control over eating and fluctuations in plasma glucose [165]. Maintenance cycles of sustained disordered eating behaviour involve dietary restriction leading to hypoglycaemia, binge eating and hyperglycaemia, and purging or insulin restriction [132, 166].

In addition, interpersonal conflicts with carers or peers around what should or should not be eaten can perpetuate the problem, as described in recent transdiagnostic and cognitive behavioural theoretical models [132, 165, 166]. For example, the thoughts and cognitions driving insulin restriction behaviour range from fear of weight gain, fear of hypoglycaemia (because of adverse past

experience or due to high hypoglycaemia symptom threshold), feeling of control through manipulating insulin, to feeling of emotional numbness at marked hyperglycaemia [131, 132].

Aetiology

The causes of eating disorders are incompletely understood, but dieting appears to be an important risk factor, although only a small proportion of all those who diet go on to develop a disorder. Other known risk factors include female sex, early puberty, a history of obesity or gaining weight, peer and cultural influences, and certain personality traits including perfectionism and low self-esteem. Family relationships are often disturbed, although this may be either a cause or consequence of the disorder, or both.

Several of these factors may be magnified by the demands of the diagnosis or management of diabetes. People with type 1 diabetes have to match their insulin injections to carbohydrate intake, exercise, illness, and glucose levels, which involves a relentless self-care routine that puts a focus on food and self-management. People with type 2 diabetes are encouraged to make lifestyle changes, including dietary changes with reduction of high-calorie fatty and sugary foods, and increased exercise while aiming for weight reduction. This can lead to a preoccupation with food and body weight. Instead of relying on physiological cues related to hunger and satiety, food intake is brought under cognitive control, which can lead to feelings of low self-esteem and mood if self-imposed targets are missed. This in turn may drive further dietary restraint with a greater likelihood of subsequent failure, thereby causing a vicious cycle.

On average, people with type 1 diabetes are heavier than their peers and this may trigger dieting, weight preoccupation, and altered body image perception. Furthermore, there is a conflict between optimal glycaemia and body weight, as weight tends to increase as HbA_{1c} comes down [167]. Insulin treatment can lead to weight gain due to insulin's anabolic properties and the need for hypoglycaemia to be treated with additional carbohydrates. The pronounced weight fluctuation at diagnosis of type 1 diabetes can be very unsettling and reinforce eating disorder cognitions [132]. People with diabulimia have reported self-experimenting with insulin omission, considering insulin as their secret tool for weight loss, and also the empowerment through the insulin restriction being the one element of their diabetes self-care they can control [131].

In contrast, there may also be protective factors, for example self-compassion, resilience, aiming for 'good enough' diabetes management (not perfection), acceptance of diabetes as part of, but not defining, their identity, and prioritizing health over weight concerns [132].

Impact on diabetes outcomes

Eating disorders, especially if persistent, are a major cause of poor outcome in people with diabetes [145]. In the short term severe hypoglycaemia, diabetic ketoacidosis, and hospital admission are all more common in those with eating disorders [144, 168]. Rates of serious micro- and macrovascular complications and mortality are significantly increased, even if the eating disorder is relatively short-lived. However, the incidence of long-term complications increases with the duration of insulin omission. In one study, 86% of females with type 1 diabetes and severe eating disorders developed retinopathy after four years compared to 24% of those without eating disorders [147]. In a 10-year follow-up study of females with type 1 diabetes, a quarter of those who reported insulin omission had nephropathy, compared with 10% of those who did not [146].

Mortality rates in females with type 1 diabetes are increased ~16-fold in those with an eating disorder compared to those with diabetes alone (34.6 vs 2.2 per 1000 person-years) [142].

Clinical features

Anorexia nervosa

The hallmark of anorexia nervosa is weight loss, usually achieved by a combination of extreme dieting, exercise, and, less commonly, self-induced vomiting. Misuse of laxatives and other weight-reducing substances (e.g. diuretics, thyroxine) may also occur. In addition to these features, people with type 1 diabetes may resort to insulin omission as a purging mechanism, whereby rapid body weight loss can occur, associated with dangerous acute metabolic complications such as diabetic ketoacidosis, dehydration, and electrolyte disturbances.

People with anorexia nervosa experience a characteristic set of attitudes and values concerning body shape and weight, which include intense feelings of fatness and extreme fear of loss of control over eating and consequent weight gain. Their body image is distorted and they express a level of dissatisfaction with their shape and weight, which is far beyond that seen in the general population. There is a tendency to judge their self-worth almost solely in terms of weight, shape, and ability to control food intake.

Anorexia nervosa usually begins in adolescence, although prepubertal and adult onset may occur. For some the natural body changes of adolescence appear to be a risk factor; weight loss associated with a diagnosis of type 1 diabetes and then commencement of insulin treatment and subsequent weight gain may therefore act as a trigger [132].

The low weight of people with anorexia nervosa gives rise to the physiological and psychological features of starvation, including ritualized eating habits, cognitive rumination about eating, irritability, poor concentration, constant feelings of cold and misery, and decreased activity. Social withdrawal and isolation are common, and anxiety, obsessional features, and suicidal thoughts sometimes occur. ‘Fattening’ foods are typically avoided and the diet contains an average daily intake of calories in the region of 600–900 kcal/d, with very low fat and mineral intake. Most people with anorexia continue to feel hungry, and as such the term anorexia is a misnomer. The effects on hunger and appetite of persistent hyperglycaemia combined with insulin deficiency and ketosis in people with type 1 diabetes remain controversial. Some report paradoxical craving for sweet drinks, whereas others lose their appetite completely.

Common physical symptoms include gastrointestinal complaints (constipation, fullness after eating, bloating, and abdominal pain), lack of energy, reduced libido, early waking, and postural dizziness. Amenorrhoea is often present, with infertility and osteopaenia being significant risks. Those with prepubertal onset are often small in stature and show failure of breast development. Bradycardia, hypotension, and peripheral neuropathy are also reported, and a range of endocrine abnormalities may be found, including low sex hormone and tri-iodothyronine levels (with normal thyroxine and thyroid-stimulating hormone [TSH]), and raised growth hormone and cortisol. Autonomic and peripheral neuropathy are common in people with diabetes and anorexia nervosa, as the combination of starvation, extreme glycaemic variability [169], too rapid improvement of glycaemia during treatment, and long-term hyperglycaemia drastically increases the risk of microvascular complications [170].

People with type 1 diabetes can often be clinically severely ill at a BMI range that in conventional eating disorders care might not yet meet the threshold for inpatient admission. This is due to the additional physical health risks arising from the combination of type 1 diabetes, starvation, and insulin restriction. The risk of severe hypoglycaemia is high, due to lack of glycogen storage for counter-regulation and reluctance to take hypoglycaemia treatment that is perceived as extra calories. The risk for severe electrolyte disturbances from fluctuating insulin and glucose levels, dehydration, and inappropriate rehydration, as well as the risk for diabetic ketoacidosis are high. Overexercising and carbohydrate and calorie restriction are dangerous for a person with type 1 diabetes as these increase the risk of severe hypoglycaemia.

Bulimia nervosa

Bulimia nervosa is characterized by recurrent episodes of binge eating in which large amounts of food are consumed (typically ≥ 2000 kcal) during which the individual feels unable to control the eating. This behaviour is accompanied by a range of *compensatory* behaviours designed to prevent weight gain, including dietary restriction, vomiting, exercise, and laxative or diuretic misuse. Insulin restriction and omission (primarily in people with type 1 diabetes) and/or withholding other glucose-lowering agents are often used as compensatory or purging behaviour in bulimia nervosa.

People with bulimia nervosa have broadly the same set of attitudes and beliefs to those seen in anorexia nervosa. Although most individuals fall within the normal weight range, some have a history of underweight and may have previously met the diagnostic criteria for anorexia nervosa, while others are overweight. The vicious cycle of dieting, bingeing, purging, and fear of weight gain invariably has a detrimental impact on other aspects of functioning, such as work and social relationships, and can have financial implications resulting from the cost of the food. For some, binge eating seems to serve an important function by regulating unpleasant emotional states. Others have different impulse control problems and a history of interpersonal difficulties. Depression and self-harming behaviours such as cutting, overdosing, or substance misuse may occur; insulin omission can be considered as a form of self-harm. For a person with diabetes, hypoglycaemia can be an important trigger for binge eating episodes and vice versa [132, 169].

Physical complications of bulimia nervosa include enlargement of the parotid glands, erosion of dental enamel, and hypokalaemia from vomiting or laxative or diuretic misuse. With comorbid diabetes, the electrolyte and fluid imbalance can be more pronounced and dangerous, due to the large fluctuations of glucose and insulin causing osmotic and electrolyte shifts between intra- and extracellular compartments. Vomiting and overexercising increase the risk of severe hypoglycaemia. Vomiting may also have adverse effects on pre-existing diabetic retinopathy. Insulin restriction and omission can cause rapid dehydration and diabetic ketoacidosis.

Binge eating disorder

Binge eating disorder is defined by recurrent episodes of binge eating (eating in a discrete period of time an amount of food larger than most people would eat in a similar amount of time under similar circumstances and a sense of lack of control over eating during the episode), occurring on average at least once a week for three months, and associated with marked distress [14]. Binge episodes are also associated with ≥ 3 of the following:

- Eating rapidly.
- Eating until feeling uncomfortably full.

- Eating large amounts of food when not feeling physically hungry.
- Eating alone because of feeling embarrassed by how much one is eating.
- Feeling disgusted with oneself, depressed, or guilty afterwards.

Unlike those with bulimia nervosa, persons with binge eating disorder do not regularly engage in compensatory behaviours. Although many people with binge eating disorder have obesity, more than half have a BMI <30 kg/m², including 19% whose weight is normal [155].

The cognitions driving binge eating disorder can impact diabetes self-care and vice versa in a vicious cycle. For example, the feeling of guilt after a binge eating episode can increase the fear of diabetes complications, which then leads to the impulse of giving too much short-acting insulin to correct the hyperglycaemia following a binge eating episode, thus driving hypoglycaemia, which then may trigger the next binge eating episode [169].

Type 1 diabetes and disordered eating and diabulimia

Although the development and refinement of clinical criteria for these conditions are currently a work in progress, we have included the terms T1DE and diabulimia here as they are increasingly used by health professionals, people with diabetes, and researchers to describe disordered eating in type 1 diabetes [131, 150]. The key feature in the definition of T1DE or diabulimia is the pervasive fear of insulin as weight gaining leading to direct insulin restriction (complete insulin omission with the intention of losing weight) or indirect insulin avoidance through food restriction. Clinical severity indicators include very low BMI (below 15 kg/m²), HbA_{1c} consistently above 86 mmol/mol (10%) for more than 12 months, more than one admission in diabetic ketoacidosis in the past two years, and one or more severe hypoglycaemic episodes in the past year.

There will be significant overlaps between the classical eating disorders and the wider spectrum of T1DE and further research is under way to develop subtype classifications and clinical diagnostic and screening tools.

Management of eating disorders

Detection

Although some people with diabetes may volunteer information about eating problems or insulin restriction to control their body weight, many will be secretive as a result of factors including denial, guilt, or shame [131]. Thus an essential first step in management is successful detection of the problem. It is important to note that although eating disorders are generally associated with poor self-care and erratic glycaemic levels, alternating periods of hypo- and hyperglycaemia may be undetected by HbA_{1c}, although they may be uncovered with continuous glucose measurement [169]. Warning symptoms include:

- Marked weight fluctuation or loss.
- Symptoms of hyperglycaemia (thirst or tiredness).
- Persistently increased HbA_{1c}.
- Marked glycaemic variability.
- Frequent episodes of ketoacidosis (often requiring hospital admission) or severe hypoglycaemia leading to loss of consciousness, seizures, or needing third-party assistance.
- Growth retardation and pubertal delay in younger people with type 1 diabetes.

Most of these features are not specific for eating disorders and are only indicative of poor diabetes self-care. The only way to establish

a diagnosis of an eating disorder is by a clinical interview, although brief self-report scales may be a useful means of screening.

General diagnostic questionnaires for detecting eating disorders are inappropriate for individuals with type 1 diabetes, as they do not identify features that are unique to type 1 diabetes, such as insulin omission. Furthermore, some aspects of normal diabetes management may be viewed as disturbed eating in the general population. DEPS-R is a 16-item diabetes-specific self-report measure of disordered eating that was designed specifically for people with diabetes [152], while the mSCOFF questionnaire is a simple five-item screening to be used by diabetes healthcare professionals [153]. Neither questionnaire, however, replaces a thorough assessment by a multidisciplinary team with expertise in diabetes and eating disorders.

Treatment of eating disorders

There are no evidence-based treatments or comprehensive treatment protocols that lead to sustained improvements in glycaemia and diabetes-related outcomes in people with type 1 diabetes and eating disorders [148]. Consequently, advice is currently based on existing guidelines for people with diabetes or with eating disorders, with some pragmatic integration of the two [171, 172]. For example, the NICE guidance for the treatment of eating disorders now includes a subchapter with general principles for managing a person with diabetes [172]. Likewise, the NICE guidance for managing type 1 diabetes alerts the diabetes healthcare professionals to the possibility of bulimia nervosa, anorexia nervosa, and insulin dose manipulation in adults with type 1 diabetes with overconcern about body shape and weight, low BMI, hypoglycaemia, and suboptimal glucose management [171]. The key strategy is a multidisciplinary and multiprofessional team approach that integrates the physical and mental health aspects pertinent to both diabetes and eating disorders [150]. There are ongoing clinical research and clinical quality improvement projects in the UK that incorporate a multidisciplinary approach and step-wise re-insulinization, combined with psychotherapy and close monitoring of physical and mental health [173].

Although most people can be managed on an outpatient basis, the risk of impaired physical health necessitating inpatient admission is increased in those with diabetes. Regular physical monitoring is needed to manage the high risk of complications and mortality. Challenges in treating acute metabolic decompensation and inpatient care in eating disorder units for a person with T1DE lie in the combination of re-insulinization and refeeding that can cause dramatic shifts of electrolytes and fluids between extra- and intracellular compartments, sensation of pseudo-hypoglycaemia, rapid weight gain due to fluid retention, and stopping the catabolism by reintroducing insulin. Dehydration caused by hyperglycaemia mandates appropriate access to fluids, which is conflicting with standard eating disorder care where fluid overload to imitate weight gain is avoided by limitations of fluid intake. Nutrient and vitamin deficiency in combination with chronic hyperglycaemia and following rapid improvement of glycaemia can exacerbate autonomic and/or painful peripheral neuropathy.

Severe T1DE has to be treated cautiously in a step-wise titration process to avoid treatment side effects, with a slow reduction of HbA_{1c} by no more than 20 mmol/mol (2%) in two months. Treatment-induced worsening of pre-existing retinopathy can occur following too rapid improvement of glycaemia, particularly in those with pre-existing diabetic retinopathy at baseline, and a large reduction in HbA_{1c} [174]. Retinal screening and assessment

are mandatory before initiating treatment that may result in rapid improvement of glycaemia. Another possible side effect of too rapid improvement is treatment-induced neuropathy, presenting as neuropathic pain, autonomic dysfunction, or a combination of both. As insulin neuritis can lead to severe, disabling pain, there should be a focus on controlling symptoms while they gradually improve over the subsequent weeks or months.

Psychotherapeutic treatment may include cognitive behavioural therapy, family therapy, or psychodynamic therapy among other approaches [175]. Ideally, there should be close collaboration between the psychotherapist and the diabetes team to avoid conflicting messages and to provide adequate training in the other specialism to enable joint care management using a stepwise approach that integrates both diabetes and eating disorder care. Dietary and refeeding plans should be coordinated with the diabetes therapy; some people with T1DE tend to prefer lower-carbohydrate diets (with ~150 g of carbohydrates/d) and so access to hypoglycaemia treatment carbohydrates and consideration of hypoglycaemia risk in those who purge are needed.

Insulin administration should be closely supervised, or even taken over by healthcare professionals in the inpatient setting, as insulin injections often are manipulated by those with a pervasive fear of insulin being weight gaining, in a similar way to supervised meal times in inpatient treatment of anorexia nervosa [173]. Insulin pump therapy is not indicated in the acute stages of severe T1DE due to risk of diabetic ketoacidosis, but may be reinstated in advanced stages of recovery on an individualized basis, if it is clinically safe.

Anorexia nervosa

A necessary first step for all is restoration of weight towards normal levels. During this process it is usually necessary to aim for slow stepwise glycaemia improvement rather than tight glycaemic management. Diet should focus on healthy foods with a high satiety index. Severe hypo- or hyperglycaemia must be avoided; as it is necessary to consume calories to prevent or treat hypoglycaemia, this can cause anxiety in the person with diabetes. Glucagon injections for treatment of severe hypoglycaemia are much less effective in people with anorexia nervosa and T1DE, as the glycogen stores are depleted. As the insulin dose and blood glucose levels will change with eating habits and weight, close liaison will be needed between the eating disorder and diabetes teams.

Bulimia nervosa

Treatment for bulimia nervosa, particularly by means of CBT, is widely accepted, although there has been less study of its suitability for people with diabetes. The coexistence of diabetes with bulimia inevitably complicates management. For example, purging by vomiting after a meal insulin bolus is associated with a high risk for hypoglycaemia. Successfully engaging people in treatment may be more difficult, and approaches such as motivational interviewing may play a role. Modification to standard treatment approaches includes the monitoring of self-care behaviours; again, it is desirable that the eating disorder team has knowledge and experience of the usual management of diabetes. Conflict may arise between the modifications to eating behaviour advocated for bulimia nervosa treatment (promoting a more flexible approach to eating) and the dietary advice often given for diabetes management (regular controlled eating and avoidance of certain food groups). The development of structured education that offers a more person-centred approach may help in this dilemma.

Other forms of treatment for bulimia nervosa include interpersonal psychotherapy and the use of antidepressants. Fluoxetine has been approved for acute and maintenance treatment of binge eating and vomiting behaviours in people with moderate to severe bulimia nervosa. A group educational programme for people with bulimia and type 1 diabetes was better than standard care in improving eating behaviour, but did not lead to improved glycaemic levels [176]. Inpatient treatment also appears to be successful, but relapse may occur rapidly after discharge [177]. The applicability of this approach in most healthcare systems remains to be tested.

Binge eating disorder

For the management of binge eating disorder, psychological treatments such as CBT are recommended as first line and supported by meta-analytic reviews [178]. Treatment approaches for binge eating disorder with comorbid diabetes have not been extensively studied, but in one small study in type 2 diabetes no significant difference was found in HbA_{1c} between those with and without binge eating disorder [179].

Psychotic disorders

Psychotic disorders include schizophrenia, psychotic depression, and bipolar disorder and are often known as *severe (and enduring) mental illness* (SMI). The presence of psychotic symptoms, which include delusions and hallucinations, has a profound effect on well-being and functioning of many aspects of daily life. When they co-occur with a chronic physical illness such as diabetes, they create complex management challenges.

Case definitions

Schizophrenia is characterized by psychotic symptoms (delusions, hallucinations), disorganization of speech and other behaviour, and so-called *negative* symptoms that include loss of drive and blunting of affect (Table 65.4). Schizophrenia is also associated with cognitive decline. The illness tends to run a chronic clinical course, and most people with the condition will be under the long-term care of specialist mental health services.

Although bipolar disorder is often thought to be a disease whose hallmark is the occurrence of one or more episodes of mania (elevated mood; Table 65.5), bipolar disorder can be conceptualized as predominantly a depressive disorder, based on the amount of time people with bipolar disorder have depressive symptoms [180]. On average, the ratio of the number of depressive episodes to manic or hypomanic episodes is 3:1 for bipolar I disorder, and the ratio of

Table 65.4 Diagnostic criteria for schizophrenia.

- A. Two or more of the following symptoms, at least one of these must be (1), (2), or (3):
 - 1. Delusions.
 - 2. Hallucinations.
 - 3. Disorganized speech.
 - 4. Grossly disorganized or catatonic behavior.
 - 5. Negative symptoms (affective flattening, alogia, or avolition).
- B. Social/occupational dysfunction.
- C. Features continuously present for at least 6 months.

Source: American Psychiatric Association 2013 [14].

Table 65.5 Diagnostic criteria for a manic episode [14].

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week.
- B. During the period of mood disturbance, three or more of the following symptoms have persisted (four if mood only irritable):
 1. Inflated self-esteem or grandiosity.
 2. Decreased need for sleep.
 3. More talkative than usual or pressure to keep talking.
 4. Flight of ideas or subjective experience that thoughts are racing.
 5. Distractibility.
 6. Increase in goal-directed activity or psychomotor agitation.
 7. Excessive involvement in pleasurable activities that have high potential for painful consequences (e.g. spending, sexual activity).
- C. Marked impairment in occupational functioning or in usual social activities or relationships with others, or need for hospitalization to prevent harm to self or others, or psychotic symptoms.

depressive episodes to hypomanic episodes is 39:1 for bipolar II disorder. In addition, the strict diagnostic criteria for bipolar disorders are complex, and there is a degree of overlap with schizophrenia, such that some people may be diagnosed as having a *schizo-affective* disorder [181].

Epidemiology

Schizophrenia is estimated to have a point prevalence of between 1 and 7 per 1000 in the general population, with an annual incidence of 13–70 per 100 000, and a lifetime risk of 1–2%. There is little variation in incidence across the world. The clinical course of the illness is variable, ranging from a single brief episode (rarely) to a lifelong illness with marked deterioration over time. There are many theories about the causation of schizophrenia; it has a marked genetic risk profile, but is also associated with early cerebral insults (e.g. birth anoxia) and environmental stress.

Bipolar disorder is much less common than unipolar depression, with an estimated lifetime prevalence of 1% for bipolar I disorder and another 1% for bipolar II disorder. Again, genetic factors

are thought to play an important role in the aetiology of bipolar disorder, which is among the most heritable of mental disorders.

People with SMI have standardised mortality rates that are approximately two- to threefold higher than the general population, equating to a loss of 10–20 years of life [182]. The average life expectancy for men and women with schizophrenia in the UK is 62.8 years and 71.9 years, respectively [183]. While suicide and trauma account for the highest relative risk of death, the commonest causes of death are from physical illness, principally cardiovascular disease. Over the last 30 years, while the life expectancy of the general population has improved, this has not been experienced by people with SMI, leading to a widening health inequality gap [184, 185].

Diabetes and severe mental illness

It is challenging to obtain precise diabetes prevalence rates in people with SMI because of the high prevalence of undiagnosed diabetes, which is estimated to be up to 70% of all cases in some settings [3]. Nevertheless, there is a general consensus that the prevalence of diabetes is two- to threefold higher than in the general population. A meta-analysis of 118 studies including 438 245 individuals with SMI found that the estimated weighted mean prevalence of type 2 diabetes was 10.2% [186]. There were no significant differences in the estimated rates of diabetes between different SMIs, but diabetes was more common among women than men. Compared with the general population, people with multiple episodes of psychosis had significantly increased risk of type 2 diabetes (relative risk [RR] 1.85). The increased prevalence is driven by an excess of type 2 diabetes, as there is no evidence of enhanced pancreatic autoimmunity. The incidence of diabetes is higher and the onset of diabetes appears to be 10–20 years earlier than in the general population [187] (Figure 65.3). As is seen in the general population, Black and Asian minority background and socioeconomic deprivation increase risk of type 2 diabetes in people with SMI [188]. Furthermore, the incidence of diabetes increases with age until around the age of 60 years [188]; however, as diabetes is uncommon in young healthy adults, the increased relative risk of diabetes is greatest in adolescents and young adults with SMI [3].

Although subtle metabolic abnormalities have been found in people with a first episode of psychosis, the majority of studies show that metabolic abnormalities develop rapidly after treatment initiation and meta-analyses have found no appreciable increase in

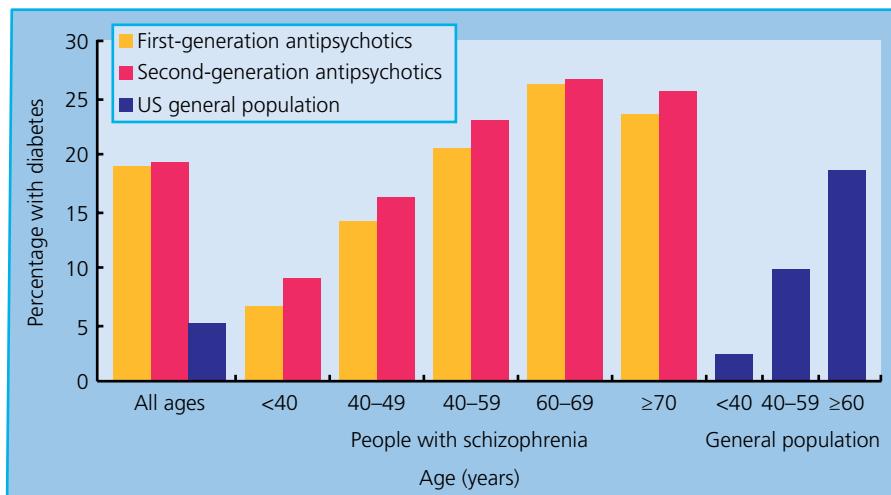

Figure 65.3 Age-specific prevalence rates of diabetes in people with schizophrenia compared with the general US population. Source: Data from Sernyak et al. 2002 [187] and National Health and Nutritional Examination Survey 2001–2002 (<https://www.cdc.gov/nchs/nhanes/index.htm>).

diabetes in people prior to the initiation of antipsychotic treatment [186, 189].

People with SMI experience higher rates of microvascular and macrovascular complications, acute metabolic dysregulation, and three- to fourfold more diabetes-related deaths [3]. In one study from Denmark, among those aged ≤ 50 years, 15.0% died within seven years of a diagnosis of diabetes; the corresponding figures for those aged 50–69 years and ≥ 70 years were 30.7% and 63.8%, respectively. A third of deaths from physical causes were attributed to diabetes, while 14% of deaths were attributed to the interaction between diabetes and SMI [190]. In a recent observational matched nested case-control study using routinely collected data from primary healthcare in England, SMI was associated with an almost twofold increased risk of all-cause mortality and more than twofold increased cardiovascular-specific mortality in people with diabetes [188].

Why psychotic disorders are linked to diabetes

Unlike depression, most evidence indicates that diabetes does not predispose to psychotic illness. Psychotic illnesses tend to present in early adulthood and precedes the onset of diabetes. While psychosis may also present in older age, it is unclear whether diabetes increases the risk of psychosis in this age group [191].

Conversely, it has been noted for over a century that people with SMI are at increased risk of glucose abnormalities [3]. An interest in the physical health of those with SMI was stimulated following the introduction of first-generation antipsychotics that for the first time allowed people with SMI to achieve reasonable control of their psychotic symptoms and live independently. Following concerns about metabolic side effects of the second-generation antipsychotics around the turn of the millennium, further effort was made to understand the link between psychosis and diabetes, and a greater comprehension of the highly complex inter-relationship between the person with SMI, their treatment and environment, and risk of diabetes has been gained. Although concerns about the side effects of antipsychotics triggered the resurgent interest in diabetes, to blame the antipsychotics alone for the increased risk of diabetes misses the full picture and may hinder attempts to prevent and treat diabetes in this population.

Genetics

Both schizophrenia and type 2 diabetes are highly heritable disorders and it is conceivable that there may be genes that increase the risk of both conditions. Many schizophrenia genes are expressed in the brain and include those involved in glutamatergic neurotransmission and the D₂ dopamine receptor (*DRD2* gene), while type 2 diabetes is associated with polymorphisms in genes that influence hepatic and peripheral insulin resistance, adipogenesis, and pancreatic β-cell mass and function (Chapter 12). Recent studies have identified at least 37 common genes that increase the risk of both type 2 diabetes and schizophrenia [192]. It is estimated that ~11% and 14% of these risk genes for type 2 diabetes and schizophrenia, respectively, may account for the risk of the other disease. Several candidate genes that may affect the risk of both conditions have been identified (Table 65.6) [192, 193].

In addition to affecting an individual's risk of type 2 diabetes directly, genetic polymorphisms in various genes, including the promoter region of the 5-hydroxytryptamine_{2C} receptor, leptin, methylenetetrahydrofolate reductase (*MTHFR*), and *MC4R* genes, appear to modify the risk of antipsychotic-induced weight gain [194]. Polymorphisms in the *HRH1*, *BDNF*, *NPY*, *CNR1*, *GHRL*, *FTO*, and *AMPK* genes may also affect the risk of weight gain.

Table 65.6 Genes that have been linked to both diabetes and schizophrenia.

Gene	Function
Glycogen synthase kinase 3 (GSK3)	Regulates both glucose metabolism and cognitive function
Serine-threonine protein kinase AKT1	Reduced expression in lymphocytes and the frontal cortex in schizophrenia. Mediates insulin signalling and glucose metabolism; reduced action leads to diminished phosphorylation of its substrates, including GSK3
Dopamine D ₂ receptor (<i>DRD2</i>) gene	Implicated in obesity and type 2 diabetes, through alteration of insulin sensitivity and secretion. Affects risk of schizophrenia
Tyrosine hydroxylase gene <i>TCF7L2</i> gene	Associated with insulin resistance and schizophrenia
	Encodes for a transcription factor involved in Wnt/beta-catenin signalling that has a role in pancreatic β-cell function and is a susceptibility gene for type 2 diabetes. Wnt signalling pathway plays a role in central nervous system development and is associated with schizophrenia
Brain-derived neurotrophic factor and related pathway genes	Major member of the neurotrophin family, which has been linked with a range of clinical features of schizophrenia and is involved in regulation of cardiometabolic function

Source: Data from Lin and Shuldiner 2010 [192] and Perry et al. 2022 [193].

Environment and biological effects of the illness

Many of the environmental factors that mediate the association between diabetes and depression are also relevant for the links between diabetes and SMI, including intra-uterine environment, adult health behaviours (diet and physical activity), neighbourhood environment, and poverty (Figure 65.2) [3]. Several inflammatory and neuroendocrine changes, including HPA dysfunction, also occur in SMI.

Antipsychotic medication

Antipsychotics are an integral element of the treatment of SMI that also comprises multidisciplinary psychological, social, and rehabilitation interventions. They are frequently taken over a long period to prevent relapse and hospitalization and to decrease mortality [195]. The first generation of antipsychotics was introduced in the 1950s, but their use was blighted by a high incidence of a range of unwanted side effects, including hypotension, weight gain, sexual dysfunction, sedation and extrapyramidal side effects. In order to reduce the likelihood of these movement disorders, second-generation antipsychotics (also known as atypical antipsychotics) were developed. Although the second-generation antipsychotics are generally better tolerated, an association with weight gain and other metabolic abnormalities rapidly became apparent [196].

Large pharmaco-epidemiological database studies reported that antipsychotics were associated with more diabetes than no treatment, while treatment with a second-generation antipsychotic is associated with a 32% (15–51%) increase in diabetes risk compared with first-generation antipsychotics (Figure 65.4) [197]. Overall, the risk appears to be low, however, with number needed to harm (NNH) estimates ranging from 19 to 333 for clozapine, 22 to 3333 for risperidone, 21 to 747 for olanzapine, and 24 to 500 for quetiapine [198]. Although the risk of diabetes for the latest

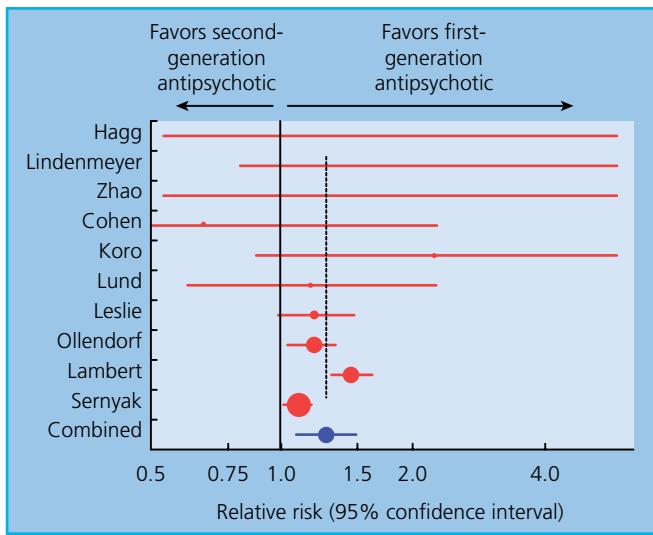

Figure 65.4 Forest plot of relative risks and 95% confidence intervals for diabetes in individuals with schizophrenia receiving first-generation antipsychotics compared with second-generation antipsychotics. Source: Modified from Smith et al. 2008 [197].

second-generation antipsychotics is widely believed to be lower, this has not always been apparent in pharmaco-epidemiology studies. For example, aripiprazole and ziprasidone were not associated with lower rates of diabetes than olanzapine, quetiapine, and risperidone in a pharmaceutical claims database [199], perhaps because of channelling bias, whereby people at higher risk for diabetes are prescribed antipsychotics that are perceived to be safer.

Although pharmaco-epidemiological studies can assess small risks in large populations who may be followed for a longer period of time than clinical trials by design, methodological flaws can affect the interpretation of results. They rely on data from administrative databases with inherent problems of data quality, such as convenience reporting of adverse effects, prescriber bias, and omission of important confounding diabetes risk factors [200]. Furthermore, individuals with either undiagnosed diabetes or those treated with lifestyle interventions alone will not be recorded in prescription databases.

Treatment assignment is not randomized and so differences in diabetes rates may be explained by factors other than the treatment. For example, clozapine is usually reserved as a second-line antipsychotic because of its risk of causing agranulocytosis, requiring ongoing monitoring of the white blood cell count. As a result, it is used in people with the most serious mental illness who are resistant to treatment with at least two other antipsychotics. By virtue of their illness, these individuals may be at higher risk of diabetes, and so higher rates of diabetes among people treated with clozapine may reflect a person receiving the antipsychotic rather than treatment *per se*. Another potential reason for the observed increase with clozapine is *screening bias*. People receiving second-generation antipsychotics, particularly those receiving clozapine, are much more likely to be screened for blood glucose abnormalities than individuals receiving first-generation antipsychotics [201]. Since there are high rates of undiagnosed diabetes in people with SMI, increased screening will inevitably result in an increased detection of diabetes without the need to invoke a causal relationship between drug and diabetes.

RCTs are considered the gold standard when assessing the effect of an intervention, but antipsychotic trials are underpowered to detect changes in incident diabetes and consequently most trials have reported no differences [202]. Examining blood glucose changes is a more sensitive way of assessing an antipsychotic's metabolic effects, and a systematic review of 48 head-to-head comparison studies found a greater, albeit small, increase in glucose following treatment with olanzapine compared with amisulpride, aripiprazole, quetiapine, risperidone, and ziprasidone [203]. There were no differences in glucose changes between the other antipsychotics studied. Another systematic review found similar increases in glucose following treatment with the newer antipsychotics asenapine, iloperidone, and paliperidone [204]. In the European First-Episode Schizophrenia Trial, which examined treatment effects in treatment-naïve people with first-episode psychosis, the mean change in glucose over a year ranged between 0.2 and 0.5 mmol/l, with no differences between drugs [205]. Although small, these increases in glucose concentration may translate into meaningful differences in incident diabetes with the long duration of treatment needed to treat SMI.

There are several mechanisms by which antipsychotics increase the risk of diabetes. All antipsychotics may be associated with weight gain [196]; however, the effect size is markedly heterogeneous, with weight gain being less problematic for haloperidol, ziprasidone, and lurasidone in contrast to large effects observed with olanzapine, zotepine, and clozapine (Table 65.7) [206]. Overall, 15–72% of treated individuals experience more than 7% of body weight gain in the first year of treatment [207]. From the short-term pivotal trials of the different antipsychotics, the NNH versus placebo for weight gain of ≥7% from baseline ranges from 6 for olanzapine and quetiapine immediate release to 67 for lurasidone [208]. Weight gain is most marked in people naïve to antipsychotics, where weight gain is up to three- to fourfold greater than in those with chronic illness [209]. Most weight gain occurs early in treatment, although people can continue to gain weight for at least four years after treatment initiation, albeit at a slower rate and gradually reaching a plateau.

Weight does not explain all the excess diabetes risk, as some individuals develop diabetes without being overweight or gaining weight. As weight gain is likely to increase diabetes risk through

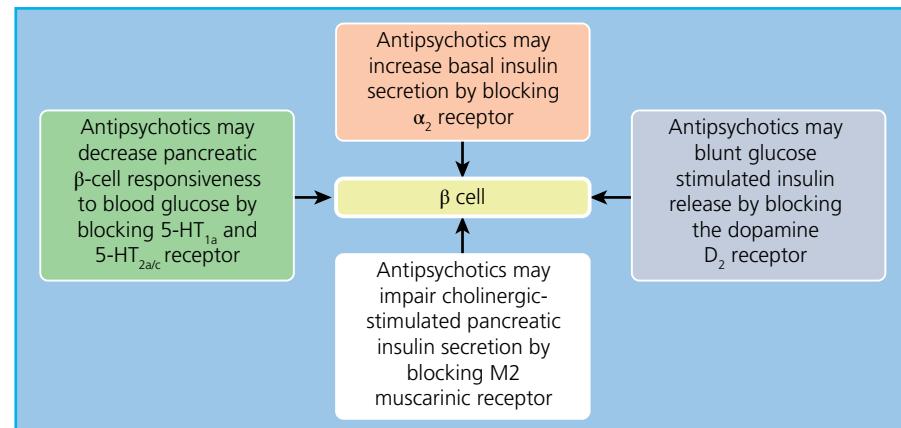

Figure 65.5 Possible pharmacological effects of antipsychotics on β -cell function.

increased insulin resistance, it does not explain why some people develop diabetic ketoacidosis, which occurs as a result of markedly impaired insulin secretion. Through their interaction with multiple receptors, antipsychotics may affect insulin secretion by the β cells of the pancreas. Blockade of α_2 receptors may increase basal insulin secretion, while blockade of 5-HT_{1a} and 5-HT_{2a/c} receptors may decrease pancreatic β -cell responsiveness to blood glucose (Figure 65.5). Central control of glucose homeostasis may also be affected by antipsychotics [210]. In addition to these pancreatic effects, *in vitro* work suggests that antipsychotics may directly impair insulin action by inhibiting insulin-mediated glucose uptake and glycogen synthesis.

Contribution of different mechanisms

Given the complex pathophysiology of type 2 diabetes, it is perhaps unsurprising that multiple mechanisms are involved in the association between SMI and diabetes. It is also likely that the contributions of these risk factors operate differently between individuals. Overall, it appears that an excess of traditional diabetes risk factors, such as obesity, poor diet, physical inactivity, and family history, conveys a higher risk than treatment, but this does not discount the possibility that antipsychotics are the major contributor to the development of diabetes in certain individuals, particularly where the onset of diabetes is rapid after treatment initiation and other risk factors are absent [3].

Screening of diabetes in those with severe mental illness

Given the large numbers with undiagnosed diabetes, there have been moves to screen at-risk individuals in the general population for diabetes. As people with SMI constitute a high-risk group, several national and international guidelines have recommended regular screening for diabetes, regardless of antipsychotic treatment (Table 65.8) [212, 213]. Although there are differences in detail, all guidelines recommend screening before the start or change of treatment, several months later to identify the few who develop diabetes rapidly after antipsychotic initiation, and annually thereafter. Although the oral glucose tolerance test has been implemented successfully in some settings, this test is no longer widely used in the general population and measurements of fasting or random glucose, or HbA_{1c}, are more practical alternatives. There is a debate about the relative sensitivity and specificity of each of these tests, but a pragmatic view should be taken; both random glucose and HbA_{1c} are more convenient and this probably outweighs any small loss of sensitivity. One caveat about HbA_{1c} is that it may be falsely

negative if glucose concentrations are rising rapidly, as may happen shortly after treatment initiation. In the setting, combining HbA_{1c} and glucose is a sensible option.

Despite clear guidance and potential benefit, screening has not been implemented into routine clinical practice (Figure 65.6) [214, 215], perhaps because people with SMI may be less likely to undergo opportunistic health screening. Professional barriers to screening, including inertia or prejudice, lack of clarity about whose responsibility it is, lack of understanding about the most appropriate test and its interpretation, and lack of access to necessary equipment, may also be responsible for the poor screening rates within mental health settings [216]. In the UK, general practitioners are offered financial incentives through the Quality Outcomes Framework to improve routine physical health checks for people with SMI, including screening for and monitoring of diabetes.

Prevention of diabetes

There have been no specific diabetes-prevention studies in people with SMI, but RCTs of lifestyle interventions that aim to treat or prevent obesity, which encompass similar principles to diabetes prevention, have been undertaken. Despite widespread pessimism that lifestyle interventions in people with SMI would be ineffective, the early studies suggested the contrary [217]. A meta-analysis of lifestyle interventions reported a mean reduction in weight of

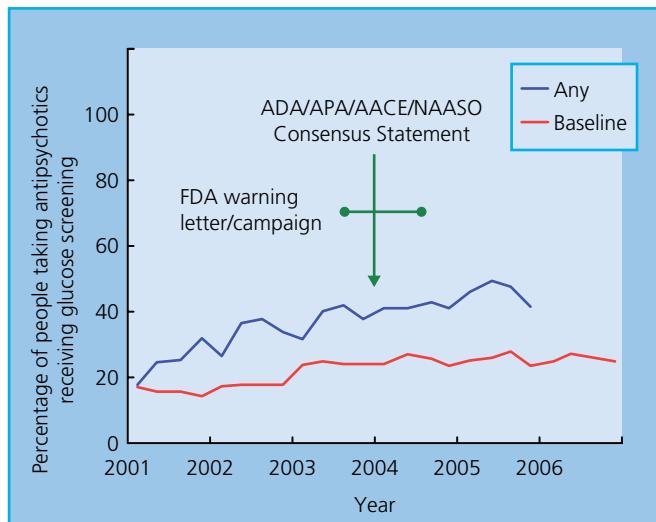

Figure 65.6 The effect of the American Diabetes Association (ADA), American Psychiatric Association (APA), American Association of Clinical Endocrinologists (AACE), and North American Association for the Study of Obesity (NAASO) consensus statement and US Food and Drug Administration (FDA) guidance on glucose testing in people receiving antipsychotic medication. Source: Modified from Morrato et al. 2009 [214], Figures 1 and 2.

3.12 kg over a period of 8–24 weeks, with commensurate reductions in waist circumference and improvements in cardiovascular risk factors [217]. The conclusions were, however, limited by the short duration of most trials (12–16 weeks) and the low number of participants (median 53, range 15–110). NICE published an expanded literature review of 24 studies in 2014 that came to broadly the same conclusions but was more critical of the evidence, highlighting the high risk of bias and substantial heterogeneity of effect size between studies [213]. The most recent meta-analysis, which included 41 RCTs and 4267 participants, reported a much smaller effect size that is likely not to be clinically relevant [218]. Overall the interventions reduced mean BMI by 0.63 kg/m², equivalent to a weight loss of 2.2 kg, in association with a reduction of waist circumference. Intervention participants were 50% more likely to lose weight than control participants. More recent and more rigorous studies were less likely to demonstrate a beneficial effect [219, 220], which may explain the smaller effect size than in earlier meta-analyses.

No pharmacological diabetes-prevention trials in people with schizophrenia have been reported, but short-term trials of various drugs have been undertaken to reduce weight or attenuate weight gain in people with schizophrenia receiving antipsychotics. Although metformin has very little effect on body weight in the general population, this drug is the most extensively studied in the context of SMI and is associated with a mean reduction in body weight of 3.3 kg over 3–6 months [221]; it is unclear, however, whether this weight loss is maintained in the long term. Many other drugs have been studied, of which orlistat, reboxetine, and topiramate are associated with a small reduction in weight; however, no drugs have been sufficiently evaluated to recommend their routine use, not least because of their potential for adverse effects (Table 65.9) [222].

The most promising new drug class is the glucagon-like peptide-1 (GLP-1) receptor agonists. Three studies have evaluated the use of GLP-1 receptor agonists using the diabetes dose as a treatment for

Table 65.9 Drugs that have been tested as potential agents to prevent or reduce weight gain.

Amantadine
Nizatidine
Topiramate
Metformin
Betahistine
Fluoxetine
Reboxetine (not available in the USA)
Sibutramine (withdrawn because of safety concerns)
Exenatide
Orlistat (approved for the management of obesity)
Lorcaserin (withdrawn because of safety concerns)
Phentermine topiramate combination (approved for the management of obesity in the USA)
Naltrexone bupropion combination (approved for the management of obesity in the USA)
Liraglutide (approved for the management of obesity)

antipsychotic-induced weight gain, two using exenatide and one using liraglutide [223–225]. A meta-analysis of these studies reported a mean 3.71 kg greater weight loss after 16 weeks of treatment in people treated with the GLP-1 receptor agonists [226]. Weight loss was greater in those treated with clozapine or olanzapine compared with other antipsychotics. A further trial of the 3 mg obesity dose of liraglutide demonstrated a 5.7 kg weight loss in people with schizophrenia [227].

Given the varying propensities to weight gain and metabolic disturbance associated with different antipsychotics, it is reasonable to consider whether switching antipsychotics may reduce the subsequent risk of diabetes. A meta-analysis of 40 RCTs and 15 uncontrolled studies including 12 279 individuals found reducing that the dose, discontinuing the antipsychotic, or switching to a partial agonist antipsychotic reduced weight by a mean of 1.5 kg compared to maintaining the current treatment. This suggests that altering the antipsychotic will reverse only part of antipsychotic-induced weight gain [228].

Management of those with diabetes

The management of diabetes in people with SMI should follow currently available treatment algorithms for the general population, but agents that induce less weight gain or promote weight loss, such as incretin-based therapies or sodium–glucose cotransporter 2 (SGLT-2) inhibitors, may have advantages given the high prevalence of obesity in people with SMI.

Diabetes self-management is key to managing diabetes and there are concerns that SMI may interfere with the lifestyle changes, regular monitoring, and self-medicating that make up diabetes self-management. Consequently, it is reassuring that a systematic review reported medication-taking rates among those with mental illness of between 51% and 85%, with two studies finding higher rates than in the general population [229]. Nevertheless, living with and managing both diabetes and SMI imposes a considerable burden, which often results in diabetes being overshadowed by the more immediate challenges arising from the mental illness [230]. Tailored diabetes education and self-management support for people with SMI is needed, and evaluation of the effectiveness of such approaches is an identified research gap [230, 231].

When an individual develops diabetes while receiving an antipsychotic, it is important to assess what role this is likely to have played in the onset of diabetes. Under some circumstances, it may be appropriate to switch to an alternative antipsychotic if the mental state will not be adversely affected [212].

It is important that healthcare professionals, both in primary care and in mental health teams, ensure that people with SMI are not disadvantaged with regard to their diabetes care. Despite increased contact with primary care, there is evidence that people with mental illness receive less education about diabetes, are less likely to be examined for retinopathy or diabetic foot

complications, and are less likely to be screened for HbA_{1c} and other cardiovascular risk factors [6].

Acknowledgements

Key points

Driving

- Potential hazards facing the driver with diabetes include hypoglycaemia, visual impairment, and disability from severe neuropathy or leg amputation.
- Hypoglycaemia can severely disrupt driving skills by causing cognitive dysfunction and mood changes. Motor skills and judgement may become impaired when blood glucose falls before hypoglycaemic symptoms are experienced. Impaired awareness of hypoglycaemia is a relative contraindication to driving. Drivers with diabetes must take precautions to avoid hypoglycaemia and know how to treat it if it occurs while driving.
- Corrected visual acuity that is worse than 6/12 in the better eye precludes driving in the general population. People with diabetes may fulfil this criterion, but still have significant visual impairment (e.g. field loss, poor night vision, and perception of movement) secondary to retinopathy, laser treatment, or cataracts.
- In many countries, drivers with diabetes are legally required to declare the diagnosis for their driving licence and motor insurance. Failure to do this will invalidate insurance claims.
- Driving licences are often issued for fixed terms and only renewed following satisfactory medical review. In many countries, insulin-treated drivers are debarred from driving passenger-carrying vehicles and large goods vehicles, although the regulations in Europe have been changed to allow this. In other parts of the world no such licensing restrictions exist, to the detriment of safe driving and public safety.

Employment

- Diabetes is not a bar to most occupations, and people with diabetes are protected in many countries by legislation against discrimination on the grounds of disability.
- People with insulin-treated diabetes are barred from certain occupations because of the risk of hypoglycaemia. These include the armed forces, emergency services, commercial pilots (in some countries), prison and security services, and jobs in potentially dangerous areas (e.g. at heights, underwater, and offshore).
- Severe hypoglycaemia in the workplace is uncommon and shift work seldom compromises glycaemic management. Depressive illness and diabetes-related disability are associated with higher unemployment and sickness absence in people with diabetes.

Prison and Custody

- Glycaemic levels may be suboptimal in prison because of restrictions in diet, exercise, and blood glucose monitoring. Intercurrent illness and metabolic abnormalities may not be recognized or treated promptly.
- Input from a diabetes specialist may improve the quality of care. Knowledge of diabetes among prison officers and staff of short-term custodial units is often limited and may be improved by liaising with local diabetes specialist services.

Insurance

- Diabetes should be declared to insurers, who may impose higher premiums or limited coverage. Many insurers' decisions are based on outdated actuarial data or misconceptions about the current prognosis of diabetes. National diabetes organizations can provide details of insurance brokers who do not weight policies against people with diabetes.
- Life expectancy in type 1 diabetes can be modelled from age, sex, and the presence of proliferative retinopathy and nephropathy. As the latter is a major determinant of survival, life insurance premiums should be reduced for all those who reach the age of 50 years with no evidence of renal impairment.

Alcohol

- The association between excessive alcohol consumption, chronic pancreatitis, and secondary diabetes is well established. Alcohol excess is also associated with central obesity and poor medication taking; both could increase the risk of type 2 diabetes and compromise the management of established diabetes. Most epidemiological studies, however, have demonstrated a J-shaped relationship between alcohol consumption and diabetes, with moderate intake being associated with a lower risk of diabetes.
- In type 2 diabetes, moderate alcohol consumption is associated with a 35% reduction in total mortality and lower risk of cardiovascular disease compared to abstinence. Excessive alcohol consumption is associated with hypertriglyceridaemia and resistant hypertension; affected individuals have an increased vascular risk.
- Ethanol inhibits hepatic gluconeogenesis and increases the risk, severity, and duration of hypoglycaemia. Alcohol obscures the ability, both of the individual and of observers, to recognize and treat hypoglycaemia, and intoxication can simulate hypoglycaemia.

Recreational Drugs

- Approximately one-third of young people with diabetes use recreational drugs at some time. The most common class of drug taken is cannabis, but nitrous oxide, amphetamine-type stimulants (including ecstasy), cocaine, and opiates are also used. New psychoactive drugs are also increasingly popular.
- Recreational drug use is associated with a sixfold higher risk of death from acute metabolic complications of diabetes. Intravenous drug use is uncommon, but is dangerous and is associated with omission of insulin therapy, frequent hospital admissions (usually with diabetic ketoacidosis), and high mortality.
- Cocaine and amphetamine-type stimulants can have profound haemodynamic effects through sympatho-adrenal activation. In addition to an increased risk of cardiac arrhythmias and myocardial ischaemia, the sympathetic activation antagonizes the action of insulin and can precipitate diabetic ketoacidosis.

Travel

- Diabetes is not a bar to travelling, but changes in meals, physical activity, and anti-diabetes drug treatment on route and after arrival all need careful consideration. Important issues include travel insurance, medical identification, supplies and storage of medication and monitoring equipment, and immunizations.
- During long flights, blood glucose should be monitored frequently and glycaemic levels relaxed to avoid hypoglycaemia. Insulin injection schedules may require in-flight adjustment, especially if the time shift exceeds four hours.

Leaving Home

- In the Diabetes UK Cohort Study, living alone was associated with a more than fourfold increase in risk of death from acute metabolic complications of diabetes.
- Leaving home is potentially a period of high risk for young people with diabetes; particular concern has been expressed about the welfare of university students with type 1 diabetes.

Diabetes influences many aspects of daily life, principally through the effects of treatment and its potential side effects, particularly hypoglycaemia. The development of diabetes-related complications, such as neuropathy and retinopathy, can also affect everyday activities, particularly when these are severe with clinical manifestations, or require time-consuming treatment such as dialysis for chronic renal failure.

Driving

Driving is an everyday activity that demands complex psychomotor skills, visuospatial coordination, vigilance, and satisfactory judgement. Although road traffic accidents are common, medical disabilities are seldom responsible. Diabetes is designated a *prospective disability* for driving because of its potential to progress and cause complications, while side effects of treatment (principally hypoglycaemia) can affect driving performance. In most high-income countries, the duration of the licence of a driver with diabetes is period restricted by law, and its renewal is subject to review of medical fitness to drive. The problems associated with diabetes and driving, and the limitations of relevant research data, have been reviewed [1, 2].

The main problems for the driver with diabetes are hypoglycaemia and visual impairment resulting from cataract or retinopathy. Rarely, peripheral neuropathy, peripheral vascular disease, and lower-limb amputation can present mechanical difficulties with driving (Table 66.1), but these problems may be overcome by adapting the vehicle and using automatic transmission systems.

Despite these challenges, drivers with diabetes do not appear to be involved in more accidents than their counterparts without diabetes [3]. Population studies have shown no excess in accident rates among drivers with diabetes in Northern Ireland [4], Scotland [5], England [6], Germany [7], Iceland [8], or Pittsburgh in the USA [9], while a large survey of over 30 000 drivers in Wisconsin, USA, found only a modest increase [10]. In most surveys, however, incidents were self-reported and probably underestimated, while fatal accidents (in which a diabetes-related cause, such as hypoglycaemia, could have had a role) were excluded. Accident rates may

Table 66.1 Reasons for drivers with diabetes to cease driving.

- Newly diagnosed people with diabetes, especially insulin-treated, should not drive until glycaemic levels and vision are stable
- Recurrent daytime hypoglycaemia (particularly if severe)
- Impaired awareness of hypoglycaemia, if disabling
- Reduced visual acuity in both eyes (worse than 6/12 on Snellen chart) – note that use of mydriatics for eye examination will affect visual acuity
- Severe sensorimotor peripheral neuropathy, especially with loss of proprioception
- Severe peripheral vascular disease
- Lower-limb amputation

also have been lowered by regulatory authorities debarring high-risk drivers and by drivers with advancing diabetes-related complications who stop driving voluntarily [4, 5]. Practical advice for drivers with diabetes is given in Table 66.2.

Table 66.2 Advice for drivers with diabetes.

- Inform licensing authority^a (statutory requirement) and motor insurer of diabetes and its treatment
- Do not drive if eyesight deteriorates suddenly
- Check blood glucose before driving (even on short journeys) and at intervals on longer journeys
- Flash glucose monitoring and real-time continuous glucose monitoring (CGM) can also be used
- Take frequent rests with snacks or meals; avoid drinking alcohol
- Keep a supply of fast-acting and complex carbohydrate in the vehicle for emergency use
- Carry personal identification to indicate the driver has diabetes (and is prone to hypoglycaemia)
- If hypoglycaemia develops, stop driving, switch off engine, leave the driver's seat, and then treat with carbohydrate
- Do not resume driving for 45 min after blood glucose has returned to normal (delayed cognitive recovery)

^a In the UK, the licensing authority is the Driver and Vehicle Licensing Agency (DVLA), Swansea, SA99 1TU, UK.

Hypoglycaemia

Drivers with insulin-treated diabetes often experience hypoglycaemia while driving [4, 5, 11] and this can interfere with driving skills by causing cognitive dysfunction, even during relatively mild hypoglycaemia that does not induce symptoms. Studies of people with type 1 diabetes using a driving simulator showed that driving performance often became impaired at arterialized blood glucose concentrations of 3.4–3.8 mmol/l and deteriorated further at lower levels [12]. Problems included poor road positioning, driving too fast or too slow, inappropriate braking, and causing crashes by stopping suddenly. Alarmingly, most did not experience hypoglycaemic symptoms or doubt their competence to drive; only one-third treated the hypoglycaemia, and only when blood glucose had fallen below 2.8 mmol/l [12]. In the UK, the Driver and Vehicle Licensing Agency (DVLA) does not distinguish between type of diabetes, and the restrictions are based on the use of insulin as therapy, as this can cause hypoglycaemia in any person using this treatment. The risk of hypoglycaemia in insulin-treated type 2 diabetes rises with duration of insulin therapy.

Judgement and insight become impaired during hypoglycaemia, and some drivers with diabetes describe episodes of irrational and compulsive behaviour while at the wheel [11, 12]. Hypoglycaemia also causes potentially dangerous mood changes, including irritability and anger [13]. In addition, asymptomatic hypoglycaemia impairs visual information processing and contrast sensitivity, particularly in poor visibility [14, 15], which may diminish driving performance.

Poor perception of hypoglycaemia is also potentially dangerous. Many drivers with diabetes subjectively overestimate their current blood glucose level and feel competent to drive when they are actually hypoglycaemic [16]. Impaired awareness of hypoglycaemia, often associated with more frequent severe episodes, is potentially hazardous and is a common reason for revocation of the driving licence. It is not an absolute contraindication to driving if it can be demonstrated, by frequent self-monitoring, that there is prolonged freedom from hypoglycaemia [17].

Hypoglycaemia is a recognized cause of motor vehicle incidents, but its true frequency and causal relationship to a particular incident are often difficult to ascertain. Blood glucose is seldom estimated immediately after a road traffic accident, and evidence for preceding hypoglycaemia is typically circumstantial. Hypoglycaemia was the main cause of non-fatal motor vehicle accidents in the Diabetes Control and Complications Trial; hypoglycaemia was three times more common in the intensively treated participants, but the rate of major accidents was no higher, perhaps because of better precautionary advice [18]. Other studies have found that the frequency of hypoglycaemic episodes during driving correlates with the total number of accidents [4, 5] and hypoglycaemia-related driving mishaps are related to the frequency of severe hypoglycaemia in the preceding year [19]. The frequency of hypoglycaemia-related accidents is substantially lower than those caused by alcohol and drugs.

Avoiding and treating hypoglycaemia while driving

General measures to avoid hypoglycaemia are discussed in Chapter 40. All drivers with insulin-treated diabetes should keep some fast-acting carbohydrate in the vehicle; disturbingly, some do not [20]. Each car journey, no matter how short, should be planned in advance to anticipate possible risks for hypoglycaemia, such as traffic delays. It is essential to check glucose before and every two hours during long journeys, and to take frequent rests

and meals. Unfortunately, these measures are not always undertaken [20, 21]. The use of intermittently scanned (flash) and real-time continuous glucose monitoring (CGM), where the device has an alarm, may alert the driver to a falling glucose concentration [22]. Driving expends energy and – as with other forms of exercise – prophylactic carbohydrate should be taken if the blood glucose is <5.0 mmol/l and driving should be avoided if <4.0 mmol/l [23].

If hypoglycaemia occurs during driving, the car should be stopped in a safe place, and the engine switched off before the driver consumes some glucose. In the UK, the individual should vacate the driver's seat and remove the keys from the ignition, as a charge can be brought for driving while under the influence of a drug (insulin) even if the car is stationary. Driving should not be resumed for at least 45 minutes after blood glucose has returned to normal, because cognitive function is slow to recover after hypoglycaemia [13].

Many features of hypoglycaemia resemble alcohol intoxication, and mentally obtunded hypoglycaemic drivers with diabetes are sometimes arrested on the mistaken assumption that they are intoxicated. Drivers with insulin-treated diabetes should therefore carry a card or identity bracelet stating the diagnosis. Individuals with newly diagnosed insulin-treated diabetes may have to stop driving temporarily until their glycaemic levels are stable.

Insulin secretagogues, sulfonylureas and glinides, are the only oral anti-diabetes drugs that may cause hypoglycaemia while driving, and people treated with these agents should be informed of this possibility. While glucagon-like peptide 1 (GLP-1) receptor agonists alone are not associated with a risk of hypoglycaemia, this may be a problem when they are used in combination with a sulfonylurea. Blood glucose testing in relation to driving is not a requisite for drivers with Group 1 driving licences (see later), but may be required for holders of Group 2 driving licences who are taking this treatment combination.

Visual impairment

In the UK, monocular vision is accepted for driving, provided that the person meets the minimum legal requirement; that is, to be able to read a number plate with letters 8.9 cm high at a distance of 30 m, wearing spectacles if necessary. This corresponds to a distance visual acuity of approximately 6/10 on the Snellen chart. The number plate test has deficiencies: it is poorly reproducible under clinical conditions and does not assess visual fields, night vision, or the ability to see moving objects. All of these may be severely reduced by retinal ischaemia in pre-proliferative retinopathy [24], while visual field loss can be caused by extensive laser photocoagulation for diabetic retinopathy [25, 26] or macular oedema (Figure 66.1) [27]; careful containment of laser burns can preserve vision [28]. Cataracts often accentuate glare from headlights, and in such cases driving in the dark should be avoided.

Previous surveys have identified very few drivers with diabetes who would fail the standard eyesight test. Impaired vision is an uncommon reason for the driving licence to be refused or revoked, although many people stop driving voluntarily because their eyesight is deteriorating. Worsening vision from diabetic (or other) eye disease should be reported by the individual to the licensing authority.

Eye screening is a crucial part of assessing medical fitness to drive. Pupillary dilatation for fundoscopy or retinal photography temporarily reduces visual acuity, particularly if the usual binocular visual acuity is 6/9 or worse [29]. People with diabetes should

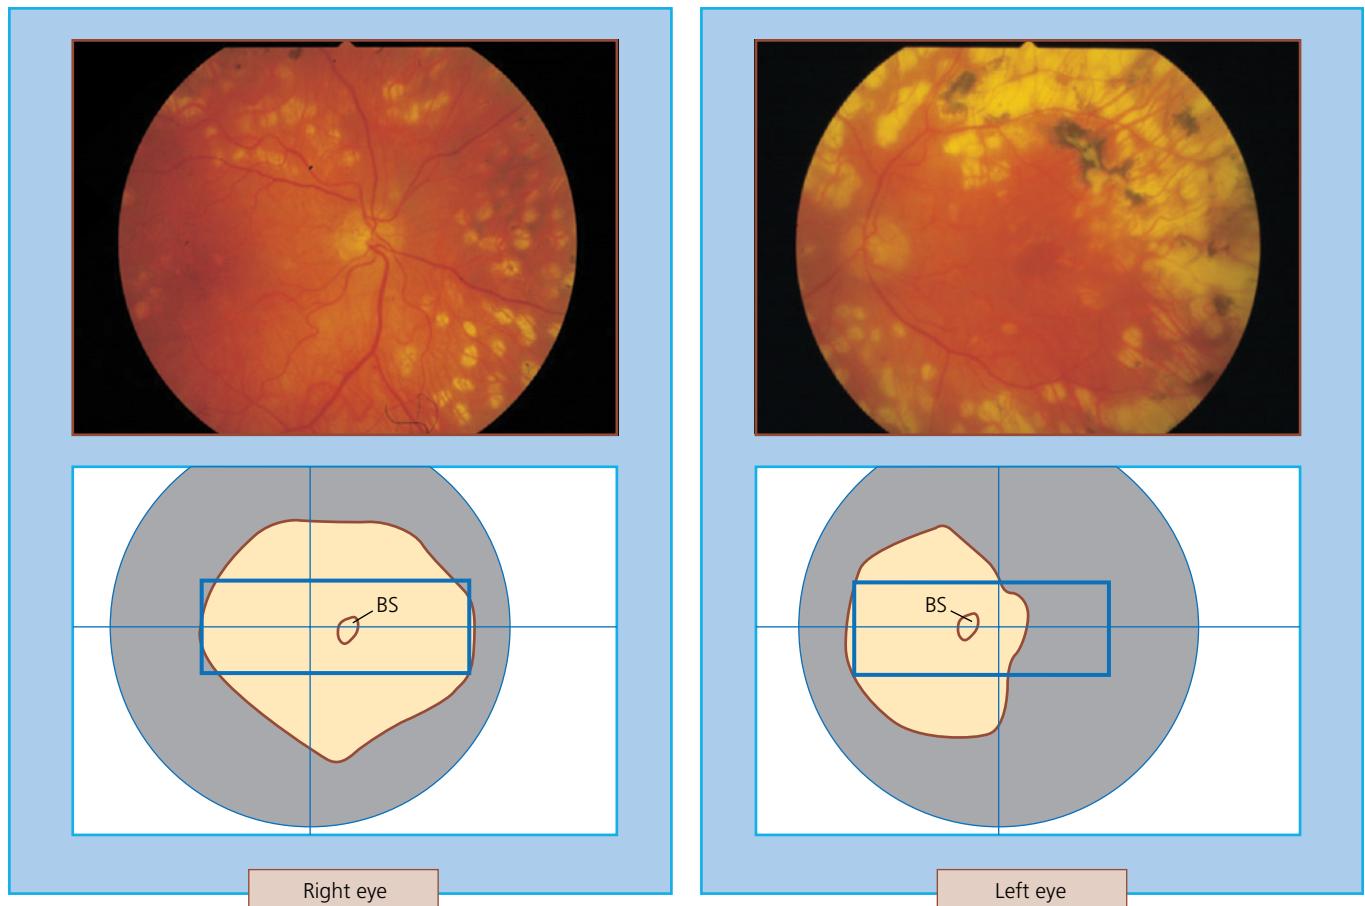

Figure 66.1 Visual field loss caused by photocoagulation. This 60-year-old man with diabetes needed extensive laser photocoagulation to the temporal retina of the left eye, causing nasal visual field loss that caused this eye to fail the standard test for driving. The right eye required less intensive laser treatment and the visual field was adequate for driving. BS, blind spot. Blue rectangle: minimum area recommended for safe driving. Source: Courtesy of D. Flanagan, Addenbrooke's Hospital, Cambridge, UK.

be told not to drive for at least two hours after the use of mydriatics. The driving regulatory authorities require perimetry to assess the visual fields of people who have had photocoagulation (Figure 66.1).

Statutory requirements for drivers with diabetes

In most high-income countries, drivers with insulin-treated diabetes are required by law to declare their diabetes to the relevant regulatory authority (in the UK this is the DVLA). The statutory requirements for ordinary and vocational (professional) driving licences vary considerably around the world, and in many countries no restrictions are imposed on insulin-treated drivers [30]; the national licensing authority should be contacted for details. Licensing restrictions have been criticized as being draconian and discriminatory against people with diabetes, but the civil rights of the person with diabetes have to be balanced against the need to safeguard public safety.

European driving licences

Ordinary driving licences (group 1)

The European Union (EU) member states and the UK all use the same classification for driving licences, but this is not applicable to other parts of the world. In the UK, the DVLA must be informed when a person with insulin-treated diabetes applies for, or renews,

a driving licence, or if insulin dependence develops in a driver with diabetes. Failure to do this constitutes *concealment of a material fact*, which can incur a fine, but more importantly can invalidate a claim to the motor insurer; professed ignorance of the law is not accepted as an excuse. The onus to declare rests with the individual driver, but doctors who provide diabetes care, including general practitioners, have a responsibility to inform individuals with diabetes of this legal requirement, and should offer practical advice (Table 66.2). Drivers with diabetes who are treated with diet alone or with oral glucose-lowering medications do not have to notify the DVLA unless they have visual impairment or other diabetes-related problems that could affect medical fitness to drive. In the UK, a driving licence for a person with diabetes is period restricted, is usually issued for a maximum of three years, and is renewed after completion of a medical questionnaire. The DVLA requests further medical reports in some cases, and always when an applicant reports a medical problem that may seriously affect driving (e.g. recurrent hypoglycaemia). GLP-1 receptor agonists (given by injection) can be used without restriction, other than when prescribed in combination with a sulphonylurea for drivers with Group 2 (vocational) licences, when this must be notified to the DVLA and requires assessment of medical fitness to drive.

The member states of the EU have an agreed policy on restrictions on driving licences for people with insulin-treated diabetes, and these were changed after publication of the Third Directive on

driving licences (Annex III to European Directives 91/439/EEC and 2006/126/EC: Driving Licence Standards for Diabetes) in 2006 and implemented thereafter. The main provisions are as follows:

- The interval between regular medical reviews should not exceed five years; stricter rules are allowed.
- A driver must not experience more than one episode of severe hypoglycaemia within the preceding 12 months. This criterion raised concerns that it would lead to deliberate concealment of severe hypoglycaemia by insulin-treated drivers, which was strongly suggested by a Danish study [31] and in a further study in Denmark more than 20% of drivers admitted that they would under-report the frequency of severe hypoglycaemia [32]. No time was specified for when severe hypoglycaemia had occurred, so nocturnal episodes of severe hypoglycaemia during sleep were included. Several countries lobbied the European Commission to accept that severe hypoglycaemia during sleep should not hold the same weight in the assessment of fitness to drive as that occurring during waking hours. This led to the European Commission issuing Directive 2016/1106/EC, which amended the Third Directive on driving licences to exclude nocturnal events, and this legislation was implemented in January 2018. The rationale and appropriateness of the European regulations and this latest amendment can be questioned [33].
- A driver must not have impaired awareness of hypoglycaemia. No definition of this syndrome was given, and its interpretation was left to the discretion of individual states. The latest amendment changed the wording to *inadequate awareness of hypoglycaemia*. This altered terminology still fails to define precisely what this clinical problem represents, its nature and severity, and how it should be assessed and applied in relation to fitness to drive. In the UK it has been defined as ‘an inability to detect the onset of hypoglycaemia because of a total absence of warning symptoms’, which is rare in clinical practice.

Vocational driving licences (group 2)

It is extremely difficult to estimate the risk and likely outcome of a motor vehicle accident as many factors can be involved. Professional drivers have a much higher annual mileage than ordinary car drivers and a higher rate of driving mishaps overall. In the absence of scientific evidence, risk and hazard are gauged by the size of vehicle being driven, which is perhaps not unreasonable, given the potential consequences of a person losing control of a large heavy vehicle through hypoglycaemia. Before 2010 drivers with insulin-treated diabetes could not be issued with a Group 2 vehicle driving licence except in (undefined) *exceptional circumstances*, subject to (unspecified) authorized medical opinion, and were debarred from driving Group 2 vehicles, with the exception of C1 vehicles (3.5 to 7.5 t). However, in some European countries exceptional cases appeared to be the norm and the inconsistent application of EU regulations, inadequacy of assessment of medical fitness to drive, and lack of harmonization between states were very unsatisfactory. As these professional drivers were able to cross state borders and drive in countries with much stricter regulations for Group 2 driving licences, this was politically unacceptable. The EU regulations on driving have been relaxed and now allow all drivers with insulin-treated diabetes to apply for a Group 2 driving licence, provided they meet strict criteria including having no episodes of severe hypoglycaemia, having normal hypoglycaemia awareness, and undertaking frequent blood glucose monitoring at times relevant to driving (Annex III to European Directives 91/439/EEC and 2006/126/EC).

Oral anti-diabetes medication is not a bar to holding a vocational driving licence in the UK. In practice, however, many public transport companies restrict the employment of drivers with type 2 diabetes who take sulfonylureas; metformin or treatment with GLP-1 receptor agonists is not a contraindication, but medical assessment is normally necessary. Progression to insulin therapy usually terminates the employment of bus and train drivers. Taxi, ambulance, and police pursuit drivers are not covered by the statutory regulations. In the UK, taxi licences are issued by local authorities, which vary considerably in how medical fitness to drive is assessed, although many have now adopted Group 2 licensing standards. The employment of insulin-treated drivers in these other categories is determined by employers, who usually seek advice from occupational health physicians.

Driving outside Europe

Outside Europe, the regulations in different countries range from a complete ban to no restriction other than a medical examination for prospective or current drivers who require insulin [30]. Differences in approach between countries are influenced by the level of economic development and the prevalence of insulin-treated diabetes; many low- and middle-income countries impose no restriction on vocational driving licences for people with insulin-treated diabetes [30]. The American Diabetes Association has published a position statement with valuable practical recommendations about how to evaluate risks to driving associated with diabetes, and how these should influence licensing decisions in the USA [34]. Drivers with insulin-treated diabetes are prohibited from driving commercial motor vehicles across state borders in the USA, but within most states drivers with insulin-treated diabetes can drive commercial vehicles, with the exception of lorries transporting hazardous materials and passenger-carrying buses [35].

In most other countries, insulin treatment alone is targeted by legislation, even though hypoglycaemia can occur with other glucose-lowering drugs. A Canadian survey of crashes involving truck and commercial vehicle drivers with diabetes revealed an increase in risk for drivers with type 2 diabetes treated with sulfonylureas [36], the presumption being that unsuspected hypoglycaemia is a causal factor. Similarly, an insurance-based study in the USA of people with type 2 diabetes treated with (unspecified) non-insulin therapies showed that those who had made claims for hypoglycaemia had greater rates of motor vehicle incidents requiring hospital treatment [37], indicating that hypoglycaemia-related mishaps also occur in people with type 2 diabetes who are not being treated with insulin.

Aircraft pilot licences

Pilots with insulin-treated diabetes have been employed for several years by a Canadian commercial airline without any incidents, but in Europe pilots on insulin have not been allowed to fly commercial aircraft. However, the UK Civil Aviation Authority, in collaboration with the Republic of Ireland and the Austrian Aviation Authorities, is currently using an agreed protocol to certify individual pilots with insulin-treated diabetes to fly commercial aircraft, provided they meet strict medical fitness criteria, monitor glycaemic levels, and fly along with a co-pilot without diabetes [38]. Preliminary data have shown that the protocol is both practical and safe [39] and will merit

consideration by the European Aviation Safety Agency to allow certification of insulin-treated pilots in other European countries. Private pilot licences can be issued to individuals with diabetes treated with sulfonylureas (provided that they have a safety licence endorsement), but not with insulin. People with insulin-treated diabetes cannot work as air traffic controllers.

Employment

With a few provisos, people with diabetes can successfully undertake a wide range of employment. There remains some prejudice against people with diabetes, but employment prospects in the UK and many other countries have improved with the introduction of legislation that makes it unlawful to treat a disabled person less favourably.

The main concern when considering people with diabetes for employment is the risk to safety associated with the condition or its treatment. Employers often fail to make the crucial distinction between a *hazard* (something with the potential to cause harm) and a *risk* (the likelihood that such harm will occur). The potential problems of diabetes relevant to employment are the hazards of acute hypoglycaemia related to insulin and sulfonylureas, the lability of glucose levels, and the development of serious diabetes-related complications that may affect ability to work or interfere with performance at work.

Employment is generally restricted where hypoglycaemia could be hazardous to the worker with diabetes, their colleagues, or the general public. Employment-related issues, however, are not confined to people with type 1 diabetes. The rising prevalence of type 2 diabetes in the population of working age, along with the increasing use of insulin, has become an issue for occupational health assessment. Access to employment may be limited through discriminatory employment practices and restrictions posed by companies (rather than by legislation) because of perceived problems associated with diabetes or to job-sensitive issues related to the potential risks of hypoglycaemia or to visual impairment. Diabetes can also affect employment through increased sick leave and absenteeism and by adversely influencing productivity. Diabetes in general has a negative long-term influence on the economic productivity of the individual; health-related disabilities can cause work limitations, especially in older employees in whom early retirement is more common on medical grounds.

A prospective survey in Edinburgh of 243 people with insulin-treated (mainly type 1) diabetes in full-time employment found that hypoglycaemia occurred uncommonly at work (14% of all severe episodes) and had few adverse effects [40]. The study cohort, however, may have been subject to selection bias in terms of occupational diversity and many had suboptimal glycaemic levels; surprisingly few participants had impaired awareness of hypoglycaemia. An internet survey of the effects of non-severe hypoglycaemia in people with type 1 diabetes and type 2 diabetes in employment has suggested that work time and productivity are lost by around one in five people when hypoglycaemia occurs at work, though such an uncontrolled study may be open to overestimation of the magnitude of the problem [41].

For some occupations (e.g. train drivers) any risk of hypoglycaemia is considered unacceptable. Elsewhere, the case for employment restrictions may be less clear-cut. Jobs that restrict the employment of workers with insulin-treated diabetes are listed in Table 66.3. People treated with insulin are not usually permitted to

Table 66.3 Forms of employment from which people with insulin-treated diabetes may be excluded in the UK.

Vocational driving

Drivers of passenger-carrying vehicles (PCVs)
Drivers of locomotives and underground trains
Professional drivers, such as chauffeurs (depends on employer)
Taxi drivers (variable; depends on local authority policy)

Civil aviation

Commercial pilots and flight engineers (licensing may be allowed with strict operational restrictions and in-flight testing regimens)
Aircrew (as above)
Air-traffic controllers (as above)

National and emergency services

Armed forces (army, navy, air force)
Police force
Fire brigade or rescue services (some exceptional cases)
Merchant navy
Prison and security services

Dangerous areas for work

Offshore: oil rigs, gas platforms
Moving machinery
Incinerators and hot-metal areas
Work on railway tracks
Coal mining
Heights: overhead lines, cranes, scaffolding

Source: Data from Waclawski 1989 [42] and Waclawski and Gill 2013 [43].

work alone in isolated or dangerous areas, or at unprotected heights. Shift work is not necessarily a contraindication: one study in a car assembly plant found no difference in glycaemic levels between day- and night-shift workers with diabetes, although glycaemia deteriorated if shift rotas were changed frequently [44].

In one British survey, the prevalence of diabetes in the workforce was 7.5 per 1000, including a lower than anticipated rate of 2.6 per 1000 for people treated with insulin [42]. Employment is generally debarred in the armed forces, emergency work such as firefighting, civil aviation, jobs in the offshore oil industry, and many forms of commercial driving [42]. Workers with diabetes seldom conceal their medical condition from their employers, and any blanket policy that debars workers with diabetes from a specific occupation may be inappropriate or even discriminatory. Individual assessment is crucial, as employment regulations may not differentiate between different types and treatments of diabetes. Some bureaucratic regulations have been successfully challenged on medical grounds: for example, active firefighters in the UK and a US air traffic controller were reinstated following appeals against dismissal.

In some cases, entering or persevering with a specific occupation may not always be in the individual's long-term interests (e.g. with the advance of disabling complications). This is clearly a difficult issue, which may require sympathetic medical counselling because of possible repercussions on the individual's income, self-esteem, future quality of life, and the financial support of dependants.

Unemployment, sickness, and diabetes

According to a British survey, employers do not generally believe that diabetes *per se* limits employment prospects, because most workers with diabetes have few medical problems and can tackle a wide range of occupations [45]. Discrimination by employers, however, may affect hiring practices. Some British and Dutch surveys

reported no apparent excess of unemployment among people with diabetes compared with the general population [46–49], but other studies in the UK [50, 51] found that relatively more people with diabetes were not earning because of inability to work, intercurrent illness, early retirement, or by being housewives. Although in many cases there was no apparent reason why an individual with diabetes could not obtain employment [51], depressive illness is strongly associated with unemployment and difficulties with work performance [52]. Adolescents with diabetes appear more likely than their peers without diabetes to lose jobs, or to fail to follow their desired occupation or cope with shift work [53]. Reduced employment and income in workers with diabetes in North America have been related to work disability [54], which was seven times more common than among siblings without diabetes and was mainly related to diabetes-related complications [55], and was associated with lower employment income [43, 56]. Sickness absence rates among employees with diabetes are moderately to substantially higher than in workers without diabetes [57–60], which has economic and social consequences. Workers with insulin-treated diabetes and optimal glycaemic management had fewer sickness absences than those with suboptimal management, but HbA_{1c} is not a good index of capacity to work [61]. Diabetes reduces employment and contributes to work loss through absenteeism and health-related work limitations in the workplace [62]. A systematic review of type 2 diabetes and employment showed that it reduces the ability of an individual to work, principally in terms of absenteeism, loss of productivity, and early retirement, and exerts a significant burden on the workforce [63].

Prison and custody

Imprisonment and short-term custody are unusual but troublesome life situations that can interfere with the management of diabetes. Hypoglycaemia can occur if food is withheld after arrest and may be confused with intoxication by alcohol or drugs. Diabetes is generally managed badly in prison because of the unsuitability of prison diets, lack of exercise, and the practical difficulty of using some insulin regimens (e.g. basal bolus); also, self-monitoring may be prohibited, and glucose to treat hypoglycaemia may be unavailable during long lock-up periods. Most prison medical personnel have no specialist knowledge of diabetes and there may be no access to specialist supervision during custody.

Some prisoners with diabetes deliberately manipulate their treatment (e.g. by omitting insulin to induce ketoacidosis to have themselves removed to hospital, which arguably offers a more amenable environment [64]). By contrast, treatment of intercurrent illness may be delayed by prison staff, who think that the prisoner is ‘misbehaving’.

In some cases, withdrawal of alcohol, better diet, and weight loss may actually improve glycaemic levels while in prison, and structured diabetes care can be provided effectively by an attending specialist physician [65, 66]. Facilities for people with diabetes in police custody are generally limited, with an inability to measure blood glucose, treat diabetic emergencies, or provide insulin and appropriate meals [67]. A Scottish liaison initiative between a specialist diabetes department and the local police force identified and successfully addressed deficiencies in its custody facilities, including the provision of glucose monitoring equipment and the training of police staff [67]; this has been assisted by the development of a forensic nursing service.

Insurance

In many societies, insurance is viewed as essential to protect individuals and their families from the financial risk of unexpected events or illness, and insurance is often necessary to secure a financial loan, as for house purchase. This chapter does not address how models of healthcare insurance are provided in different countries, an example being Medicaid in the USA, or how expansion of that insurance system has influenced diabetes-related biomarkers [68]. Different healthcare insurance systems may limit reimbursement or ration access to specific medications, glucose monitoring equipment, or sophisticated technologies to treat diabetes.

People with diabetes are sometimes refused insurance or have to accept higher premiums and limited coverage, because the disorder is associated with reduced life expectancy, the risk of complications, and greater use of healthcare services. Several factors are important for insurance underwriting, including the severity and duration of the diabetes, and the existence of diabetes complications and other concurrent medical disorders. It is reasonable for an insurer to be cautious in dealing with applicants who have suboptimally managed long-standing diabetes and established complications.

There is wide variation in insurance terms and premiums among different European countries [69], in the USA [70], and even within the UK [71], which suggests that insurers work from assumptions about diabetes rather than using scientific evidence from actuarial studies. The presence of type 1 diabetes may be the only factor considered by insurers [70], and many still base potentially discriminatory decisions on outdated information that reflects the poor outcome of diabetes diagnosed and treated decades ago. There are no standardized guidelines, nor is there any uniformity in the approach to diabetes and insurance [71], although risk classifications for life insurance have been published [72]. Some companies do not accept applicants with diabetes, while others do so without financial penalty. People with diabetes seeking insurance cover should therefore request quotations from several companies and should be supported by a medical assessment from a physician who is competent in the specialty. Many national patient organizations have negotiated favourable terms with insurance brokers and will provide details on request.

The prognosis of people with diabetes (particularly type 1 diabetes) has improved considerably during the last 50 years, and the impact of this on life insurance for people with type 1 diabetes has been analysed in Scandinavia [73]. In the last 30–40 years, median life expectancy has increased by over 15 years, largely because of substantial reductions in diabetic nephropathy. It has therefore been suggested that life insurance in type 1 diabetes should focus entirely on the risk of developing diabetic nephropathy [74], and a model to calculate insurance terms has been proposed, based on current age, age at diagnosis, sex, presence of nephropathy or proliferative retinopathy, and other pre-existing disease [73]. As the risk of developing new nephropathy falls after 25 years of diabetes, all people who reach the age of 50 years without nephropathy should have their insurance premium reduced. This approach has been adopted by most insurance companies in the Nordic countries, and by some in other European countries. To avoid penalizing people with diabetes, there must be regular updating of mortality and life expectancy data, and this information must be transmitted to actuarial advisers and insurance underwriters.

People with diabetes also face higher premiums for accident insurance, which is unjustified because there is no evidence that they have more accidents or permanent disability than the general population [75]. Neither is there any rationale for higher motor insurance premiums [70, 71, 76], particularly for those not treated with insulin, because no excess in road traffic accidents has been demonstrated. A US study of the insurance cost of employees with diabetes showed that while healthcare expenditure was three times higher than all healthcare consumers, it was not more expensive than other chronic illnesses such as heart disease, asthma, and cancer [77].

Diabetes must always be disclosed to the insurer: concealing the diagnosis constitutes the withholding of a material fact, which nullifies the contract with the insurer and thus the insurer's liability in the event of a claim.

Alcohol

Many people enjoy drinking alcohol and diabetes should not be a barrier to social drinking. Moderate alcohol consumption not only reduces the risks of developing type 2 diabetes, but improves metabolic management and restricts diabetes-related complications. By contrast, alcohol can promote hypoglycaemia and chronic excessive consumption may be deleterious both to long-term diabetes management and to general health. Patterns of alcohol consumption vary substantially across the world. Consumption of excess alcohol is linked in some countries to social deprivation and so it might be presumed that there would also be a strong link to type 2 diabetes. However, in the USA for example, alcohol consumption in older people with diabetes appears to be lower than in individuals without chronic health problems, although approximately 4.5% of older people with diabetes still drink to excess [78]. In adolescents with type 1 diabetes, alcohol consumption is probably similar to that in peers without diabetes [79], but some studies have reported higher levels of overall consumption and /or greater binge drinking than in adolescents without type 1 diabetes [80, 81].

Alcohol consumption and risk of diabetes

Chronic high consumption of alcohol can predispose to the development of secondary diabetes. Alcohol has a direct toxic effect on the pancreas, resulting in both acute and chronic pancreatitis. Diabetes complicates about 45% of cases of chronic pancreatitis (Chapter 23). Insulin treatment is usually required to manage hyperglycaemia in people with chronic pancreatitis, although diabetic ketoacidosis is rare. This may be because the pancreatic damage also destroys the α cells that secrete glucagon, which is an essential factor in ketogenesis (Chapters 8 and 41). Insulin therapy can be particularly challenging in this situation, as many individuals with alcohol-related chronic pancreatitis have chaotic lifestyles, with poor diet and ongoing excess alcohol consumption. A heavy alcoholic binge, with concomitant low food intake, can result in alcoholic ketoacidosis.

By contrast, modest alcohol consumption appears to protect against type 2 diabetes, reducing risk by up to 30% [82, 83]. A J-shaped relationship has been observed between alcohol consumption and risk of type 2 diabetes (Figure 66.2). Moderate alcohol consumption is associated with enhanced insulin sensitivity, which may in part explain the relationship. The pattern of drinking behaviour also appears to be important, with binge drinking associated with an increased risk of type 2 diabetes [84].

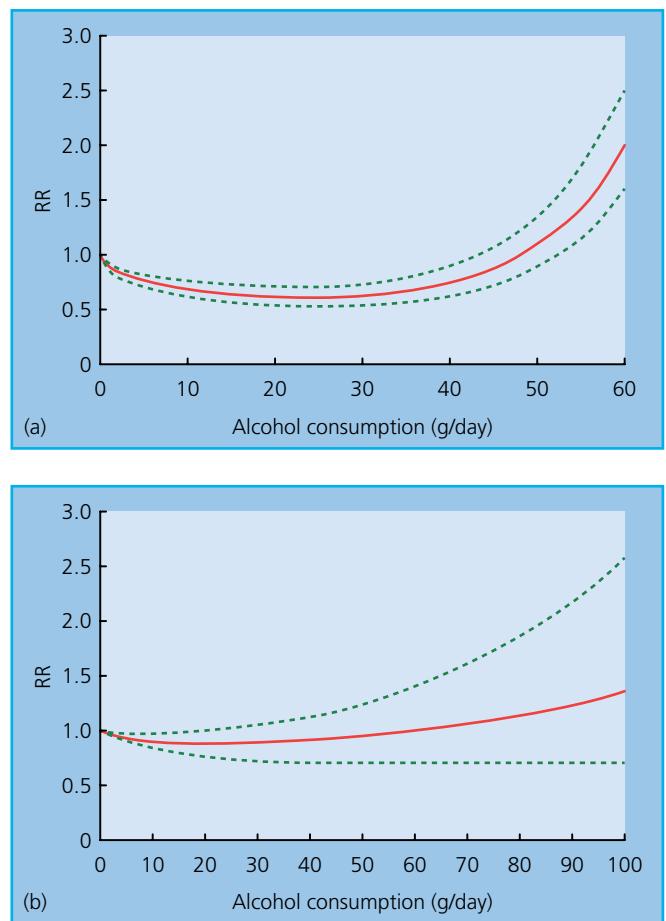

Figure 66.2 Relationship between alcohol intake and risk of diabetes in (a) women and (b) men. Solid lines represent the pooled and fitted relative risk (RR) estimates and the dotted lines are the 95% confidence intervals. Source: Pietraszek et al. 2010 [84]. Copyright 2010 Elsevier.

Alcohol and glycaemic levels

Alcohol consumption in a real-life setting can have very variable effects on blood glucose [85]. In part, this is because the nature of alcohol consumption can vary considerably, ranging from a glass of wine with a meal to an episode of excessive binge drinking. Alcoholic beverages vary significantly, not only in their content of alcohol, but also in their physical volume and carbohydrate and glucose content. Some forms of alcoholic drinks, such as white wine, may be more prone to cause hypoglycaemia, while others, such as red wine, may be more prone to cause hyperglycaemia [85]. Patterns of food ingestion with alcohol also vary substantially and alcohol ingestion may be accompanied by the use of one or more recreational drugs.

Hypoglycaemia

Ethanol has marked metabolic effects on the liver, which metabolizes over 90% of an alcohol load. Gluconeogenesis is suppressed, even at blood alcohol levels that are not usually associated with intoxication [86–88], while the processes of recycling carbon as glucose and lactate between hepatic gluconeogenesis and muscle glycolysis [87] and fatty acid oxidation are also inhibited by alcohol. Thus, alcohol has the potential both to predispose to hypoglycaemia and to inhibit glucose recovery. In individuals without diabetes, total hepatic glucose production is not reduced by alcohol, despite the inhibition of gluconeogenesis [88], and alcohol-induced

hypoglycaemia only occurs if hepatic glycogen stores are already depleted; for example, by fasting for at least 36 hours [89].

In people with diabetes, alcohol consumption may impede recovery from insulin-induced hypoglycaemia. This effect is often delayed, occurring up to 24 hours after alcohol ingestion, and may occur during the night or the following day [90]. Those with a deficient glucagon response to hypoglycaemia (Chapter 40) may be at greater risk, because they are unable to increase hepatic gluconeogenesis. The signs of hypoglycaemia may be missed or mistaken for those of alcohol intoxication by the individual or by observers, and even moderate alcohol consumption increases the cognitive impairment that occurs during hypoglycaemia [91]. People with insulin-treated diabetes should be advised not to drink *any* alcohol before driving.

Overall, alcohol is an important contributory factor to many episodes of hypoglycaemia in people with diabetes, an estimated 20% in one study [92]. Hypoglycaemia-induced brain damage is rare, but when it occurs it is often preceded by excessive alcohol consumption, which presumably promotes protracted neuroglycopaenia. Severe hypoglycaemia caused permanent neurological damage after binge drinking in five alcoholic people with insulin-treated diabetes, two of whom died [93].

Hyperglycaemia

Excessive alcohol consumption is associated with central obesity [94], which may be a consequence of the adverse lifestyle factors that tend to accompany high alcohol intake. It should also be noted that alcohol provides 7 kcal energy/g (1 unit = 10 g alcohol) in an easily consumable form and can therefore provide a substantial caloric intake, particularly as beer and lager. This is a commonly overlooked source of calories in middle-aged men with type 2 diabetes and obesity, who are having difficulty in achieving weight loss by dietary means. The caloric content of spirits is much lower but may be augmented by adding sugar-rich mixers to drinks. Low-carbohydrate beers and lagers have been marketed as being suitable

for people with diabetes, but should not be recommended because of their high alcohol content.

Heavy drinking has also been linked with poorer medication taking, outpatient follow-up, and self-blood glucose monitoring [95, 96]. Despite this, and the association with increased central obesity, excessive alcohol consumption does not appear to be associated with worse long-term glycaemia. Indeed, in most studies there is a linear inverse relationship between glycaemic levels and alcohol consumption [84, 97]. However, people with very heavy alcohol consumption tend to be under-represented in such studies.

Alcohol and the complications of diabetes

Moderate alcohol consumption in people with type 2 diabetes is associated with a 35% reduction in total mortality compared with non-drinkers (i.e. a similar magnitude to the effect of moderate alcohol on the risk of developing type 2 diabetes [98]) (Figure 66.3). These favourable effects of alcohol consumption may be a consequence of enhanced insulin sensitivity, lower blood pressure, and favourable changes in lipids and haemostatic factors [84]. These observations again do not include data on substantive numbers of very heavy drinkers, and it is well established that excessive alcohol consumption increases serum triglyceride concentrations in susceptible individuals and raises blood pressure; excess alcohol consumption is an important cause of hypertension failing to respond to treatment (Chapter 47). In the Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified-Release Controlled Evaluation (ADVANCE) trial, mortality and risk of cardiovascular events were indeed higher in people with type 2 diabetes who drank more than the UK-recommended limits [99].

With regard to microvascular complications, a J-shaped relationship is observed between risk and alcohol consumption [100]. Moderate consumption (30–70 g/wk) is associated with a 40% reduction in risk of proliferative retinopathy and neuropathy in type 1 diabetes, and over 60% reduction in risk for macroalbuminuria. Conversely,

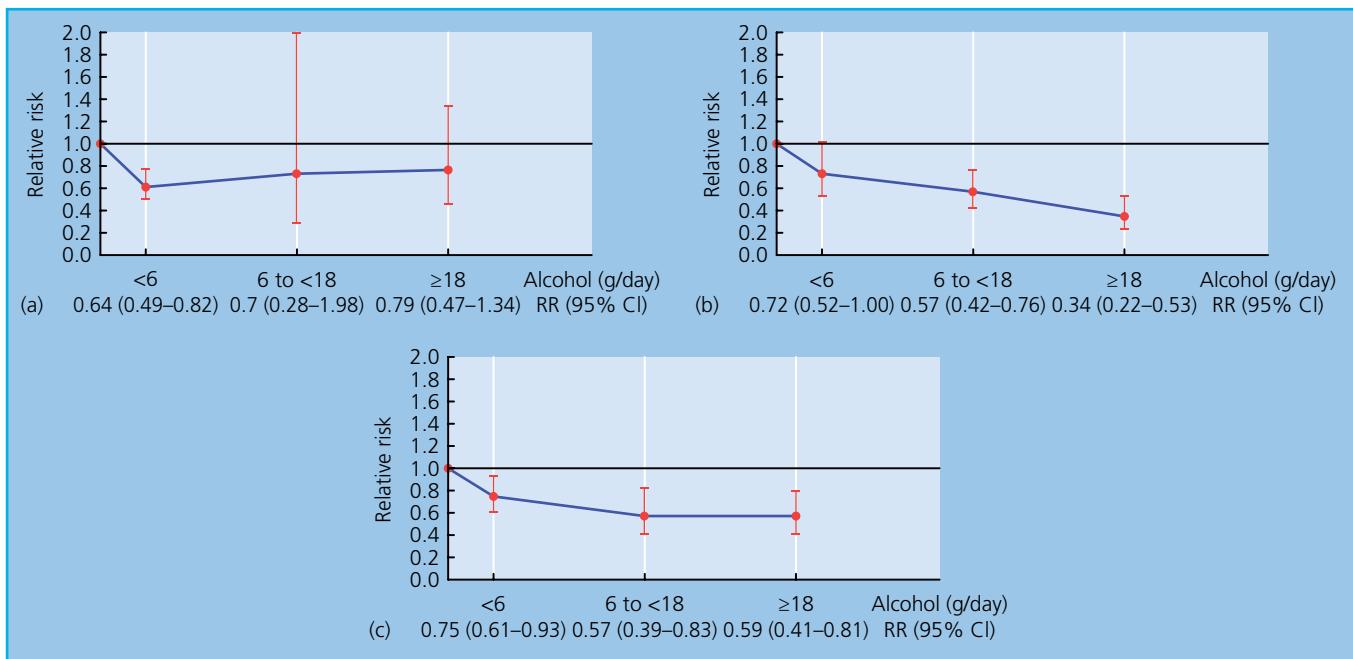

Figure 66.3 Pooled relative risk estimates (with 95% confidence intervals) of (a) total mortality; (b) coronary heart disease mortality; and (c) coronary heart disease incidence for three alcohol consumption categories, with non-drinkers as the reference. Table 66.4 General advice on alcohol for people with insulin-treated diabetes.

Small to moderate amounts of alcohol taken with a meal should not have a major effect on blood glucose levels
Larger amounts of alcohol can make blood glucose rise or fall
Avoid drinking on an empty stomach, as it may let the alcohol be absorbed more quickly and cause a hypo (low glucose)
Always ensure you have taken some carbohydrate before and after drinking alcohol
Check your blood glucose and consume a carbohydrate snack before going to bed.
A severe hypo can occur with larger quantities of alcohol, especially if insufficient carbohydrate has been eaten
A hypo may be delayed and occur up to 16 h after heavy drinking, so in addition check your glucose levels regularly during the next day
A hypo can be confused with being drunk. Tell people you have diabetes and wear or carry some form of diabetes identification
All types of alcoholic drinks contain calories and may contribute to weight gain
Low-carbohydrate beers and cider generally have a higher alcohol content
Low-alcohol wines are often higher in sugar than ordinary ones
Mixer drinks should be diet or sugar-free, such as diet tonic water and diet cola
Drinking and driving should be avoided

chronic excessive consumption of alcohol in people with diabetes is associated with peripheral neuropathy and exacerbation of neuropathic symptoms, erectile dysfunction, and increased risk of foot ulceration [101]. This may be in part a direct toxic effect of alcohol on the nervous system, though acute alcohol intoxication also impairs erectile function, while poor self-care and hygiene behaviours may contribute to the association between alcohol and foot ulceration.

Recommended alcohol intake

Overall, reflecting many of these factors, studies on the effects of blood glucose in diabetes are very heterogeneous and it is difficult to draw firm conclusions. This is particularly the case because observational studies generally do not discuss the actions taken by individuals to alter their diabetes treatment to reduce the risk of hypo-/hyperglycaemia. However, it is probably reasonable to conclude that consumption of low to moderate amounts of alcohol does not have a major negative effect on glycaemia in diabetes [102], but it may increase glycaemic variability in type 1 diabetes [103] and so caution is required. Large binges of alcohol and/or chronic consumption of excess alcohol are likely to have negative short- and long-term consequences. Recommendations for average alcohol intake in people with diabetes are, therefore, comparable with advice given to the general population; that is, women with diabetes should drink no more than 2 units of alcohol per day and men no more than 3 units. General advice for people with insulin-treated diabetes regarding alcohol is summarized in Table 66.4.

Recreational drugs

Use of recreational drugs is a serious problem in the general population and can pose particular difficulties for people with diabetes [104]. The main traditional classes of drugs involved are cannabis, amphetamine-type stimulants (including ecstasy), cocaine, and opiates, with cannabis being the most commonly used drug by far. In recent years, numerous new psychoactive drugs have been

developed to mimic the effects of the main illicit drug classes, but to remain legal; they were previously known as 'legal highs'. The rapid proliferation of these chemicals is a challenge for authorities, not least in determining which should be subject to legal controls. There are four main categories of new psychoactive drugs:

- Synthetic cannabinoids (e.g. Spice, Black Mamba, and Clockwork Orange).
- Stimulant-type drugs that mimic drugs like amphetamine, ecstasy, and cocaine (e.g. mephedrone, benzylpiperazine [BZP]).
- Tranquillizer-type drugs that mimic the effects of drugs like benzodiazepines (e.g. etizolam, pyrazolam).
- Hallucinogenic drugs that mimic the effects of drugs like lysergide (LSD) (e.g. 25i-NBOMe, Bromo-Dragonfly).

Other legal drugs are also being used increasingly for their psychoactive properties, including nitrous oxide and salvia.

Regulation

In the UK, drugs that are associated with dependence or misuse are regulated under the Misuse of Drugs Act 1971. This Act specifies a classification system for drugs according to harm associated with misuse and specifies controls over manufacture, supply, and possession (Table 66.5). The list of drugs within each class can be amended by order of the Home Secretary. The Misuse of Drugs Regulations 2001 define the classes of individuals who are authorized to supply and possess controlled drugs and lay down the conditions under which these activities may be carried out. Drugs are classified under five schedules, which specify the requirements governing import, export, production, supply, possession, prescribing, and record keeping. Cannabis and LSD are classified as Schedule 1 (drugs with no therapeutic value), while opiates, cocaine, and amphetamine are classified as Schedule 2 (drugs that can be used if appropriately prescribed) and are subject to full controlled drug requirements.

Table 66.5 Classification of controlled drugs.

Class A includes: ^a
Cocaine
Diamorphine (heroin)
Methadone
Methylenedioxymethamphetamine (MDMA, ecstasy)
Morphine
Opium
Pethidine
Methamphetamine (crystal meth)
Class B includes:
Oral amphetamines
Barbiturates
Codeine
Cannabis
Synthetic cannabinoids
Synthetic cathinones
Ketamine
Class C includes:
Most benzodiazepines
γ-Hydroxybutyric acid (GHB)
Cathinone (khat)
Zolpidem
Androgenic and anabolic steroids

^aIncludes Class B substances when prepared for injection.

Source: Data from UK Misuse of Drugs Act 1971.

New psychoactive drugs are regulated in the UK by the Psychoactive Substances Act 2016. This Act makes it an offence to produce or supply these drugs, but possession is not an offence. However, some synthetic cannabinoids, such as Spice, have been classified as Class B under the Misuse of Drugs Act.

Prevalence of recreational drug use

On a global scale, it is estimated that in 2018 between 5.4% of the world population aged 15–64 years (269 million people) had used recreational/illicit drugs at least once in the preceding year [105]. In England and Wales in 2019–2020, 9.4% of adults aged 16–59 years had taken a recreational drug in the preceding year, but this figure rose to 21% in adults aged 16–25 years [106]. Around 70% of use of new psychoactive drugs was by individuals aged 16–24 years and approximately one-third of adults had used recreational drugs at least once in their lifetime [106]. Trends in recreational drug use have changed over the years, with a decline in the use of LSD, amphetamine, and solvents and an increase in the use of cocaine, nitrous oxide, and new psychoactive drugs, particularly associated with the night-club and rave culture. Cannabis and powder cocaine remain the most commonly used illicit drugs in the UK.

Specific data about the use of recreational drugs by people with diabetes are sparse. Two uncontrolled questionnaire surveys of young adults with type 1 diabetes, one from the USA and one from the UK, have reported a similar prevalence and pattern of recreational drug use to that observed in the general population [107, 108]. In the UK survey, approximately 30% of respondents had used recreational drugs, with cannabis (28.2% of respondents), amphetamine-type stimulants (13%), and cocaine (12%) being used most commonly [108]. Many (15% of respondents) used more than one drug. Another questionnaire study in the USA in younger people with type 1 diabetes (aged 12–20 years) reported lower rates of recreational drug use (23.4% of respondents), with cannabis use overwhelmingly being the most used drug [109]. A report from Chile suggested that use of recreational drugs was lower in school-aged adolescents with type 1 diabetes than in the general population (9.6% vs 22.2%), although this difference disappeared during later years at school [110]. In all studies examining the prevalence of recreational drug use, under-reporting by respondents is highly likely, related in part to fear of retribution.

Impact of recreational drug use on diabetes

In the Diabetes UK Cohort Study, acute metabolic complications (diabetic ketoacidosis and, to a lesser extent, severe hypoglycaemia) were the most common causes of death in adults with type 1 diabetes under the age of 30 years, closely followed by accidents and violence [111]. In that study, a history of previous drug abuse was associated with a nearly sixfold increased risk of death from acute complications. More than 50% of young adults presenting with diabetic ketoacidosis to a tertiary referral hospital admitted to using recreational drugs; a history of recreational drug use was volunteered by only 20% on initial questioning [112]. Drug misuse has also been identified as a major cause of death in young people with type 1 diabetes [113]. Substance abuse co-occurring with mental illness is associated with a particularly high mortality [114]. There are relatively few data on the effects of new psychoactive drugs on diabetes [115].

Intravenous drug abuse

Recreational drug use often disrupts normal lifestyle and a person with diabetes may abandon the daily routine of regular meals and insulin injections. Recreational drug use may also be only one aspect

of a chaotic lifestyle associated with other high-risk behaviours. This can result from the use of any recreational drug, but intravenous drug abuse (particularly of opiates, but also amphetamines) is particularly damaging and is strongly associated with poor social support, criminality, and mental illness. Intravenous drug use is uncommon in people with diabetes (as it is in the general population), but is associated with omission of insulin therapy, frequent admissions to hospital, and high mortality, both from diabetic ketoacidosis and from deliberate or accidental opiate overdose [116]. Unsurprisingly, intravenous drug abusers with diabetes may also present with complications related to the route of drug administration: deep venous thrombosis and abscesses at groin or limb injection sites. Intravenous drug abusers often default from outpatient clinic attendance (this may be associated with imprisonment) and maintaining contact with such individuals is usually difficult.

Cocaine, amphetamines, and other stimulants

Cocaine and amphetamine-type stimulants can have dramatic effects on the cardiovascular system through activation of the sympathetic nervous system [117]. Cocaine is a sympathomimetic that inhibits reuptake of norepinephrine and dopamine at sympathetic nerve terminals. Amphetamine and ecstasy potentiate the release of norepinephrine, dopamine, and serotonin from the central and autonomic nervous systems. Cocaine toxicity may be potentiated by cannabis, while amphetamine toxicity is enhanced by alcohol. Drug-induced sympathetic activation leads to tachycardia, vasoconstriction, and hypertension. Myocardial ischaemia and infarction, supraventricular and ventricular tachyarrhythmias, and severe hypotension can all occur. Prolonged use can result in a dilated cardiomyopathy. The sympathetic activation produced by these drugs antagonizes the action of insulin and use of stimulants such as cocaine and mephedrone has been identified as a risk factor for diabetic ketoacidosis [118, 119]. The risk of diabetic ketoacidosis may be increased by the omission of insulin due to behaviour change induced by these substances and/or to avoid the potential risk and embarrassment of hypoglycaemia.

Ecstasy is also associated with severe hyponatraemia, secondary to a combination of inappropriate secretion of antidiuretic hormone, polydipsia, and a proximal renal tubulopathy [108, 112].

Ketamine

Ketamine acts as an N-methyl-D-aspartate receptor antagonist and so reduces excitatory neurotransmission. It induces a state of relaxation and dissociation ('K-land'), but hypertension, hyperthermia, tachycardia, and seizures can occur in severe intoxication. Ketamine can precipitate diabetic ketoacidosis, with a metabolic acidosis that is severe and disproportionate to the degree of ketosis. It can also be associated with metabolic acidosis without ketoacidosis and rhabdomyolysis [112].

Cannabis

Cannabis plants produce a whole array of cannabinoids; tetrahydrocannabinol (THC) is the major natural cannabinoid with psychoactive effects. The endocannabinoid system in humans is important in the regulation of weight and food intake. Cannabis is not known to have major effects on glucose metabolism (other than by stimulating weight gain), but its effects on the central nervous system may increase appetite, affect behaviours with regard to insulin and other diabetes medications, and impair recognition of hypoglycaemia. Use of cannabis in low doses is associated with sympathetic activation and tachycardia; at high

doses, parasympathetic activation may predominate, resulting in bradycardia and hypotension. In the absence of any structural heart disease, these effects are usually well tolerated.

A wide variety of cannabis extracts and synthetic cannabinoids exist, some of which have little or no psychoactive effects. Many of these are purported to have health benefits, but with very little scientific evidence to support these claims. Δ9-tetrahydrocannabivarin (THCV), a non-psychoactive cannabinoid, reduces blood glucose in type 2 diabetes [120]. Leaving aside its potential therapeutic use in the future, this acts a reminder that cannabis extracts and synthetic cannabinoids may have differing degrees of agonism and antagonism on cannabinoid receptor subclasses and thus have differing effects on diabetes.

Nitrous oxide

Nitrous oxide is used in the food industry as a foaming and whipping agent. It is cheap and legally available in many outlets in canisters and balloons. It is increasingly being used as a recreational drug. Inhalation provides a very rapid onset of euphoria and disinhibition, which in turn is of very short duration and is usually not associated with a hangover effect. In theory, nitrous oxide should not pose any particular issues in relation to diabetes, other than a transient reduction in the ability to recognize and treat hypoglycaemia. It is associated with relative hypoxaemia; this is not a problem in healthy individuals, but could be harmful in individuals with cardiovascular disease.

Hypoglycaemia

While the association between recreational drug use and diabetic ketoacidosis is well established, there are few data suggesting any association with hypoglycaemia. Such drugs, however, are often taken in conjunction with alcohol and may be associated with poor oral intake of carbohydrate, both of which will increase the risk of hypoglycaemia. Moreover, amphetamine-like stimulants can induce frenetic behaviour at night clubs and raves, which can induce hypoglycaemia in people treated with insulin [121]. The hallucinatory, or central nervous system, depressant effects of recreational drugs may impair an individual's ability to recognize and treat hypoglycaemia. Furthermore, the sympathomimetic effects of cocaine and amphetamine-type stimulants may mimic the autonomic signs and symptoms of hypoglycaemia.

Advice on recreational drug use in diabetes

Recreational drugs cause significant morbidity and are hazardous for people with diabetes. Their dangers must be emphasized to people with type 1 diabetes (particularly teenagers and young adults), but advice must be given in a sensitive and non-judgmental manner. When exposed to recreational drugs and alcohol, modest reductions in insulin dosage and regular consumption of carbohydrate-based snacks or non-alcoholic sugary drinks are required, particularly if strenuous dancing is to be undertaken. In such situations, significant dehydration can occur, and water should be regularly consumed. Music festivals are increasingly popular, and the ready availability of alcohol and recreational drugs poses additional risks due to the more prolonged nature of the events over several days, poor sanitation, limited food choices, and the potential for significant peer pressure. People with type 1 diabetes attending such events should be advised of the potential hazards and the need to moderate consumption of alcohol and recreational drugs, while maintaining a regular intake of food and non-alcoholic beverages. Regular

glucose monitoring should be strongly advised, although the reality is that frequent monitoring is likely to fall by the wayside during the excitement of the event.

Travel

Diabetes should not be regarded as a bar to short- or long-distance travel, although careful planning may be required to avoid metabolic disturbances and other problems of diabetes that could have particularly serious consequences away from home. Diet and an adequate fluid intake may be disrupted while travelling or staying abroad, and local differences in climate, food, endemic diseases, and medical facilities may compromise diabetes control. Blood glucose levels should be monitored frequently during travel and holidays, and people with diabetes must be able to take a pragmatic approach to deal with contingencies (e.g. loss of insulin, delays during travel) that could perturb their diabetes. Occasionally, specific diabetes complications or other medical disorders such as uncontrolled hypertension or ischaemic heart disease can jeopardize health and safety during travel and periods away from home.

Preparation for travel

Personal identification

Travellers with diabetes should carry a doctor's letter stating the diagnosis and treatment, and ideally some other form of identification such as medical identification jewellery or tags (these contain personalized medical information and are recognized worldwide). These should also allay the suspicions of airline security, immigration, and customs officials who discover syringes and drugs in luggage. Many national diabetes associations provide an identification card that shows the person's photograph, doctor's name, and contact telephone number.

If a prolonged stay abroad is intended, it is useful to carry a prescription letter listing all medications (with generic names, as brand names often vary between countries), insulin-injection devices, and blood-testing items.

Insurance and medical care abroad

Comprehensive medical insurance is essential to cover accidents and illness that require medical assistance, and loss of medical equipment and drugs. The insurance policy must cover diabetes and other pre-existing medical conditions, as claims relating to these may otherwise be rejected. Most travel policies contain exclusions and diabetes is frequently listed; a person with diabetes may not be covered for conditions such as a stroke or myocardial infarction for which diabetes is a recognized risk factor. When appropriate, insurance must be adequate to cover any dangerous sporting activities (when hypoglycaemia could be particularly hazardous), and the costs of emergency air transport home in the event of a serious accident or illness.

Most countries in the EU provide emergency medical attention free or at reduced rates to visitors from other member states, although immediate payment for treatment may be demanded in some countries, such as France. Travellers from EU countries can obtain a European Health Insurance Card (EHIC) in their home country, which confirms their entitlement to this scheme, although full medical travel insurance is still recommended. Following Brexit, British travellers can continue to use their EHIC card until it

expires; the UK has introduced its own version, the Global Health Insurance Card (GHIC). This card functions similarly to its predecessor, allowing British citizens access to state healthcare when visiting the EU. Some non-EU countries (e.g. Australia and Russia) offer free or reduced-rate medical care for EU members. In the USA, emergency medical treatment can be extremely expensive, and insurance premiums are correspondingly high. A list of insurers who do not load premiums against people with diabetes can be obtained from national diabetes associations.

Irrespective of medical insurance cover, it should be appreciated that emergency medical care available in some countries is suboptimal or even potentially dangerous for a diabetes-related emergency. In some parts of the world, insulin is not readily obtainable and intravenous fluids are in short supply. These considerations may influence the choice of holiday destination for people with diabetes.

Drugs and equipment

Essential items for the traveller with diabetes are listed in Table 66.6.

- **Immunization.** Routine recommendations should always be followed for the relevant destination. Occasionally, a severe reaction to a vaccine may cause a temporary rise in insulin requirements.
- **Medication.** Air travellers treated with insulin should carry an ample supply in their hand luggage. Preferably, another supply of medication should be carried by a relative or friend in case of loss or theft. When travelling by air, medication and blood monitoring equipment should not be consigned to the hold, because of the risk of losing luggage and the deleterious effects of extremely low hold temperatures on the insulin. During travel,

Table 66.6 Checklist of essential items for travellers with insulin-treated diabetes.

Health checks

Diabetes annual review – if prolonged travel

Vaccinations

Visit general practitioner for prescriptions, including possible antibiotics and anti-diarrhoeal agents

Documents

Diabetes identity card/bracelet

Document stating diagnosis and treatment; letter from insulin pump company regarding X-ray machines and scanners

Copy of repeat prescription

Medical insurance and EHIC

Insulin pump company care-line number

Insulin pump settings

Equipment

Insulin vials or cartridges (also required by those on pump therapy)

Syringes and needles/pens and spare pen needles

Flask or cool bag for insulin storage

Blood glucose meter; spare meter and batteries; ketone meter (if used)

Finger pricking device and spare lancets; container for used needles

Spare glucose sensors (for continuous or flash glucose monitoring)

Spare insulin pump, batteries, and consumables

Hypoglycaemia treatment

Quick-acting carbohydrate:

Glucose drinks (screw-top container; no more than 100 ml if flying)

Glucose tablets/confectionery

Slow-acting (complex) carbohydrate:

Biscuits or cereal bars

insulin can be carried in an insulated cool bag. Treatment for hypoglycaemia should also be carried in the hand luggage; this is best in the form of dextrose tablets or sweets, as the regulations on the amount of liquid that may be carried through airport security may pose difficulties.

- **Insulin pumps.** People using insulin pumps should carry spare batteries, vials of long-acting insulin, and syringes (or pens) as a back-up in case of pump failure, and the contact details of the pump manufacturer so that a replacement can be ordered. Some insulin pump manufacturers will provide users with the temporary loan of a spare pump for a holiday. It is important that insulin pump users carry a written note of their insulin pump settings, including basal rates, bolus ratios, sensitivity factor, blood glucose targets, and active insulin time, as well as the consumable types and the pump serial number. Some insulin pumps should not be passed through X-ray security or body scanners, as these may interfere with the electronic software in the pump; pump manufacturers will provide an explanatory letter, which can be shown to security staff. Insulin pumps can pass safely through security metal detectors. The delivery of insulin from a pump may be increased if the atmospheric pressure is reduced suddenly, because bubble formation displaces insulin from the cartridge and may provoke hypoglycaemia. If cabin depressurization is severe, this could increase insulin delivery by as much as 8 units [122]. Even during normal ascent and descent, there can be slight increases and decreases, respectively, in the amount of insulin administered. Insulin pumps can also be targets for theft, as they may be mistaken for mobile phones or other electronic devices; it is important to check that travel insurance covers theft of the insulin pump.

- **Glucose and ketone monitoring.** Extremes of temperature and high altitude can disable some blood glucose meters and affect the accuracy of blood glucose test strips, although the cabin pressure of passenger aircraft (equivalent to an altitude of up to 2500 m) should not pose problems [123]. While on holiday, it is sensible to carry a spare glucose meter (and blood ketone meter if used), test strips, a replacement meter battery, and spare sensors if using CGM. If a new glucose meter is purchased overseas, it is important to remember that its default display could be in different units to the standard for an individual's home country; that is, mg/dl instead of mmol/l or vice versa. As with insulin pumps, some CGM systems should not be passed through X-ray security or body scanners, though they can be passed through metal detectors. The wireless link between CGM and the insulin pump can be an issue for some airlines; some pumps have an 'airplane' mode that can be used during take-off and landing. Current advice is that people with diabetes should discuss any medical devices that they intend to take on board an airplane with their airline.

- **Other considerations.** Those prone to motion sickness should take an anti-emetic to prevent nausea and vomiting from disrupting glucose levels. Anti-diarrhoeal agents and a broad-spectrum antibiotic should be carried, particularly if travelling to regions with a high risk of acquiring gastroenteritis. People with peripheral sensory neuropathy should take comfortable and appropriate footwear for travel and for holiday use, as foot ulceration may be caused by wearing ill-fitting sandals or walking barefoot across rocks or even hot sand.

Long flights and crossing time zones

Long flights pose several potential problems, ranging from the timing and composition of airline meals to ensuring that insulin dosages will cover the flight and adjust to local time on arrival.

Meals

Times of serving in-flight meals after take-off can usually be obtained from the airline. In-flight meals can be supplemented with a personal supply of suitable carbohydrate, but it is impractical to carry large quantities, not least because of the limits of what foods may be imported into many countries. Allowance may have to be made for delayed flights or long intervals between meals, while fatigue or travel sickness may blunt appetite.

Alcohol

Drinking alcohol before and during air travel is best avoided because of the risk of hypoglycaemia; also, the diuretic effects of alcohol favour dehydration, which has been implicated in deep venous thrombosis and pulmonary embolism during long-haul flights (although diabetes does not appear to confer greater risk) [124]. Water or non-alcoholic sugar-free drinks should be drunk liberally.

Glucose monitoring

Blood glucose levels should be monitored frequently while in transit and when changing time zones. It is often safer to allow in-flight glucose values to be slightly higher than usual to avoid the risk of hypoglycaemia.

Insulin treatment

There is no evidence-based information on how to adjust insulin dosages during flights that cross several time zones, and this probably accounts for the variability in the advice that is given [125]. Each case should be discussed individually, considering the

duration of the flight and the change in time zone, the usual insulin preparations and dosages, the size and timing of meals, and the results of glucose monitoring. Some general guidelines are suggested in Table 66.7 and Figure 66.4.

Guiding principles are as follows:

- Do not aim for strict blood glucose targets while flying. A few hours of mild or moderate hyperglycaemia will do no harm and, as long as glucose levels are monitored regularly, it is safer to reduce usual insulin dose and use small additional insulin dosages rather than risk hypoglycaemia.
- Glucose levels should be checked every 2–3 hours.
- Time changes of less than 4 hours in either direction normally need no major adjustment of the usual insulin schedule: simply give

Table 66.7 Management of diabetes during long-distance air travel.

- | |
|---|
| Obtain advice from the diabetes clinic before travelling |
| Obtain essential information, including the local time of departure, flight duration, and local time of arrival |
| Inform the airline that you have diabetes, especially if you are treated with insulin |
| Carry extra supplies of carbohydrate |
| Anticipate that delays may occur |
| Time-zone travel may necessitate two consecutive morning or evening insulin doses, before and after the flight |
| Ensure that you can monitor your blood glucose frequently during travel |
| Do not strive for meticulous control of blood glucose while travelling |
| Adjust insulin doses if necessary |

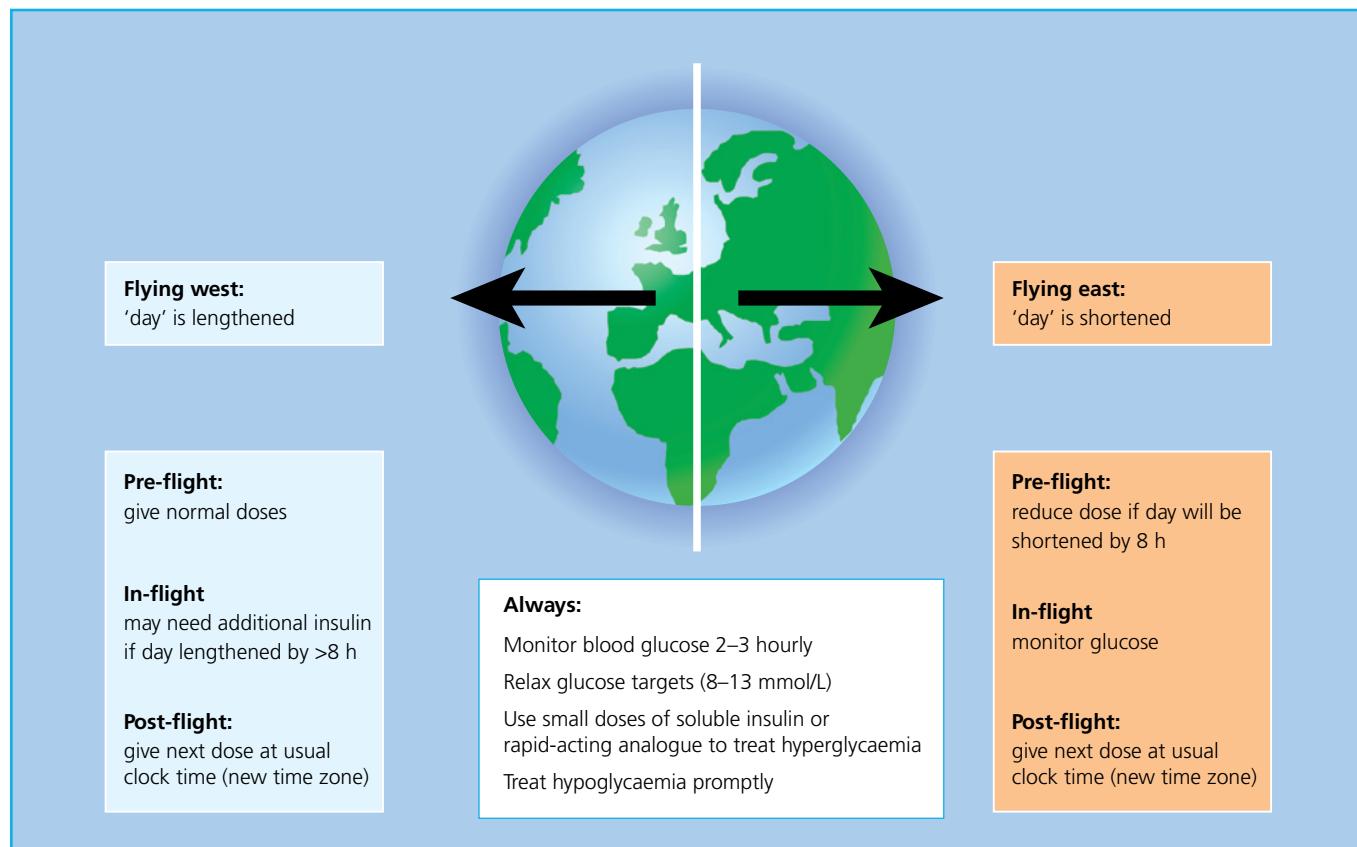

Figure 66.4 Scheme for adjusting insulin dosages during flights that cross time zones.

the next dose of insulin at its usual clock time, using the destination's time zone.

- Westward flights *lengthen* the day. Give the next dose of delayed-acting or premixed insulin at its usual clock time (using the destination's time zone). If this injection is delayed by more than 12 hours, then additional insulin with food will be needed in the interim. The most convenient way to do this is with small doses (usually a few units) of soluble insulin or a rapid-acting analogue, injected every 4 hours or so on the basis of blood glucose measurements.
- Eastward flights *shorten* the day. The next dose of delayed-acting or premixed insulin should again be given at its usual clock time (destination time zone), but because this injection will effectively be earlier than usual, the previous dose of delayed-action insulin should be reduced if the interval between the injections is less than 12 hours.
- Extremely long flights with a time shift of 12 hours or more may require two *morning* or two *evening* insulin dosages to be injected consecutively, before and after the flight.
- Any additional insulin needed to fill in long gaps between delayed-action injections or to correct hyperglycaemia is best given as small doses of soluble or a rapid-acting analogue, ideally using a pen injection device.
- Travelling across time zones is generally easier to manage when using insulin pump therapy. The *temporary basal* feature can be helpful, depending on the length of the flight and activity levels, and it is easier to administer correction boluses. It is important to adjust the clock time on the pump to the local time, to ensure that the correct basal rates of insulin are being administered [126].

Oral glucose-lowering agents

Additional doses are not usually required to cover an extended day.

Insulin treatment in hot climates

An individual's insulin requirements may change markedly in different countries, the main factors being differences in diet and daily physical activity. Subcutaneous insulin absorption can be accelerated by high ambient temperatures, such as in a sauna, and this effect has variable clinical significance in very hot climates.

Modern formulations are quite stable, but sometimes denature if exposed to high temperatures and shaken; in this case, discoloured particles or a granular appearance (distinct from the normal cloudiness of delayed-action preparations) may be seen when the insulin is resuspended. Sometimes there are no visible changes, but the insulin appears to lose its effect, with the usual dosages failing to lower blood glucose. Particularly in hot countries, insulin is best stored in a refrigerator; if one is not available, insulin can be protected by a damp flannel or a porous clay pot containing some water or wet sand, placed in a cool part of the room. Even these measures may be unnecessary, as most insulin preparations can survive being kept at 25 °C or more for up to six months and will retain most of their biological activity [127].

Food and drink

When travelling abroad, it is essential to know the basic form of carbohydrate that is eaten locally, and useful to learn to judge quantities of foods such as pasta or rice. Items selected from local menus can be supplemented with bread, biscuits, or fruit. Sugar-free drinks are difficult to obtain in many countries, but bottled water is safe and usually available.

Quick-acting carbohydrate to treat hypoglycaemia should always be carried and stored appropriately: dextrose tablets may disintegrate or set hard in hot and humid climates unless wrapped in silver

foil or stored in a suitable container, while the temperature dependence of chocolate is well known. Cartons of fruit juice cannot be reused once opened; a plastic bottle with a screw top is preferable. Sealed packets of powdered glucose may be the best option for hot, damp climates.

Travelling companions should carry a supply of quick-acting carbohydrate (and glucagon) for emergency use and should know how to test the blood glucose and how to treat hypoglycaemia.

Intercurrent illness

Any intercurrent infection should be treated promptly and appropriately, with adequate replacement of fluids and carbohydrate in the form of drinks if possible. Insulin therapy must never be discontinued and dosage may have to be increased, and blood glucose should be checked every 3–4 hours, with testing for urinary ketones if possible. Usual *sick-day* rules should be followed.

Recreational activities

The impact of physical exercise and sport on diabetes is discussed in Chapter 28. People need advice about strenuous and unaccustomed exercise during holidays, such as beach sports or prolonged and vigorous dancing. Swimming alone should be avoided. The risks of alcohol and recreational drugs have been described earlier.

Leaving home

As a child with diabetes grows up, inevitably parental input to the day-to-day management of diabetes is reduced with the increasing autonomy of the adolescent. In teenage years this is often manifest by a deterioration in glycaemic levels (Chapters 69 and 70). Even in adolescence, parents or guardians still play an important role in the provision of regular meals and in the recognition and treatment of hypoglycaemia, particularly at night. Therefore, the eventual move away from the parental home can pose problems, especially if the individual with type 1 diabetes is living alone and if they move to another town. Social isolation may exist until new friends are made and access to alcohol and recreational drugs may increase, with the attendant risks that have been highlighted. Sexual activity may commence or increase, introducing issues of sexual health and pregnancy, and novel forms of exercise may be more readily available. On leaving the parental home, individuals often become removed from the familiar support of the healthcare professionals in their local diabetes centre and initially do not have the similar contact and immediate access to advice from doctors and nurses about diabetes, precisely at a time it may be most needed. It is a disturbing fact that 'living alone' was associated with a more than fourfold increased risk of mortality from acute metabolic complications of diabetes in the Diabetes UK Cohort Study [112].

Students with diabetes

Particular emphasis has been placed on the welfare of students with type 1 diabetes who have left home to attend university or college. In part, this has been because of high-profile instances where individuals with type 1 diabetes have died shortly after commencing university [128]. Several surveys have suggested that students find diabetes more difficult to manage, although this does not necessarily translate into a rise in glycated haemoglobin concentrations [129–134]. Barriers to diabetes management include fear of hypoglycaemia, diet, irregular schedules, lack of parental

involvement, limited finances, recreational drugs, and alcohol. There is a natural desire for students with diabetes not to appear different from their peers, and this may lead them to assign a lower priority to diabetes management than they would normally and to undertake potentially high-risk activities [135].

Diabetes services need to be responsive to the needs of adolescents and young adults who are leaving home. Such individuals are often poorly informed about the inherent risks associated with, for example, alcohol and drugs [108, 134] and these and other needs may not be addressed in the context of a routine diabetes consultation [133]. Before the individual leaves home, a formal re-education programme should be offered in which alcohol, drugs, exercise, sex, and sick-day management are discussed [136]. Individuals leaving home need to think about their mealtimes; it can be difficult for someone living alone to motivate themselves to prepare substantial meals and many adolescents have limited cooking skills. Regular meals are provided in university halls of residence, but the nature and content of the food, particularly the carbohydrate content, may not be ideal.

Students should be advised to monitor glucose levels frequently during examination periods. Many students report that studying and undertaking examinations can cause marked fluctuations in glucose levels; this may partly be associated with stress or varying carbohydrate intake. Both acute hypoglycaemia

and hyperglycaemia impair cognitive function and can cause mood changes and may affect examination performance adversely. Therefore, students should try to optimize glucose levels during examinations and ensure that a supply of rapid-acting carbohydrate is available. People with diabetes may not recognize their condition as a 'disability', but in many countries diabetes is covered by equality or disability laws. Students with diabetes may apply for 'special arrangements' during examinations, such as taking a break if they develop high or low glucose levels, and permission to use monitoring equipment and take insulin and food/drink as required.

Many students may prefer to remain under the care of their home diabetes team, but it is important that they know how to contact local specialist diabetes services in the university town for advice or assistance. There is a real risk that students with diabetes can become 'lost to follow-up' during the transition from home to higher education. Medical practitioners in university health services have a duty to ensure that students with diabetes are offered regular diabetes follow-up. The student should be encouraged to confide at an early stage in a reliable friend or colleague about their diabetes and the potential problems that may arise [136]. Talking to recent acquaintances about having diabetes may cause embarrassment. It should be remembered that university authorities have a pastoral responsibility for students with diabetes [129].

Key points

- Across Westernized nations, indigenous, racial, and ethnic minority populations have a disproportionate burden of type 2 diabetes.
- The conditions in which people are born, grow, work, live, and age shape the risk of type 2 diabetes, including the racial or ethnic inequities in diabetes risk, over the life course.
- These factors are collectively referred to as *social determinants of health* and describe the macro (i.e. policies and systems) and meso (i.e. neighbourhood characteristics) contexts in which individuals live.
- Meso factors that shape the risk of type 2 diabetes include local area resources and constraints (e.g. greenspace, grocery stores, safety) that

shape the options individuals have for engaging in healthy behaviours that mitigate the risk of type 2 diabetes.

- Meso factors are themselves shaped by macro-level policies and regulations that affect infrastructure, zoning, workplaces, food access, and educational and economic opportunities.
- Using illustrative examples from the USA and Canada, this chapter describes how social determinants of health drive racial inequities in type 2 diabetes.
- Addressing social inequities in diabetes risk requires remedying these macro- and meso-level determinants that put minority populations 'at risk of risks'.

To accept one's past – one's history – is not the same thing as drowning in it; it is learning how to use it. An invented past can never be used; it cracks and crumbles under the pressures of life like clay in a season of drought.

James Baldwin

Diseases deemed untreatable as recently as a decade ago are now managed effectively. But each of these triumphant truths must be qualified by 'for some.' Your generation will have to deal with a growing outcome gap as some populations have ready access to increasingly effective interventions while others are left out in the cold.

Paul Farmer

Type 2 diabetes is a multifactorial disease. While the specific pathophysiological mechanisms are not fully understood, type 2 diabetes risk is influenced by both genetic liability and health behaviours. Heritability estimates for type 2 diabetes range from 20% to 80% [1], and genome-wide association studies have identified hundreds of loci [2]. Furthermore, health behaviours and their correlates (e.g. tobacco use, excess alcohol use, physical inactivity, having overweight or obesity, sleeping disturbances) are predictive of an elevated risk of type 2 diabetes. However, these individual-level genetic and behavioural factors alone do not fully explain the variation in type 2 diabetes risk. Specifically, these factors do not

explain why there are substantial, and in some cases growing, disparities in type 2 diabetes risk as a function of place, race, ethnicity, and socioeconomic status [3–5]. Neither do they explain why, within Westernized, industrialized countries, marginalized groups consistently have a higher burden of type 2 diabetes despite substantial national differences in healthcare systems. Instead, research points to another set of factors, which are fundamentally social and environmental in nature, as driving these inequities.

In the past decade there has been increasing attention to the role of social determinants of health, including their role in exacerbating health inequities. The World Health Organization (WHO) defines social determinants of health as the set of conditions in which people are born, grow, work, live, and age, and the wider set of forces and systems shaping the conditions of daily life [6]. Social determinants of health are 'the social characteristics within which living takes place' [7]. This phrasing points to a fundamental element of the social determinants of health framework, which is that health and health behaviours are shaped by contextual factors beyond the individual; thus, population health, and health inequities, are multi-level phenomena [8]. Studies in the USA suggest that social factors are the most robust predictor of population health, even surpassing healthcare and health behaviours [9]. Environmental characteristics such as air, water, and housing quality, mobility and transportation infrastructure, availability of grocery stores and the cost of food, access to recreation facilities, and social capital and cohesion are all

factors beyond the individual that shape health [10]. Moreover, these environmental characteristics are themselves shaped by economic policies and systems, development agendas, social norms, social policies, and political systems [10]. In sum, the social determinants of health framework reflects the complex and interdependent nature of *person* and *place* to situate *person in place*.

While social determinants of health have been examined as determinants of various aspects of diabetes care (i.e. medication taking [11], glycaemic management [12]), there also is a growing body of literature on how social determinants shape the risk of developing type 2 diabetes [13–16]. Leaders in the field have called for focused attention to understand how social determinants of health contribute to type 2 diabetes. As one example, in her 2018 address to the American Diabetes Association, Dr Felicia Hill-Briggs put forth a new initiative on establishing the scientific evidence base regarding social determinants of diabetes to inform clinical and community-based programming and priorities [17]. In 2021, this commission released its report, concluding: ‘Inequities in living and working conditions and the environments in which people reside have a direct impact on biological and behavioural outcomes associated with diabetes prevention and control. Life-course exposure based on the length of time one spends living in resource-deprived environments – defined by poverty, lack of quality education, or lack of health care – significantly impacts disparities in diabetes risk, diagnosis, and outcomes’ [18].

How do macro-level factors and meso-level factors shape health behaviours that influence the risk of conditions like type 2 diabetes?

As this chapter will describe how macro- and meso-level factors influence the risk of type 2 diabetes by structuring the dimensions on which individuals can make choices about health behaviours (Figure 67.1) [19, 20]. The chapter draws on Link and Phelan’s *fundamental cause* [21] and Bronfenbrenner’s *socioecological* [22] models, which collectively identify health as a multilevel phenomenon, shaped over the life course by factors at the macro (i.e. political), meso (i.e. neighbourhood, workplace), and micro/individual (i.e. behaviours, genetic liability) levels that intersect and interact. Beyond those proximal factors that influence the choice of specific behaviours in a specific scenario (e.g. individual preference for choosing between an apple or a cookie, etc.) [23], these multilevel factors shape *access* to grocery stores, *whether* an individual has fresh fruits available where they shop for groceries, *how much* the apple costs relative to the cookie, and so on [24]. These factors create affordances (i.e. features of neighbourhoods, workplaces, etc. that support health promotion) and constraints (i.e. barriers, challenges, and opportunity costs to health promotion) [25, 26]. By creating and reinforcing these affordances and constraints, macro- and meso-level characteristics differentiate *options* from *choices*, and then further delineate the options among which individuals can choose.

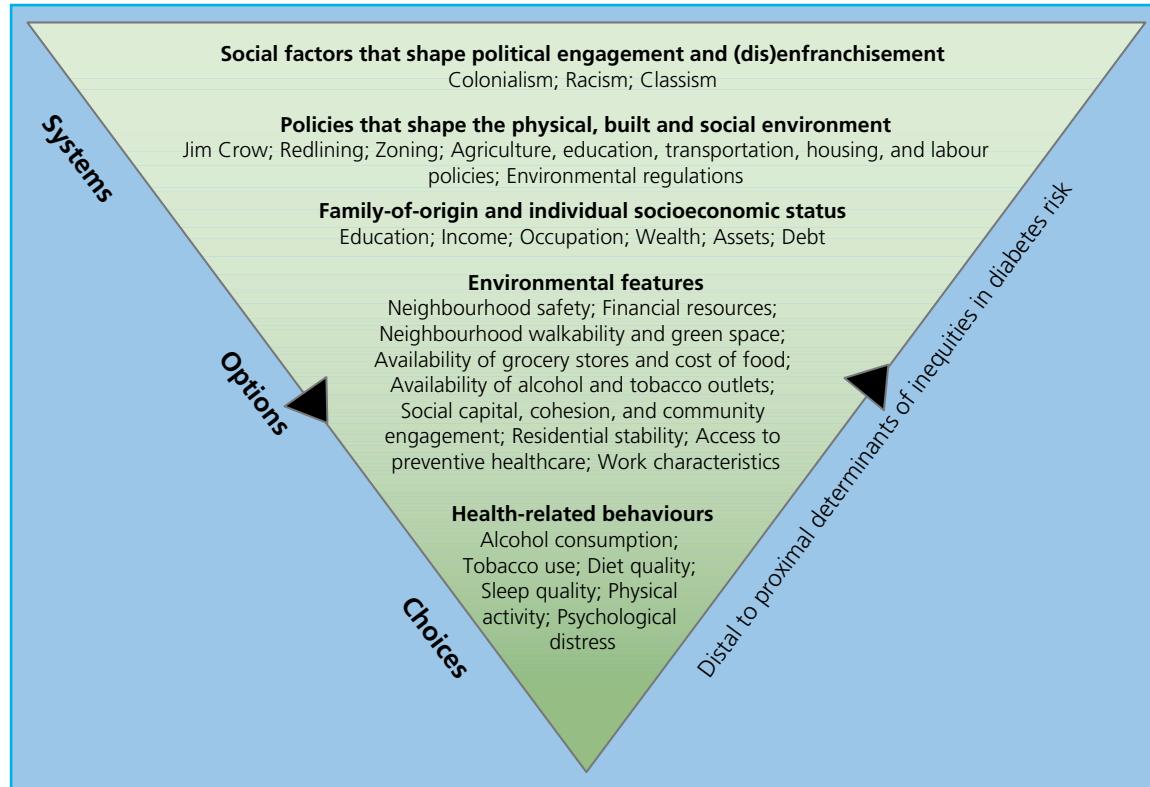

Figure 67.1 Symptoms of a system: conceptual model of how social determinants create inequities in type 2 diabetes risk. This conceptual diagram shows how pervasive systems like colonialism, historically and across generations, manifest policies that shape the options that individuals have for engaging in diabetes prevention and risk behaviours as a function of factors like place, race, and

socioeconomic status. While individuals’ health behaviours are the primary targets of intervention for healthcare providers, the underlying systems and options that create those differences are not; however, without addressing these underlying factors, efforts to address population inequities in diabetes risk will not be successful.

To illustrate this idea, this analysis will focus on nations that share a common history as part of the British colonial system (e.g. UK, USA, Canada, and Australia) and detail two examples from the USA and Canada to show how social determinants of health operate across geographical boundaries. The chapter concludes with key takeaway messages for clinicians and public health practitioners.

Scope of social inequities in type 2 diabetes in select former British colonies

Social inequities in type 2 diabetes exist across all dimensions of this disease, including incidence, prevalence, complications, and mortality. Figure 67.2 shows the prevalence of diagnosed diabetes from population health surveys of the UK, USA, Canada, and Australia as a function of race or ethnicity. While the plot represents cases of both type 1 diabetes and type 2 diabetes, given that these are based on general population samples the overwhelming majority of cases represented here are type 2 diabetes. This figure begs the questions: Why is it, regardless of the specific political system, healthcare system, geography, or specific ancestry, race, or ethnic group, that marginalized groups in former British colonies have a disproportionate burden of type 2 diabetes? What could explain this striking pattern that holds across these different healthcare systems?

This plot is only a snapshot of the disparities in diabetes burden. Not only is the prevalence of diabetes higher in these marginalized groups, but the age of onset is also significantly lower. Type 2 diabetes has become a disease of mid-life rather than later adulthood, particularly for racial minorities. For example, in the USA the prevalence of type 2 diabetes at age 45 years among African Americans and Latinos is twice that of non-Hispanic whites (10.9% and 9.4%,

respectively, vs 5.2%), and the mean age at diagnosis of type 2 diabetes among these minority groups is eight years earlier than that of non-Hispanic whites [32]. Racial and ethnic minorities also have a greater risk of developing complications from diabetes over time, including end-stage renal disease, amputation, vision impairment, and cardiovascular disease [32, 33]. Unsurprisingly, they also have greater healthcare utilization and costs associated with type 2 diabetes [32, 34, 35]. While these examples are from the USA, similar inequities exist in Canada [36]. As a result, any effort to address the substantial financial burden of type 2 diabetes within healthcare systems [37–39] must seek to address and remedy such disparities.

Beyond their influence on the risk of type 2 diabetes, social determinants of health also have impacts on disease self-management. For example, a recent mixed-methods investigation of people with diabetes living in the UK, the USA, and Australia identified many social determinants of health as common barriers to effective self-management, including financial constraints, psychosocial distress, and competing demands (particularly related to work) [40]. These barriers are strongly correlated with socioeconomic status (i.e. income, education, wealth) [41, 42]. Clinical guidelines from organizations such as the American Diabetes Association now explicitly call on clinicians to address the social determinants of health such as health literacy and food insecurity as part of comprehensive diabetes care [43].

Colonization as a frame for examining social determinants of type 2 diabetes

As defined by the WHO, social determinants of health include social, economic, and political systems. Pursuant to this broad definition, many scholars have named ideological stances, such

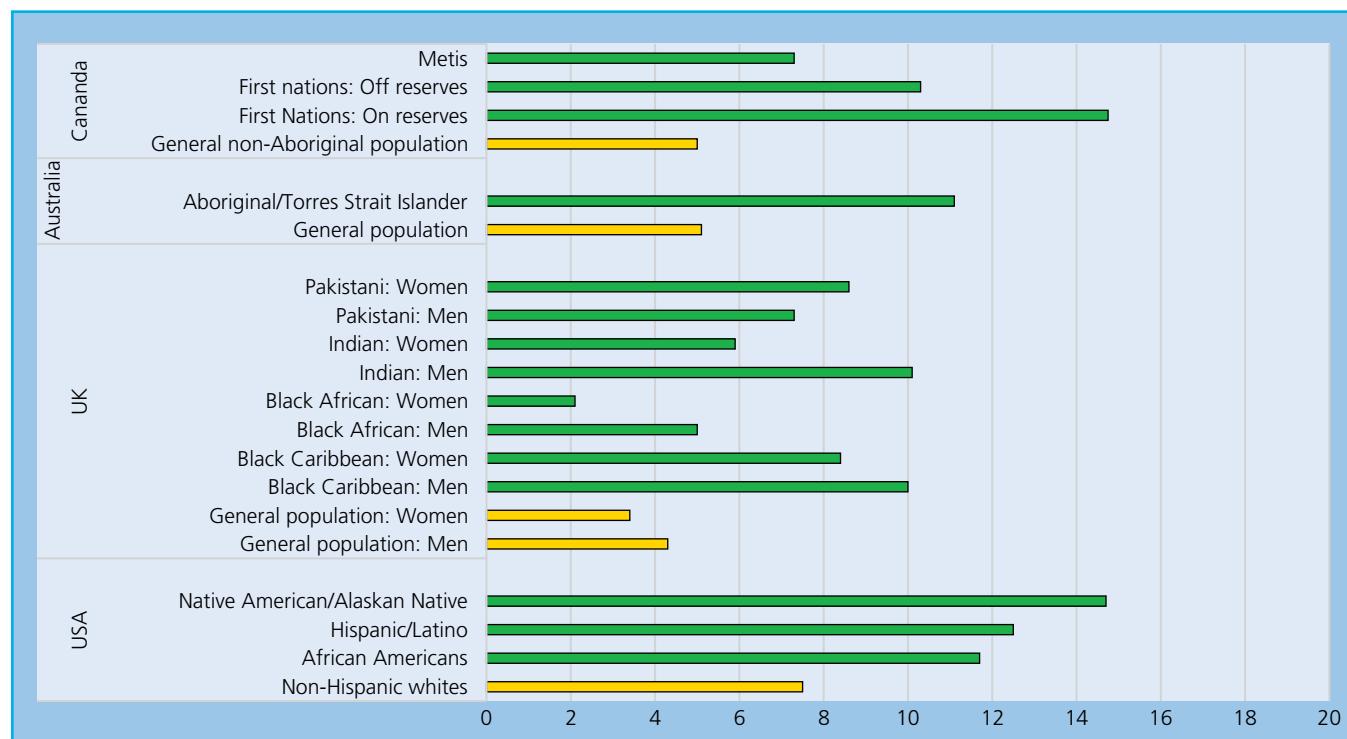

Figure 67.2 Prevalence of diagnosed diabetes by race and ethnicity in the USA, UK, Canada, and Australia. Age-adjusted prevalence of diagnosed diabetes (type 1 diabetes and type 2 diabetes) by ethnic group in select nations under the British colonial system. Source: Data for the USA from Centers for Disease Control and Prevention 2020 [27]. Data for Canada from Government of Canada 2011 [28]. Data for the UK from NHS Digital 2004 [29]. Data for Australia from Australian Bureau of Statistics 2013, 2014 [30, 31].

as racism [44], or their institutional manifestations, such as racial discrimination [45] or worker exploitation [46], as determinants of health. However, while there are exceptions, few have explicitly tied these ideas and structures to a broader historical lens, one that recognizes that while the specific terminology for these systems changes over time, they still share a common function of marginalizing particular groups from resources and status.

As the focus of this chapter is to highlight how social determinants of health shape type 2 diabetes risk in four nations that were part of the British colonial system, the term *colonialism* will be used as an overarching frame for understanding disparities in type 2 diabetes risk. This term is particularly appropriate, as the chapter will use case examples to illustrate how social, economic, and political systems have shaped type 2 diabetes risk in Indigenous populations (i.e. First Nations in Canada) and groups that were subject to the British slave trade (i.e. African Americans). Colonialism is a more appropriate term than related alternatives (i.e. racism, discrimination, other specific forms of bias) for two reasons. First, there is substantial geographical variability in the definition and measurement of race and ethnicity globally, and thus the applicability of those concepts may not be readily apparent to all readers. Secondly, terms like racism focus on between-group marginalization, while colonialism reflects a broader social construct that acts both across and within groups (i.e. colourism) [47, 48]. As such, limiting the discussion to more specific terms obscures the more general expression of this ideology, particularly its historical context [49].

Type 2 diabetes among First Nations communities in Canada

In this example we will refer to Indigenous peoples as the original inhabitants of what is now Canada, including First Nations, Metis, and Inuit populations. Aboriginal denotes the legal term used for Indigenous populations in the Canadian Constitution Act of 1982. First Nations, previously called ‘Indians’, comprise status and non-status populations. Metis are a distinct nation, who descended from First Nation and early European fur traders, and whose rights are protected under Section 35 of the Constitution Act of 1982. The Inuit are the original inhabitants of the Arctic regions of Canada, who also have their rights protected under Section 35 of the Constitution Act of 1982. Each Indigenous Nation has its own history, culture, language, and ties to its land. In this case study, we will focus on diabetes in First Nations communities in Northwestern Ontario, who are mainly made up of Anishinaabek, Oji-Cree, and Omushkego Nations. Because Canada is a part of the British Commonwealth, we will refer to the state as the Federal Crown to represent the federal government and the Provincial Crown to denote the governments of the provinces.

We explore the *fundamental causes* of type 2 diabetes in First Nations communities in Canada. Defined by medical sociologists Link and Phelan in 1995, the fundamental cause framework [21] describes how social structures put individuals *at risk of risks*, regardless of specific pathological processes, in order to explain social inequities in health more broadly. This framework posits that socioeconomic status, which shapes access (or lack thereof) to material, social, and educational resources, has direct and indirect impacts on population health [21]. It follows that health outcomes essentially pool in specific populations, because the risk factors for diseases are elevated in the socioeconomic context in which they live and limit the choices those contexts afford for responding to

those risks for all individuals in the group. In addition, the outcomes tend to persist and become cumulative in the population, because macro-level factors are slower to change and have a longer-term, intergenerational impact on health [50].

In the context of type 2 diabetes in First Nations populations in Canada, this fundamental cause framework ties outcomes to the unique constitutional relationship between the Federal Crown and Indigenous peoples. It is a relationship, and the colonial history of abuse associated with it, in which the Federal Crown gave itself a fiduciary power over Indigenous populations. Herein lies the key elements that contribute to macro-level factors causing increased type 2 diabetes in the Indigenous population. There is historical and ongoing colonial oppression in which the Crown uses its power to limit the choices available to Indigenous communities and provides substandard options for the care of their health.

Burden of type 2 diabetes among First Nations communities in Canada

As shown by Figure 67.2, while the prevalence of diabetes in the general Canadian population is approximately 6%, the lifetime risk of diabetes is 8 in 10 for First Nations people [50], with women about twice as likely to be affected as men [51]. While type 2 diabetes risk increases with age, in First Nations people there has been a rapid rise in the incidence of this condition among adolescents [52]. The prevalence of diabetes in the First Nations population in Ontario has grown significantly faster than in the non-First Nations population in the province; for First Nations people, the age-adjusted prevalence increased from 11.1% in 1995 to 16.6% in 2014, compared to from just under 4% to approximately 8% during this same period for non-First Nations people [53]. Moreover, as illustrated by Figure 67.2, this increase was particularly severe for the on-reserve population, which had a point prevalence of 18.7% in 2014 [53].

History of colonization and the development of a fiduciary relationship

The fiduciary relationship between the Federal Crown and Indigenous peoples grew out of an *unequal* relationship developed under British colonial history [54]. Legal cases such as *Sheldon v Ramsey* (1852), where the Bench’s statement that ‘the Crown should be in a situation to protect their interests and treat them as people under its care, not capable of disposing of their own possessions’ reflected the dominant perspective that Indigenous populations were unable to take care of themselves [54]. Constitutionally, the development of the fiduciary relationship is tied to several important legal documents originating from Great Britain and from within Canada. By exploring how the legal documents embodied colonialist ideology and removed choices available to Indigenous populations, we see their impact on the current type 2 diabetes epidemic in Canada.

The first document is the Royal Proclamation of 1763 by George III, which officially claimed territories in what is now the USA and Canada for the Crown. To guarantee access for the Crown to the wealth from the natural resources in the territory, the Crown declared that all lands not currently under British control were the property of the Indigenous peoples who reside on them and that only the Crown has the legal right to negotiate for their surrender. In doing so, the Crown established a nation-to-nation relationship between itself and the Indigenous populations, and established the need for the treaty system which is still in place in Canada. In short, the Royal Proclamation established that a treaty between the Crown and the Indigenous populations is required before title to the land can be transferred. It also establishes the dominance of British

colonial law in Canada, and helps establish a moral and legal stewardship of Indigenous peoples by the Crown in Canada [54].

The significance of the Crown–Indigenous relationship shifted during Confederation in Canada in 1867, when Section 91 [24] of The British North America Act identified ‘Indians and lands reserved for Indians’ as a responsibility of the Federal Crown, or Government, in Canada. The British North America Act moved the relationship from nation-to-nation to one of responsibility through Section 91 [24]. The responsibility of the Federal Crown to Aboriginal Peoples (First Nations, Inuit, and Metis populations) and the Royal Proclamation of 1763 were later enshrined in the Canadian Constitution Act of 1982. The overall result is a situation for Indigenous peoples that has been described as *Citizens plus* [55], whereby Indigenous people are part of the Canadian population, but with a unique constitutional relationship with the Crown where the Crown has a fiduciary responsibility to Indigenous people.

The interaction of law, colonialism, and control is most notable in the still-existing Indian Act, originally written in 1876, which transitioned moral understandings of stewardships into Status Indians becoming wards of the Federal Crown [56]. The Indian Act was the amalgamation of existing regulations that sought to control Indigenous populations and their lands for the benefit of the Crown. Guided by the ongoing assumption by many leaders in Canada in the late nineteenth to early twentieth centuries that Indigenous people were unable to take care of themselves, the Indian Act solidified total control over the lives of Status Indians. Among other aspects, the Indian Act decided who was a Status Indian, controlled reserve lands, limited communities’ ability to practise their culture and traditions, and replaced local leadership with Crown-controlled governments or ‘Indian agents’. The current iteration of the Indian Act (1985) continues to define and control Indian Band (Canada does not use the term tribe) membership lists, reserve lands, housing and property descent, wills, ‘mentally incompetent Indians’, guardianship of children, Band finances, loans, and education. On reserve, health falls outside of the Indian Act and the Canada Health Act, and is supported via the Health Canada First Nations and Inuit Health Branch [57].

The Indian Act, the Treaty process, and the establishment of the reserve system in much of Canada during the late nineteenth and early to mid-twentieth centuries had a significant impact on the social, political, economic, and cultural lives of First Nations peoples [58]. During this time, First Nations children living on reserve without access to a day school were required by law to attend a live-in Indian residential school, where they experienced high levels of abuse and many lost access to traditional hunting, navigation, and language skills [59]. The expansion west of the Canadian state and increased immigration significantly altered traditional food procurement and availability for First Nations peoples. As farming increased, hunting territories were decreased and traditional foods including the bison and many plants were replaced with those from Euro-Canadian farms [60]. By the mid-twentieth century, self-sufficient populations were becoming increasingly dependent on the Federal Crown and non-traditional employment for education, employment, income, and access to food [61].

The result is a context where the Federal Crown created a unique relationship with Indigenous people in Canada through the Constitution Act of 1982 and all its historical antecedents. That relationship, finally identified as a fiduciary relationship in *Guerin v The Queen* (1984), is mostly administered through the Indian Act, but with significant gaps in healthcare. In relation to type 2 diabetes the legal relationship becomes more problematic, because healthcare in

Canada through the Canada Health Act 1985 is a responsibility of the Provincial Crown. The healthcare for First Nations people living on reserve is administered by the Federal Crown through the Health Canada First Nations and Inuit Health Branch, which is separate from the standard healthcare system that other Canadians access.

The individual behavioural risk factors for type 2 diabetes are well established and documented. In contrast, a fundamental cause approach focuses on the macro-level factors, which cause those individual risk factors to accumulate within specific populations. Policies, laws, and regulations that limit choices and provide less appropriate options make any individual’s attempts to mitigate health risks, diabetes or otherwise, much more challenging.

Traditionally, First Nations communities migrated seasonally across their territories in small family units following food sources. In summer, the interconnected waterways in the regions provided the means to travel. In winter, snowshoes and dog teams aided movement. Food was unprocessed and the caloric cost of accessing it was high. Because of the remoteness of the area, many communities were relatively unaffected by colonial changes until the early twentieth century when treaties, compulsory Indian residential school attendance, and increased resource extraction brought greater changes to the area. After signing treaties communities were relocated to their allocated Reserve Lands and infrastructure, including nursing stations and housing, was provided under the direction of the Federal Crown.

History of the diabetes epidemic in Northwestern Ontario

Northwestern Ontario officially transferred to Canadian control with the signing of Treaty No. 3 in 1873, Treaty No. 5 in 1875, and Treaty No. 9 in 1905–1906 and 1929–1930. The region is still considered to be remote, with many of the northern communities being accessed only by air or waterways, with winter roads available for a short period each year. The region comprises northern boreal forest and muskeg swamp towards Hudson Bay. The medical hubs in the region include the City of Thunder Bay, located on the northwest shore of Lake Superior, and Sioux Lookout, which is in Treaty 3 territory. The Sioux Lookout Zone Hospital, a segregated hospital for Status Indians living on reserves in the area, operated until 1992 and was active in responding to the emerging diabetes epidemic.

Rare in the region prior to the changes introduced after treaties were signed, the outbreak of diabetes in First Nations communities in Northwestern Ontario began in the 1950s [62]. The increase in type 2 diabetes coincided with the rapid changes that contributed to a nutritional transition, changes to physical activity in the population, and increased stress [53, 60, 63]. Excess diabetes risk became increasingly concentrated across generations through a variety of mechanisms. For example, in 2012 Millar and Dean identified intrauterine exposure to maternal obesity as an important intergenerational risk factor for type 2 diabetes [64]. A dietary transition took place in the region as communities lost access to their traditional lands through the Indian Act’s pass system [53, 60, 63]. This transition caused a sudden shift from traditional country foods (i.e. moose, deer, caribou, fish, local plants) to store-bought, shelf-stable, high-calorie, and lower nutritional density processed foods [63]. This change in diet was associated with an increasing incidence of type 2 diabetes in these communities [65]. Moreover, the high cost of these new food sources, due in part to the remoteness of the region, is associated with an increased risk of food insecurity [66], which itself is associated with the risk of type 2 diabetes [67].

Beyond food access, the built environment itself may be a contributing factor to type 2 diabetes, particularly through the ways in which poor-quality and ageing infrastructure has impacts on chronic stress. Under the Indian Act, housing on Indian reserves is provided by the Federal Crown. Individual Band members do not own their house or the land it sits on. Robert Robson noted that 'A large portion of the estimated 89,000 on-reserve houses in Canada, are in poor condition, overcrowded, unaffordable, improperly serviced, poorly sited and generally, inappropriate given the culturally based shelter needs of the approximate 423,000 on-reserve residents' [68]. Housing quality is associated with multiple aspects of health, including type 2 diabetes [69]. Many communities continue to struggle with access to safe drinking water. First Nations communities are more than 90 times more likely to lack access to clean, running water, and Ontario-based First Nations communities experienced 402 drinking water advisories between 2004 and 2013 [70]. The biological manifestations of chronic stress associated with living in a colonial system have been identified via increased levels of hair cortisol in First Nations communities in Ontario [71, 72].

These type 2 diabetes risk factors developed together with the changes experienced by the population as a result of the policy actions of the Federal Crown. Crown efforts to gain control of the natural resources in the region, and its ability to act on the Indigenous populations through the power of the Indian Act, circumscribed the local Indigenous population's abilities to make the lifestyle choices of past generations [60]. The Act also encompassed healthcare access decisions; until the Sioux Lookout First Nations Health Authority was established in 1990 [73], healthcare access was limited to the former Zone Hospital, which was controlled by the central Canadian Government and the Inuit Health Branch of Health Canada. Centralized control of the funding mechanism has often meant that financial resources are siloed and the local level has little opportunity to reallocate funding to respond to their needs and priorities [54].

Legacy of colonialism and burden of diabetes in First Nations communities

As the example of Northwestern Ontario illustrates, both historically and in the present day, the Federal Crown limits the options available at the community level that would allow First Nations individuals to make lifestyle changes often recommended to prevent or treat type 2 diabetes. Consistent with the fundamental cause framework, this example shows how macro-level political and social factors contribute to the widespread burden of type 2 diabetes and related health conditions in Indigenous populations in Canada.

Clinical treatment guidelines continue to focus on the role of individual health behaviours as primary targets for type 2 diabetes prevention and management [60]. However, if the fiduciary relationship continues to circumscribe the options that individuals and communities have available to choose from, these efforts to change health behaviours will have little impact on the epidemic. These macro policies have shaped the environmental context of Northwestern Ontario and other First Nations communities, and these contexts are generally characterized as having limited options for engaging in physical activity, for adopting a healthy diet, and for having adequate shelter and safe drinking water. These are not simply unfortunate circumstances; they are the downstream effects of a Crown–Indigenous relationship that was founded in a colonial setting.

Type 2 diabetes among African Americans in the USA

Just as the effects of colonialism have continued to influence the health of Indigenous populations, the lasting effects of colonialism on the descendants of enslaved Africans in the USA persist within present-day social inequities, including in health. Since the Emancipation Proclamation of 1863, which freed enslaved persons in the USA, the country has found ways to perpetuate separate and unequal systems of treatment for African Americans. Perhaps the clearest demonstration of this is the enactment of Jim Crow laws in 1877 (*Plessy vs. Ferguson*), after the US Supreme Court ruled that segregation of public spaces was permissible. State and local governments, protected by this declaration, could formally marginalize the rights and opportunities of African Americans until the signing of the Civil Rights Act in 1964.

Geographical separation and exploitation in US Housing

For the nearly 100 years where these legally sanctioned, racist practices were in place, they continued to keep African Americans on an unlevel foundation in terms of the factors that we now call social determinants of health, including built environments, labour practices, educational opportunities, policing systems, and penal guidelines. The release from this not so distant past has been slow and unsteady, with new laws upholding old standards. For example, the practice of *redlining*, which is a form of lending discrimination, was federally sanctioned by the National Housing Act of 1934 [74]. This policy allowed lenders to support the practice of racial segregation by refusing mortgages in and around African American neighbourhoods, which were demarcated on maps with a red outline, hence the term. These undesirable properties cast away by the white racial majority restricted Black housing options by limiting the choice of community. The surrounding lands of these neighbourhoods, devalued by proximity, became an option for retailers and enterprises deemed unsuitable for white neighbourhoods [75]. While these lending practices were formally disallowed by the Fair Housing Act of 1968, the practice has been woven into the fabric that is the present-day USA, as issues of neighbourhood segregation and negative health outcomes are seen in communities across the country [76–79]. Many built environment features that are tied to type 2 diabetes risk, including inequitable food security [80], alcohol outlets [81], tobacco outlets [82], and gun violence [83], are echoes of historical, racist practices of land distribution and use like redlining.

Illustrating the centrality of place to racial inequities in health, work by LaVeist and others has shown that *racial* disparities in health, including in the prevalence of type 2 diabetes, are small or non-existent when comparing white Americans and African Americans who live in the same low-income, urban environment [84–86]. These racial gaps in type 2 diabetes are not eliminated because African Americans in these low-resource settings have a lower prevalence of type 2 diabetes than those in the USA as a whole (10.4% vs 10.5%, respectively). Rather, the gaps are eliminated because white Americans in these low-resource settings have a *significantly higher* prevalence of type 2 diabetes than white Americans in the USA as a whole (10.1% vs 6.6%, respectively) [84]. The implications are twofold. First, low-resource urban settings are associated with elevated type 2 diabetes risk in a similar manner for both African Americans and white Americans; and secondly, the

findings suggest that the overall prevalence of type 2 diabetes is higher among African Americans relative to white Americans because, at least in part, they are far more likely to live in such low-resource settings [74, 75].

How political and social systems narrow options for individual choice

The practice of redlining, and the social structures that supported such acts of racism, serve to minimize options and promote suboptimal choices for African Americans. The relationship between inequitable resources and access to care has been repeatedly linked to negative health outcomes in African American communities [87–90], including the devastating effects of Covid-19 [91]. Food systems, in particular, have adverse effects on type 2 diabetes disparities [92, 93]. African Americans have higher rates of morbidity and mortality for several chronic conditions that are linked to health behaviours, including type 2 diabetes (Figure 67.2). The role of social structures in these disparities is a function of the intersection of race and place [94, 95]. African Americans are more likely to reside and work in settings characterized by an imbalanced ratio of positive to negative coping resources [80, 81, 96, 97]. These contexts cannot provide the social or material support needed to address chronic stressors (i.e. financial insecurity) and broader uncontrollability and unpredictability in daily life. These conditions are inextricably affected by social inequities in the distribution of power, wealth, and resources [18].

While it is tempting to understand the case of racial disparities in type 2 diabetes as solely a function of socioeconomic resources, empirical studies indicate otherwise. While poverty contributes and exacerbates type 2 diabetes risk among African Americans [16], better socioeconomic status does not eliminate racial disparities in type 2 diabetes or related conditions. Instead, somewhat paradoxically, other systematic inequities diminish the expected returns of gains in socioeconomic status for a range of health outcomes. For example, gains in household income translate into smaller improvements in health for African Americans compared to non-Hispanic white Americans [98]. Consistent with this notion, while higher levels of education are associated with better self-rated health for all racial and ethnic groups, these gains are smaller for African Americans compared to white Americans. The inverse association between income and poor health, particularly obesity, is generally diminished in Black Americans relative to white Americans [99]. Within the African American population, numerous studies report that socioeconomic status is positively associated with depression, a contrast with the inverse or null relationship observed in other groups; this reflects, in part, different experiences of racial discrimination, particularly in the workplace [100, 101]. Additionally, even affluent African American neighbourhoods generally fall short of residential parity when compared to white American neighbourhoods of similar socioeconomic status [102].

These diminished returns are attributed to a myriad of social, political, and economic factors associated with Black race, such as experiences of discrimination, neighbourhood segregation, depreciated value of educational attainment as it relates to employment opportunities, pay inequity, and experiences in the healthcare system [45].

Understanding within-group variability to enhance the tailoring of prevention efforts

Although many social determinants of health are correlated with Black race in the USA, the heterogeneity within the African American population is understudied [98]. For example, there is

little research examining the relationship between middle-class African Americans and their type 2 diabetes knowledge, risk behaviours, and protective factors [103]. The African American middle class comprises individuals who are frequently still connected to, or recently removed from, impoverished roots [104]. Additionally, this population is not far removed from a history of segregation and discriminatory practices [84, 105–107], which has a present-day impact on learned health behaviours and the built environment it inhabits.

As another example, despite robust experimental evidence of effectiveness, standard diabetes-prevention interventions have suboptimal results among African American women [108]. These results have been attributed, broadly, to a lack of cultural relevance in these interventions [109]. Even evidence-based, largely successful programmes like the Diabetes Prevention Program (DPP) have had difficulty successfully motivating behaviour change in African American women [110]. Moreover, using the DPP's standard design, the programme has been largely unsuccessful in promoting weight loss in this group [111, 112]. Two out of every three African American women have significantly less mean weight loss than their white American counterparts while participating in DPP programmes [112]. These disappointing outcomes point to the importance of prior research describing the unique social and environmental factors that influence weight gain and/or deter weight loss in this population [113–115].

There is a need for additional efficacy trials of the DPP that acknowledge the unique context of African American women living in urban environments to ensure reliability and effectiveness in this high-risk population. Unfortunately, there are critical gaps in the literature responding to how these factors perpetuate type 2 diabetes disparities in African American women. This group experiences intersecting social stressors related to their race and gender that influence health behaviour outcomes. The outside forces and lost locus of control associated with systemic social stressors (e.g. racism, sexism) are qualitatively unique in their effects on the body. Additionally, inequalities (e.g. food quality, green spaces) in the built environments where African American women work and live also influence options and choices around health behaviour maintenance. Successful intervention design for racial minority communities must consider how these unique stressors influence health behaviours. DPP adaptations have been more effective with African American women when specifically tailored for this population [114–116]. These adaptations, however, are limited in number and setting variability.

Relationship between social determinants of health and diabetes healthcare

Best-practice guidance on addressing the social determinants of diabetes care has been presented in a rather straightforward manner [43]. However, the challenge for healthcare providers is more complex. Is it more important to examine the options available to individuals with diabetes in order to make more actionable recommendations, which will take more time than most busy clinicians have? Or is it more important to treat the issue presenting in the clinic room, which will foreshorten an exploration of social determinants? The answer is often a difficult one given that the former typically requires collaborative care that involves stakeholders outside the healthcare system (e.g. governmental social services, community health workers, community-based organizations, mental health professionals) and critical components of such collaborative care are not reimbursable by some insurances [117]. Despite ongoing challenges

regarding the implementation of collaborative care in some medical systems, evidence shows that this model can be a valuable asset in addressing the social determinants of health, including in addressing the quality of individuals' options and choices with regard to diabetes management [18].

The choices providers make when treating people who have significant challenges in the complex web of social determinants undoubtedly have impacts on the options those individuals have for self-management of conditions like type 2 diabetes. Providers could be missing valuable opportunities to explore treatment options that would enable more personalized choices for individuals with type 2 diabetes [117–119]. For example, obesity and inactivity are common targets of diabetes care [120]. Several environmental factors intersect with established solutions for addressing obesity and physical inactivity, including the walkability of a person's neighbourhood, access to quality food options in sustainable quantities, decreased housing instability, and education beyond a high school diploma that assists with generating income above the national poverty line [12, 67, 120–122].

Unfortunately, while healthcare systems are increasingly assessing and quantifying the social environments of the individuals they serve with a given disease, the burden of addressing these contextual barriers as they relate to health and diabetes care remains on the shoulders of the individual with diabetes [123]. There are other approaches that could be taken. For example, while they are an ongoing topic of scientific debate [124], there is suggestive evidence that interventions that address food environments and improve infrastructure for physical activity can influence these types of risk behaviours [125]. Addressing the quality of food sold in neighbourhoods and infrastructure that enables physical activity would be meso-level interventions that could substantively improve the options for people that enable healthier, sustained choices.

The complex, systemic barriers to type 2 diabetes treatment warrant revisiting collaborative care as a potential solution for improved diabetes care. As an example, consider the integration of community health workers into a diabetes treatment team. Their inclusion improves diabetes self-management and overall quality of life, and reduces emergency room usage and visit attendance [126–128]. In most cases, community health workers also have many social determinants of health in common with their patients with a given disease (e.g. racial or economic background, cultural norms), which enables trust building and rapport outside of visits with other medical or non-medical providers [127, 129]. A growing body of research [130] has demonstrated that the integration of community health workers into healthcare teams improves diabetes outcomes [127]. This provision of collaborative care with a person-centred approach increases the likelihood that the individual needs, preferences, and values of a person with diabetes are met within a larger systemic context [131].

Conclusion

As part of its 2017 report *Health in All Policies* [132], the WHO stated: 'Health is a political choice. Political decisions can impact on economic and social inequities, including through policies which shape unhealthy living and working environments, or which fail to address inequities of gender, race, and ethnicity'. Social determinants of health are not simply unfortunate circumstances that make it difficult to prevent or manage type 2 diabetes. Rather, they are systematic and reinforcing structures that have long-standing,

intergenerational impacts on type 2 diabetes risk. We observe that obesity, diabetes, and hypertension are more common and more severe among First Nations or African Americans, but that observation is simply a symptom of these systemic factors that drive racial inequities, including in health.

Although clinical trials such as the DPP [133, 134] and similar efforts have demonstrated that lifestyle interventions can reduce the incidence of type 2 diabetes among individuals at high risk, effectively translating such multicomponent, sustained programmes into areas and communities disproportionately affected by type 2 diabetes remains a major challenge for public health [135, 136]. Social determinants of health are an important component of this translation gap. Efforts to tailor the DPP and similar health behaviour programmes will likely continue to have only modest effectiveness, because these tailoring efforts often only affect the choices individuals make (e.g. choosing a healthy option for a meal), not the options they have to choose from (e.g. the availability of affordable, healthy food in their local grocery store) [15, 16, 97, 137, 138].

Social determinants of health systematically shape the *options* individuals have for engaging in type 2 diabetes prevention behaviours, and therefore have direct impacts on the *choices* that individuals make. In Figure 67.3, we revisit and adapt Bronfenbrenner's model to incorporate system-level considerations from the case examples laid out in this text, highlight potential consequences, and then sample considerations that healthcare systems and/or providers can implement to improve the individual's options and subsequent choices related to type 2 diabetes care [139].

Reconsidering the role of individual-level factors in the type 2 diabetes epidemic

Recall that this chapter began with the statement that type 2 diabetes is a multifactorial disease. We close with a thought experiment drawing on Rose's seminal work 'Sick individuals, sick populations' [140]. Imagine two nations. Nation A has a policy that every adult must smoke two packs of cigarettes a day, which is enforced with 100% fidelity; Nation B has access to tobacco but no such policy, and there only 20% of adults smoke. What will be true about the incidence of diseases like lung cancer, which are strongly associated with tobacco use but have a multifactorial aetiology [141], when comparing these two nations? Clearly, the rates of lung cancer will be much higher in Nation A compared to Nation B. What will be true about the association between tobacco use and risk of cancer in Nation A? Because 100% of the population smokes, there is no individual variation in the exposure, and thus there will be no relationship between tobacco use and likelihood of cancer in Nation A. Instead, as this is a multifactorial disease, the primary factors that influence risk of lung cancer in Nation A will be those that *do vary* between individuals, including genetic liability. In contrast, because there is individual variation in smoking in Nation B, tobacco use will substantially influence risk of disease in this context. Even though a macro-level factor (e.g. a policy that mandates tobacco use) is the reason Nation A has higher rates of lung cancer than Nation B, it will be an individual-level factor (e.g. genetics) that explains why any one individual in Nation A becomes sick. Nation A will see lung cancer as a disease driven by genetic liability; Nation B will see lung cancer as a disease driven by behaviour. They will both be correct, from their perspective. But the following is also true: the fundamental reason why there are more sick individuals in Nation A compared to Nation B is because of policy.

The parallel to type 2 diabetes is as follows. Historically and continuing to the present day, racial and ethnic minority groups have

Systemic level	SDOH	Individual result	Impact on options	Example action	Impact on choices
Macro	Colonial oppression	Chronic stress	Disparities in healthcare access for communities of colour	Increased healthcare funding to traditionally underserved communities	More equitable options for care
Macro	Systemic racism	Cardiovascular weathering	Limitation of options for residence, healthcare options, and provision of recommendations	Challenge inherent systems to ensure that SDOH that are made worse by race/ethnicity are addressed from the top down	Increased number of providers that can make appropriate recommendations for diabetes and comorbidities
Macro	Socioeconomic status	Restricted access and ability to pay for DPPs	Lack of exposure to evidence-based treatment	Improve accessibility of health promotion mediums (mobile treatment units, satellite clinics in relevant neighbourhoods)	Improved access to universal standards of care
Meso	Neighbourhood walkability and safety	Lack of inherent physical activity, potential safety concerns	Removal of options for active physical activity, income generation within neighbourhood	Collaborate with patient on determining feasible recommendations that support other areas of diabetes management and/or passive physical activity	Increased number of choices within accessible environment
Meso	Food insecurity	Dependence on cheaper, processed foods	Limits healthy food options in neighbourhoods	Partner with farmer's markets to generate reoccurring food delivery programmes for diabetes patients	Increased availability of fresh foods, whole foods, and non-processed foods.
Meso	Lack of grocery store access	Food deserts or swamps	Food insecurity	Food delivery/gift cards/vouchers from grocery stores that deliver	Allows patients to choose from healthier options
Micro	Lack of adherence or access to health behaviours promotion (physical activity, nutrition)	Elevated HbA1c, blood pressure, and other comorbidities	Restricted to medication as first line of treatment, which introduces medication adherence as another potentially difficult health behaviour to adhere to	Community-based participatory-based health behaviour interventions	Allows health systems and communities to collaborate and simultaneously support relevant choices that fit within system restraints
Micro	Genetic predisposition in systemically strained environment	Generational comorbidities	Limited options for parents limits options for children, perpetuates cycle of access issues	Ensure access to health behaviour coaching, family psychotherapy, and family education	New ideas for health promotion strategies, improved perception and navigation of barriers
Micro	Obesity	Increased risk of comorbid diagnoses	Tiered approach to care which may limit what patient can feasibly adhere to	Implementation of collaborative or stepped care model	Increases access to weight maintenance care points within current care

Figure 67.3 Links and applications between macro, meso, and micro levels as they relate to the development and management of type 2 diabetes. DPP, Diabetes Prevention Program; HbA_{1c}, glycated haemoglobin; SDOH, social determinants of health.

been subjected to policies and systems that have limited their resources and associated options for engaging in diabetes-preventive behaviours. Simultaneously, these groups have been exposed to readily available and accessible options for engaging in diabetes risk behaviours. Because of the reserve system and residential segregation, Indigenous people and African Americans, on average, live and work in environmental and social contexts that majority white American populations rarely encounter [142]. These contextual factors shape the risk of type 2 diabetes.

While colonialism is a historical idea, its relevance to social inequities in type 2 diabetes is observed today because of the correlation between race and the concentration of (dis)advantage across generations. While the biological mechanisms explaining these persistent effects are continuing to be identified [143–145], including ideas related to epigenetics and the *thrifty genotype* [146, 147], as the previous thought experiment illustrates the salience of any risk factor for a multifactorial disease is a function of the other risk factors in place. The relative availability of individual-level risk and protective factors is shaped by social determinants of health, and addressing the latter has more potential to shift population health as a whole, and to address health inequities, than addressing individual behaviour change [6, 18, 148].

Postscript

Just as we have intentionally used the term colonialism in this chapter, we have also intentionally used the term *health inequities*. It is critically important to recognize that *not all group differences in health are inequities*. The US Government defines health disparities as a particular type of health differences that are ‘closely linked with economic, social or environmental disadvantage’ [118, 149]. Braveman extends this to say that ‘health equity is the principle underlying a commitment to reduce – and, ultimately, eliminate – disparities in health and in its determinants, including social determinants’ [149]. Therefore, our choice of describing the type 2 diabetes epidemic in First Nations and African Americans as stemming from *inequities* illustrates our commitment to this principle.

11 Diabetes in Special Groups

68

Ethnic, Cultural, and Religious Aspects to the Management of Diabetes

Wasim Hanif¹, Sarah N. Ali², and Vinod Patel^{3,4}

¹ University Hospitals Birmingham NHS Foundation Trust, Birmingham, UK

² Department of Diabetes and Endocrinology, Royal Free London NHS Foundation Trust, London, UK

³ Warwick Medical School, University of Warwick, Coventry, UK

⁴ Acute Medicine, Medical Obstetrics, Diabetes and Endocrinology Centre, George Eliot Hospital NHS Trust, Nuneaton, UK

Key points

- People from ethnic minority groups, such as those of Black and South Asian ethnicity, are at higher risk of chronic diseases, including type 2 diabetes.
- Compared to white Europeans, South Asian people with type 2 diabetes are also at greater risk of developing diabetes-related complications.
- Furthermore, ethnic minority populations are subject to health inequalities.
- It is important to distinguish between ethnicity and race, as they are separate entities. Race refers to the biological make-up of a person, whereas ethnicity encompasses a complex interaction of factors including cultural and religious behaviours, which can have additional impacts on health and illness.
- To understand the impact of ethnicity on diabetes, its management, and health inequalities, one must consider cultural factors including patterns of migration, diet and lifestyle, socioeconomic status, religious beliefs,

language barriers, access to health services, and attitudes to medical treatment.

- This chapter explores the ethnic, cultural, and religious aspects to the management of diabetes, with the aim of improving cultural sensitivity and cultural competence.
- Greater cultural competence will allow for healthcare systems that provide care to people with diverse values, beliefs, and behaviours, with the aim of reducing health inequalities.
- Specific cultural considerations when thinking about the management of diabetes include dietary habits, physical activity, structured education, fasting, and pilgrimage.
- Ethnic minority groups remain under-represented in research studies, which hinders the development of tailored guidelines for these populations. It is of the utmost importance that the barriers to participation and retention of ethnic minority populations in research are addressed.

Recent global political and medical events have reignited discussions about race, ethnicity, and socioeconomic and health disparities; once again, the correct terminology with which to address ethnic minority groups has been challenged and scrutinized. Even before the disproportionate impact of Covid-19 on ethnic minority groups, we appreciated that people of Black and South Asian ethnicity are at higher risk of chronic diseases such as type 2 diabetes and cardiovascular disease compared to white Europeans. If we are to attempt to reduce health inequalities, including for people with diabetes, it is essential that we begin by considering the differences between race, ethnicity, and religion, and understand their relevance for health.

In this chapter we will discuss the definitions of race and ethnicity, and how ethnicity is relevant to diabetes. We consider in particular the impact of South Asian ethnicity on diabetes, as this has been documented most extensively of the ethnic minority groups; however, the general principles apply to other ethnic minority groups too.

Defining race, ethnicity, and religion

Race, ethnicity, and even religion may be of significance to the health of the person with diabetes and their diabetes management; however, the impact of this will only be appreciated if the healthcare professional and healthcare systems have an awareness of the specific definitions of race, ethnicity, and religion and the influence they have on one's life and health beliefs. Race, ethnicity, and religion are distinct from one another and each individually may have a bearing on a person's diabetes management and care.

Race is often used interchangeably with ethnicity; however, they have different nuances [1, 2].

Race refers to the biological make-up of a distinct population distinguishable from others by genetic or morphological characteristic differences [1–5]. By this definition, the world population can be divided into four major races: African (Black African), Caucasian (White, Middle Eastern, South Asian), Mongoloid (Sino-Asian

including Chinese, Japanese, Korean, Native American), and Australoid (Dravidian, Australian Aboriginal) [6].

Ethnicity, however, refers to the grouping of people by shared cultural characteristics influenced by heritage, language, history, religion, nationality, customs, and geographical and ancestral origins [1, 2].

Religion refers to the belief and worship of a sacred power, usually a deity (deities) [7]. The major recognized religions (ordered based on the approximate number of adherents) are Christianity (2.2 billion), Islam (1.6 billion), Hinduism (1.0 billion), Buddhism (490 million), Shintoism (104 million), Sikhism (30 million), Judaism (14 million), and Taoism (12 million). Other important religions include Confucianism, the Baha'i faith, Jainism, and Zoroastrianism. The numbers of atheists (and those who are secular, non-religious, or agnostic) is 1.13 billion [8, 9].

Khunti et al. make the cogent point, especially in the time of the Covid-19 pandemic, that using the definition of race to address inequalities is flawed, as it indiscriminately combines people from different geographical, behavioural, social, and cultural backgrounds, as well as focuses on skin colour [10]. The redundancy of using race is apparent from the fact that in the UK the morbidity and mortality attached to Covid-19 were greater in the Black Caribbean population than the Black African population. Defining people by skin colour does not allow for an appreciation of this heterogeneity and the cultural, social, and religious nuances that define ethnicity [11].

As such, the UK Office of National Statistics (ONS) categories, while still limited, are a good start to defining the population in groups [12]. The five ethnic groups are summarized in Table 68.1.

The UK South Asian Health Foundation (SAHF) released a statement defining ethnicity or culture as a complex interaction of a multitude of factors, giving people an ethnic belonging, which subsequently has an impact on lifestyle, health beliefs, and attitudes to illness, especially long-term conditions [13]. To understand the impact of ethnicity on diabetes and its management, one must look at these cultural factors, including patterns of migration, diet, physical activity, tobacco use, socioeconomic status, religious beliefs, language barriers, access to health services, and attitudes to medical treatment.

Table 68.1 Defining the population by five ethnic groups (Office for National Statistics categories).

White	English/Welsh/Scottish/Northern Irish/British Irish Gypsy or Irish Traveller Any other white background
Mixed or multiple ethnic groups	White and Black Caribbean White and Black African White and Asian Any other mixed/multiple ethnic background
Asian or Asian British	Indian Pakistani Bangladeshi Chinese Any other Asian background
Black, African, Caribbean, or Black British	African Caribbean Any other Black/African/Caribbean background
Other ethnic group	Arab Any other ethnic group

Epidemiology

The International Diabetes Federation (IDF) has published high-quality epidemiological data on diabetes collated from national and international databases. The figures are alarming, in 2021, it was estimated that 537 million people had diabetes, and this number is projected to reach 643 million by 2030, and 783 million by 2045. If diabetes was a country, it would be the third most populous, more than the USA with a population of 331 million, with only China and India having a larger population [14]. Currently, 1 in 8 adults in North America and the Middle East and North Africa has diabetes, but this figure is only 1 in 25 in Africa (Figure 68.1). An increase is predicted in all seven IDF regions [14].

From the epidemiology, we can appreciate that people with diabetes will have originated from different prevalence regions. This is significant for migrant ethnic minority groups; in addition to carrying the risk of their country of origin, migrants will also share the risk factors associated with the new environment to which they have migrated. The England and Wales Census data in 2021 recorded that 81.7% of the population were white British, Asian (Pakistani, Indian, Bangladeshi, other Asian British, Asian Welsh) groups constituted 9.3% of the population, Black groups 4.0%, Chinese groups 0.7%, Mixed groups 2.9%, Arab groups 0.6%, and other groups 1.6% [15].

South Asian diaspora

The South Asian diaspora constitutes nearly 1.6 billion people and is considerably heterogeneous, with distinct communities from Afghanistan, Bangladesh, Bhutan, India, Maldives, Nepal, Pakistan, and Sri Lanka [13]. Thinking specifically of the UK, the very first South Asian migrants to the UK were probably the lascars (sailors and militiamen) of the East India Company, which began trading with India in 1608. However, for over 150 years significantly larger South Asian migrant communities have been present [16]. The ONS (2020) estimates that approximately 1.7 million people born in the main South Asian countries were then resident in the UK. However, the 2011 Census data identified those of South Asian ethnicity as a much higher proportion of the UK population (Table 68.2) [17].

Religion

Globally, the fastest-growing religion at present is Islam. From the 2015 data to projections to 2060, it is estimated that the global Christian population will change very little from 31.2% to 31.8%; however, the Muslim population will grow from 24.1% to 31.1%, with the Hindu population remaining stable (15.1% to 14.5%). A

Table 68.2 The South Asian diaspora in the UK.

Country of origin	UK Office for National Statistics (2020)	Census data (2011) Numbers (% of UK population)
Bangladesh	244 000	451 529 (0.7%)
India	792 000	1 451 862 (2.3%)
Nepal	66 000	
Pakistan	519 000	1 174 983 (1.9%)
Sri Lanka	103 000

significant decrease in the Buddhist population from 6.9% to 4.5% is estimated. The Muslim population is expected to grow twice as fast as the overall global population in absolute number in all regions of the world between 2010 and 2050. Worldwide, its number is projected to increase rapidly in the upcoming decades, rising from nearly 1.6 billion in 2010 to approximately 2.8 billion in 2050 [18, 19]. Of the population of England and Wales, 46.2% identified as Christian in the 2021 Census (Table 68.3). The second largest religious group was Muslims, 6.5% of the population [15].

Diabetes

Approximately 537 million people were living with diabetes worldwide in 2021, and this number will rise to 643 million by 2030, and 783 million by 2045 [14]. In the UK, 4.8 million people live with diabetes and this is anticipated to rise to 5.5 million people by 2030 [20]. The Asia-Pacific region will see the greatest numerical increase in people with diabetes. The prevalence of diabetes in the

adult Arab population rose from 2.4% to 25.4% between 1982 and 2015. By 2035, the number of people with diabetes in the Middle Eastern region is projected to rise by 96.2% [21].

People of Black and South Asian ethnicity are at a higher risk of developing type 2 diabetes compared to white Europeans [22]. The CARDiovascular disease research using LInked Bespoke studies and Electronic health Records (CALIBER) programme reviewed extracted data from 1.9 million individuals and showed that people with type 2 diabetes were twice as likely to be of either Black or South Asian origin compared to those without diabetes [23]. Furthermore, a higher prevalence of diabetes was revealed in the UK-based NHS Health Check Programme among South Asian men (9.0% vs 3.9%; $p = 0.001$) and women (7.4% vs 3.3%; $p = 0.001$) compared to their white European counterparts [24]. A more recent large-cohort population-based study confirmed that people within the South Asian community were at higher risk of developing type 2 diabetes and that those in the Bangladeshi community were at greatest risk [25].

It is important to appreciate that within ethnic categories, there is significant heterogeneity that has impacts on health risk. A meta-analysis exemplifies this point: within the European South Asian community there are differences in the risk of type 2 diabetes; Bangladeshis have the highest odds ratio (OR) for type 2 diabetes (6.2; 95% confidence interval [CI] 3.9 to 9.8), followed by Pakistanis (OR 5.4; 95% CI 3.2 to 9.3) and Indians (OR 4.1; 95% CI 3.0 to 5.7), compared to white Europeans [26].

Type 2 diabetes in ethnic minority groups appears to develop at a younger age, with a greater risk of early onset (age <40 years) in South Asians compared to white Europeans. Scottish data showed that type 2 diabetes was up to six times more common in South Asians, particularly from the age of 25 years, rather than at 40 years as seen in white Europeans [27].

Another concern in ethnic minority groups is both the late diagnosis of diabetes as well as higher glycated haemoglobin (HbA_1c). South Asians are more likely to have undiagnosed diabetes, and among people with known diabetes, Pakistanis, Indians, and Bangladeshis more commonly exhibited higher glycaemic levels [28].

This increased risk of type 2 diabetes in ethnic minority communities is significant, as religious and other ethnic cultural practices, such as fasting and pilgrimages, can also affect diabetes management, as discussed later.

Diabetes-related outcomes in South Asian people

Overall compared to white Europeans, South Asian people with type 2 diabetes are at greater risk of developing complications, for several reasons that include genetic predisposition, early onset of diabetes, delayed diagnosis, higher glucose levels, and a higher likelihood of treatment omission or inadequate dosing [29].

Macrovascular complications

The UK Asian Diabetes Study (UKADS) has shown that South Asians have an increased risk of cardiovascular events compared to white Europeans (adjusted OR 1.4; 95% CI 0.9 to 2.2), confirmed in other studies looking at coronary artery disease in South Asians with diabetes [30–32]. Furthermore, Scottish data demonstrated that Pakistani ethnicity was an independent risk factor for cardiovascular disease in those with type 2 diabetes (hazard ratio [HR] 1.45; 95% CI 1.14 to 1.85; $p = 0.002$) [33].

The West Birmingham Stroke Project findings in South Asian people with ischaemic stroke suggest that diabetes is an independent predictor of five-year mortality (OR 1.65; $p = 0.039$) [34]. A higher incidence of stroke was also recorded in South Asians with diabetes in the Southall and Brent Revisited (SABRE) study (HR 1.97; $p = 0.038$) compared with white Europeans [35].

However, utilization of culturally appropriate prevention and management strategies over the last two decades has led to an appreciable and significant reduction in the cardiovascular mortality risk in migrant South Asians [29].

Microvascular complications

There are also differences in microvascular complications between South Asians and white Europeans. Diabetic nephropathy is more common in South Asians: a meta-analysis showed a pooled prevalence ratio of 1.14 (95% CI 0.99 to 1.32; $p = 0.065$) for microalbuminuria in South Asians compared to white Europeans, and 1.08 (95% CI 0.93 to 1.24; $p = 0.327$) compared to African Caribbean people. Furthermore, chronic kidney disease progression was higher in South Asians compared to white Europeans [36].

Sight-threatening diabetic retinopathy is more prevalent in the South Asian community, but is also more likely to occur at a younger age compared to their white European counterparts [29].

In order to reduce the higher incidence of micro- and macrovascular risk in ethnic minority groups, several initiatives are needed, including earlier diagnosis of diabetes, more aggressive and sustained management of glycaemia, earlier more aggressive blood pressure management, tailored guidelines for management, as well as improved recruitment and retention of ethnic minority people in medical research.

Cultural sensitivity and cultural competence

Spirituality, personal beliefs, and religiosity can affect individuals' health and treatment behaviours positively or negatively. There are several sociocultural and religious issues specific to South Asian communities that focus on the need for individualization of care for people with diabetes.

Cultural sensitivity is the awareness and acceptance that different cultures exist; however, having this cultural knowledge is not enough on its own, as cultural sensitivity in healthcare can be construed as being patronizing and not accommodating. To improve healthcare outcomes for culturally different groups, healthcare systems and professionals need to go one step further and become *culturally competent*. This is defined as 'the ability of systems to provide care to persons with diverse values, beliefs, and behaviours including tailoring delivery to meet individuals' social, cultural and linguistic needs' (Table 68.4) [37].

Table 68.4 The difference between cultural sensitivity and cultural competence, and its impact on healthcare systems.

Cultural sensitivity	Cultural competence
Passive	Active
Patronizing	Understanding
Accommodating	Challenging
Behavioural reinforcing	Behavioural changing
No training	Requires training and knowledge

Cultural competence is a broad principle that allows us to encompass ethnicity, religion, and culture in optimizing diabetes care. It is about respecting and appreciating the cultural contexts of the life of the individual, family, carers, and community, creating an understanding about the way we deliver healthcare and then responding to the needs of our diverse population by changing practices and creating individualized or tailored pathways and guidelines for those communities [29, 37].

Cultural competence is a key aspect of providing both high-quality and safe care. If clinical care is commissioned but not accessed by the community, then an issue related to cultural competence may be present. We should ask ourselves, 'Why does one community receive and accept care while another did not?' Making effective and evidence-based care accessible will also serve to reduce health inequalities and improve outcomes in diabetes care [29, 37].

Taboos and barriers

One challenge of managing ethnically diverse communities is addressing the taboos and barriers that impede the delivery of equitable healthcare (Table 68.5). Some of these barriers are based on the communities' previous experiences, which can be described as *legacy memory*, whether that be in their country of origin or as a result of migration to the new country of residence. Another concept, fatalism, is often used as an adaptive coping mechanism for several South Asian communities. This can be expressed as *karma* or *the will of Allah* (God). While on the surface of it fatalism appears to be a religious construct, it is not. Fatalism is a coping mechanism for death, which was a part of these communities in the developing world when there was an inability to change outcomes with interventions. The best way to address fatalism is through empowerment, by giving people the necessary knowledge such that their course of action (be it lifestyle or medication taking) can change the outcomes.

Similarly, there are other taboos, such as the restrictive use of animal-derived or alcohol-based ingredients in medicinal products or restrictions due to religious practices, including fasting, which can affect disease management. These religious and cultural beliefs should be respected, discussed, and alternative options provided where possible.

Several taboos are based on mis- and disinformation, often spread by hearsay or unregulated dissemination via social media. Despite the challenge, the disinformation must be counteracted and corrected by authoritative sources.

Table 68.5 Barriers to healthcare for ethnic minority communities.

Perception of risk
Fatalism – 'karma' or 'will of Allah'
Low confidence in the healthcare system
Distrust in healthcare professionals/healthcare system
Access barriers including language and literacy
Inconvenience
Sociodemographic context
Religious and cultural restrictions with diet, e.g. animal/alcohol-based products in medicine, fasting
Lack of communication and lack of endorsement from trusted providers and community leaders – 'familiar faces' of the community with whom people can relate
Unregulated media relaying dis- and misinformation: Indian subcontinent has some of the highest users of social media-based messaging services

Overcoming most taboos and barriers is possible by providing correct information from culturally competent healthcare professionals, in multilingual, non-stigmatizing communication in different formats (including videos, infographics, as well as written information), and with the use of community and faith champions (faces with whom people from the community can identify).

The recent Covid-19 vaccination programme initiative by NHS England, SAHF, and other organizations is a good case study where low vaccination uptake in the ethnic minority communities was turned around through positive messaging and correct information [38, 39].

The impact of ethnicity and health inequalities

Health inequalities are differences in the status of people's health, the healthcare that people receive, and the opportunities they have to lead healthy lives [40, 41]. Health inequalities can therefore cause differences in health status (e.g. life expectancy, prevalence of medical conditions), access to healthcare and treatment, the quality and experience of care (e.g. as measured by patient-reported outcome), behavioural risks to health (e.g. cervical cancer screening, smoking rates), and wider determinants of health (e.g. quality of housing) [41].

Differences in health status that lead to health inequalities can be grossly determined by four factors: socioeconomic factors (including income), geography (region as well as urban or rural), specific characteristics including those protected in law (e.g. gender, disability, and ethnicity), and socially excluded groups (e.g. people experiencing homelessness) [40]. People who experience different combinations of these factors will have varying implications for health inequalities depending on how the factors interact.

In the UK, there are health inequalities between minority ethnic minority groups and white British groups, but also between different ethnic groups and within them; the current terminology of ethnic groups does not take into consideration the heterogeneity within these groups. Access to primary care is generally equitable, but less so for other health services. People from ethnic minority backgrounds are more likely to report having poorer health and have poorer experiences of using health services compared to their white British counterparts.

The picture of health inequalities affecting different ethnic groups is complex across different conditions and is limited by a lack of good-quality data. For example, people from Bangladesh and Pakistan have the poorest outcomes across a range of indicators, together with those from Gypsy or Irish Traveller communities. Diabetes prevalence is higher among Black and South Asian groups, as is cardiovascular disease, with diabetes causing significant morbidity among these communities through diabetes complications. By contrast, the incidence of cancer is highest in the white British population [22–25, 29–36, 41].

What has the Covid-19 pandemic taught us in relation to ethnic minority groups?

These long-standing health disparities affecting ethnic minorities in the UK have been made acutely visible by the Covid-19 pandemic. Intensive Care National Audit and Research Centre figures from 1 September 2020 to 25 March 2021 showed that 24781 individuals

were admitted to intensive care with Covid-19, of whom 72% were white, 16% Asian, 5% Black, and 5% from other ethnic groups [42]. This is markedly different from 2011 census ward data (white 79.8%, Asian 11.2%, Black 5.0%, other 1.4%) [42]. Black and Asian individuals with diabetes in the UK were over-represented among those with Covid-19 receiving advanced respiratory support [42]. Public Health England later highlighted that deaths from Covid-19 among people from ethnic minority groups were 2–4 times higher than those among white counterparts [43, 44]. Disparities for some improved during the second wave. An analysis of a population-level ONS dataset reported that Black ethnic groups saw no increased risk of death from Covid-19 compared to white populations, but for South Asians the risk of poor Covid-19 outcomes was exacerbated [45].

Several reasons for these ethnic differences have been considered, including a higher prevalence of comorbidities associated with poor Covid-19 outcomes (e.g. type 2 diabetes among British South Asians, obesity), greater social deprivation, large multigenerational households, differences in occupational risk, and delayed access to healthcare, which all disproportionately affect ethnic minority groups [46]. SAHF summarizes these potential factors causing disparities in its Covid-19 and ethnic minority population report (Figure 68.2) [47].

Unpicking the causes of ethnic inequalities in Covid-19 outcomes, but also extending these to other health conditions including long-term non-communicable diseases such as diabetes, is difficult. Current evidence suggests it will be a complex interplay of factors that can be broadly categorized into structural (e.g. multigenerational housing, low income, working in healthcare or key worker roles, etc.) and biological (i.e. increased prevalence of long-term conditions) reasons. These potential explanations must be considered in the context of the wider determinants of health, including structural discrimination and racism [47].

Structural racism can reinforce inequalities among ethnic groups, for example in housing, employment, and the criminal justice system, which in turn can have a negative impact on health. Racism and discrimination can also have a negative impact on the physical and mental health of people from ethnic minority groups [41, 47].

The pandemic has overwhelmingly highlighted health inequalities and the urgent need for action to prevent and manage ill health in ethnic minority communities; this will include cross-government and health system strategies and policies for reducing health inequalities, and initiatives to tackle wider socioeconomic and structural inequalities that drive them [47].

The relationship between culture, discrimination, and impact on diabetes care

There is a large body of literature highlighting the link between reported racism and health and well-being. This is particularly striking when it comes to the health of children and young people [48–50]. A 2019–2020 audit reported that Black and South Asian children have higher HbA_{1c} and are significantly less likely to use diabetes technology such as insulin pumps and continuous glucose monitoring than White children [51]. In another survey of over 21 000 people with diabetes, those of South Asian origin had higher HbA_{1c} and higher blood pressure compared to the majority

population [52]. Furthermore, despite glycaemic management being compromised, South Asians were less likely to use insulin (4.7% vs 7.1%) [52]. Another review also concluded an increase in mortality, end-stage complications, and poorer quality of care for people with diabetes [52]. Following adjustment for confounders such as smoking rates, socioeconomic status, household income, years of education, and body mass index (BMI), most of the ethnic differences became non-significant. However, in Black and Hispanic Americans and UK Asians, an increased risk of end-stage renal disease was still seen. Additionally, Black and Hispanic Americans had an increased risk of retinopathy. Specific health disparities arising from the provision of healthcare to those of a specific religion (such as people with diabetes and Muslim background) are widespread [53].

The necessity to address these concerns in relation to diabetes was well articulated in the Transcultural Diabetes Care in the US statement from the American Association of Clinical Endocrinologists [50]. Its models of diabetes care started from a consideration of diabetes risk factors for complications and led to the creation of models of care for each of the main ethnic groups reviewed: African Americans, Latinos, Asian Americans, and Native Americans. The main focus was on addressing important differences among the ethnic and cultural backgrounds of each individual [50]. There is a pressing need for this approach to be adopted to the needs of a people with diabetes, as data clearly show poorer outcomes in certain ethnic groups.

Specific cultural considerations when considering diabetes management

Dietary habits

Food has a deep cultural impact and plays a significant social role in sustaining tradition and social relationships. Therefore, altering diet in migrant communities can be challenging. Moreover, barriers to change may prevent the adoption of dietary advice by healthcare workers; if healthcare professionals are not culturally competent, their advice to avoid certain traditional foods can be perceived as dismissive of the South Asian diet [29]. There are only a few dietary intervention trials among South Asians, and key results suggest enhancing carbohydrate and fat quality in diet plans, with particular increase in protein intake to improve serum insulin, blood glucose, inflammatory markers, hepatic fat, and lipids [54].

Exercise and physical activity

There are no ethnicity-specific recommendations for exercise; however, South Asians have lower levels of physical activity relative to other populations [55, 56]. Studies comparing metabolic effects of exercise in South Asian and white European cohorts have shown differences: South Asian adults need to undertake nearly 232 minutes of moderate physical activity per week compared to 150 minutes for white Europeans to acquire similar benefits [55]. Barriers to physical activity in South Asians include lack of time outside long working hours, fear of racial harassment or abuse while exercising, expectations to remain at home, carer commitments, fear for personal safety, lack of same-gender venues, and concerns over the acceptability of wearing Western exercise clothing for women. However, attitudes to exercise in South Asians appear to be changing, albeit slowly [56].

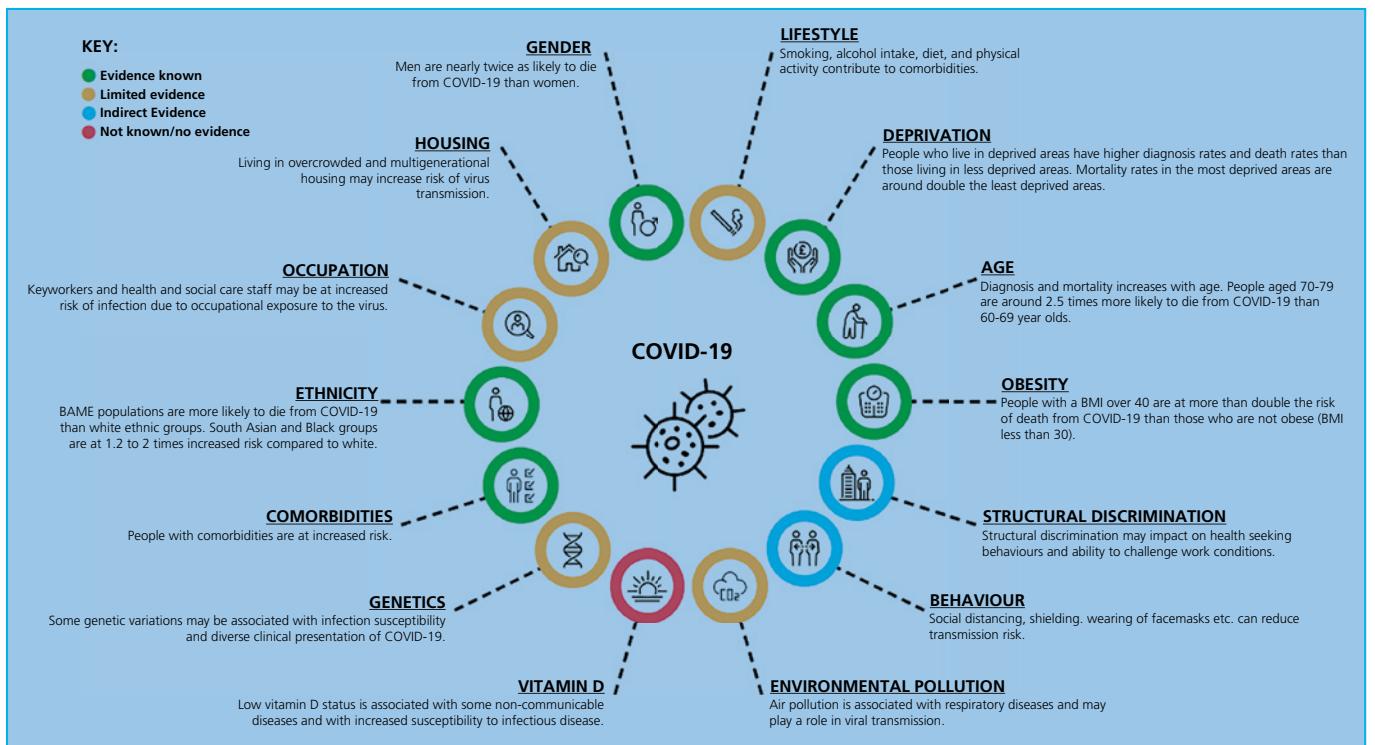

Figure 68.2 Factors associated with Covid-19 transmission and mortality. Source: Reproduced by permission from Khunti et al. (n.d.) [47].

Structured education

Structured education is integral to better diabetes management, as it enhances empowerment and autonomous self-management care [57]. For type 2 diabetes, diabetes education programmes currently available in the UK include Diabetes Education and Self-Management for On-going and Newly Diagnosed (DESMOND) and the eXPert Education versus Routine Treatment (X-PERT) diabetes programme; the former is validated in South Asian populations and has been developed for the Urdu-speaking South Asian community [29].

The Promotion Of Physical activity through structured Education with differing Levels of ongoing Support for people at high risk of type 2 diabetes (PROPELS) trial reported that ethnicity may influence the extent to which behavioural and demographic factors have impacts on physical activity and sedentary behaviour [58]. Once again, it is integral to overcoming these barriers that efforts are made to adapt screening and lifestyle interventions specifically to ethnic minority groups, such as South Asians. However, this remains challenging due to low levels of recruitment, retention, and follow-up in research trials. A feasibility study emphasized the value of community and faith centre-based screening and educational interventions in lowering the risk of type 2 diabetes among South Asians residing in the UK [59].

Impact of religious rituals on diabetes management

Fasting and feasting

Religious fasting is an important aspect of life for many South Asians, especially Muslims. The nature of abstaining from food during the day has implications for those people living with diabetes, particularly if the fasting period is prolonged, involves the abstinence of fluid as well as food, and involves continuous periods, such as weekly or over the month of Ramadan.

Specifically, for people living with diabetes religious fasting can increase the risk of hypoglycaemia, dehydration, postural hypotension, and ketoacidosis [60]. In addition to these risks, for Muslims the month of Ramadan needs to be viewed as both periods of fasting and feasting at the end of fast, which can lead to the risk of hyperglycaemia and weight gain, potentially worsened by reduced physical activity during the day [61].

While religious fasting is often associated with Muslims only, other faiths also practise fasting. Hindu fasts are distinctive owing to their day-long nature compared with the month-long fasts of Ramadan [62]. For Jains living with type 2 diabetes, most high-risk fasts may be discouraged in those taking any glucose-lowering therapy, while most low-risk fasts can be practised with an appropriate medication regimen and dose adjustments. People belonging to Judaism, Orthodox Christians, and the Baha'i faith also practise fasting, although these fasting periods are less frequent and spread out through the year.

Much of the evidence surrounding religious fasting and diabetes comes from studies during the Muslim month of Ramadan. Fasting in Ramadan is one of the five pillars of Islam and is considered a religious obligation for all Muslims, with some exceptions. Observing Ramadan fasts involves abstinence from food and drink between the hours following dawn (*suhoor*) to dusk (*iftar*); the

duration of fasting might vary from 10 to 20 hours depending on the geographical location and season [63].

Although Ramadan observance is mandatory, religious exemptions to fasting include pregnancy, lactation, travelling, or any acute or chronic conditions where fasting might predispose the person to health risks [64]. Diabetes is considered a risk state for people fasting during Ramadan, particularly if there is risk of hypoglycaemia, glucose levels are not on target, or there is evidence of diabetes complications [65]. However, most Muslim people with diabetes do not consider themselves to be unwell and therefore would wish to fast during Ramadan as a declaration of their faith, as well as a sociocultural event to develop relationships with family and friends. Subsequently, many choose to fast despite medical advice against fasting [66].

Ramadan fasting involves prolonged hours of abstinence from food and fluid, often followed by an indulgent feast-like end-of-fast meal, for 29–30 consecutive days. Hence, those Muslims living with diabetes are at risk of hypoglycaemia, hyperglycaemia (including the increased risk of diabetic ketoacidosis and hyperosmolar hyperglycaemic state), dehydration, and thromboembolic events by undertaking these Ramadan fasts [60].

For those with diabetes and a desire to fast, there exists a need to manage their diabetes effectively during Ramadan. Specific structured education programmes focusing on Ramadan could provide clinical benefits and enhanced quality of life for individuals with type 2 diabetes [63, 67, 68]. Healthcare professionals should appreciate the impact of Ramadan fasting on the health of individuals with a Muslim background living with diabetes. By appreciating the risks, they will be able to discuss them openly with these individuals. At the same time, they should appreciate that some Muslims may wish to continue to fast despite understanding the risks. In this scenario, healthcare professionals should be able to support and manage these people in a non-judgmental way to reduce their risks and allow them to fast as safely as possible. Consequently, healthcare professionals must be knowledgeable and culturally competent about the basics of and exemptions to Ramadan fasting, and the treatments and procedures that invalidate fasting [69–72].

People with diabetes should receive a pre-Ramadan assessment at least 1–2 months before Ramadan by their diabetes team. Specific programmes such as A Safer Ramadan by DESMOND and the New Safer Ramadan eLearning module from Effective Diabetes Education Now (EDEN) provide training to help healthcare professionals be better equipped to support and manage people with diabetes who wish to fast [73–75].

Various guidelines are available, including the South Asian Health Foundation's guidelines for managing diabetes in Ramadan, which expand further on adjustments of medications for safe Ramadan fasting, risk stratification for fasting, and when to break the fast (Table 68.6) [63]. Box 68.1 presents a case study on diabetes and Ramadan to exemplify the issues and principles in managing people with diabetes who wish to fast, including risk stratification and medication adjustments during Ramadan.

Pilgrimage

Pilgrimages or spiritual journeys to a place of worship are practised in a number of faiths. Often this means that UK people with diabetes will travel to warmer climates to perform spiritual rituals practised outdoors in the heat over long periods of time, as well as walking long distances. Worldwide pilgrims may bring illnesses

Table 68.6 International Diabetes Federation/Diabetes & Ramadan International Alliance risk categories for people with diabetes who fast during Ramadan.

Risk category	Characteristics of the person with diabetes	Comments
Category 1: Very high risk	One of more of the following: <ul style="list-style-type: none"> • Severe hypoglycaemia within the 3 months prior to Ramadan • DKA within the 3 months prior to Ramadan • Hyperosmolar hyperglycaemic coma within the 3 months prior to Ramadan • History of recent hypoglycaemia • History of hypoglycaemia unawareness • Suboptimally managed type 1 diabetes • Acute illness • Pregnancy in pre-existing diabetes, or GDM treated with insulin or SUs • Chronic dialysis or CKD stage 4 and 5 • Advanced macrovascular complications • Old age with ill health 	If person with diabetes insists on fasting then they should: <ul style="list-style-type: none"> • Receive structured education • Be followed by a qualified diabetes team • Check their blood glucose regularly (SMBG) • Adjust medication dose as per recommendations • Be prepared to break the fast in case of hypo- or hyperglycaemia • Be prepared to stop the fast in case of frequent hypo- or hyperglycaemia or worsening of other related medical conditions
Category 2: High risk	One or more of the following: <ul style="list-style-type: none"> • Type 2 diabetes with sustained hyperglycaemia above target^a • optimally-managed Type 1 diabetes • optimally-managed Type 2 diabetes on MDI or mixed insulin • pregnant Type 2 diabetes or GDM managed by diet only or metformin • CKD stage 3 • Stable macrovascular complications • People with comorbid conditions who present additional risk factors • People with diabetes performing intense physical labour • Treatment with drugs that may affect cognitive function 	
Category 3: Moderate/low risk	Optimally-managed type 2 diabetes treated with one or more of the following: <ul style="list-style-type: none"> • Lifestyle therapy • Metformin • Acarbose • Thiazolidinediones • Second-generation SUs • Incretin-based therapy • SGLT-2 inhibitors • Basal insulin 	People who fast should: <ul style="list-style-type: none"> • Receive structured education • Check their blood glucose regularly (SMBG) • Adjust medication dose as per recommendations

^a The level of glycaemia is to be agreed between doctor and person with diabetes according to a multitude of factors.

CKD, chronic kidney disease; DKA, diabetic ketoacidosis; GDM, gestational diabetes; MDI, multiple-dose insulin; SGLT-2, sodium–glucose cotransporter 2; SMBG, self-monitoring of blood glucose; SUs, sulfonylureas.

associated with the countries of origin to the often-overcrowded environments of pilgrimages, which can put people with diabetes at increased risk of infection.

The main risks associated with pilgrimage for people with diabetes include risks of infection, hypoglycaemia, poor access to adequate nutrition and water (resulting in hypoglycaemia, hyperglycaemia, or dehydration), heat exhaustion and heat stroke, foot ulcers, exertional angina, and the need to ensure adequate medical supplies.

Preparations for pilgrimage for people with diabetes require the following:

- Pre-pilgrimage travel consultation. This will allow any necessary medication adjustments and sick-day rules to be decided on.
- Adjustments of insulin timings depending on the travel time zone.
- Awareness of symptoms of hypoglycaemia and its management. A good source of information about longer travel journeys and timings of insulin can be found at <https://www.diabetes.org.uk/guide-to-diabetes/life-with-diabetes/travel>
- Foot checks and advice about footwear and prevention of foot ulcers.

- Ensuring sufficient medical supplies and discussion around storing insulin and carrying diabetes emergency kits.
- Advice regarding wearing identifiable medical wristbands.

Research priorities

There have been recent efforts to include more participation of people from ethnic minority groups with type 2 diabetes in clinical trials. Improving participation and reviewing research outcomes in these groups, including specific medications, will allow for more tailored guidelines for ethnic minority groups. However, despite these efforts, there remains an ongoing problem of small cohort sizes and lack of adequate data pertaining to these populations, which hinders prospects for the significant subgroup analyses that are important for ethnic susceptibility and guiding ethnicity-specific guidelines and management.

The barriers to recruitment and retention of research participants include lack of awareness about the significance of research within the community, perceived stigma around research topics, scepticism regarding study purpose and protocols, cultural

Box 68.1 Case study: diabetes care during Ramadan

Kabir Ali

- 64-year-old man.
- Type 2 diabetes for 16 years.
- Taxi driver.
- Previous laser therapy for diabetic maculopathy.
- BMI 28.2 kg/m².
- Non-smoker.

Drug history

- Atorvastatin 10 mg at night, ramipril 10 mg once daily, indapamide 2.5 mg once daily.
- Metformin 850 mg three times daily, gliclazide 160 mg twice daily, dapagliflozin 10 mg once daily.

Clinical data

- Blood pressure 136/84 mmHg.
- Total cholesterol 5.2 mmol/l, low-density lipoprotein (LDL) cholesterol 2.7 mmol/l, high-density lipoprotein (HDL) cholesterol 1.0 mmol/l.
- HbA_{1c} 63 mmol/mol (7.9%).
- Creatinine 98 µmol/l.
- Estimated glomerular filtration rate (eGFR) 64 ml/min.

Initial thoughts

- There will be no intake of lunch or fluid intake between dawn and sunset. It will therefore be prudent to move the antihypertensive therapies to iftar.
- Gliclazide could cause hypoglycaemia with no lunch (Table 68.7).
- A change to metformin 1000 mg twice daily could be justified as there is little or no benefit from increasing its dose above 2000 mg total dose daily.
- The dapagliflozin dosing does not need to be altered as there is only a mildly diuretic action.
- The National Institute for Health and Care Excellence (NICE) advised daily dose of atorvastatin for primary prevention is 20 mg, so there is an opportunity to increase the dose.

Table 68.7 Changes to treatment in Ramadan.

Pre-Ramadan treatment	Ramadan treatment
Breakfast time: ramipril 10 mg, indapamide 2.5 mg, metformin 850 mg, gliclazide 160 mg, dapagliflozin 10 mg	Suhoor: metformin 1000 mg, gliclazide 80 mg, dapagliflozin 10 mg
Lunch: metformin 850 mg	No oral intake during fast
Evening meal: metformin 850 mg, gliclazide 160 mg	Iftar: indapamide 2.5 mg, metformin 1000 mg, gliclazide 160 mg
Pre-bed: atorvastatin 10 mg	Pre-bed: atorvastatin 20 mg, ramipril 10 mg A glucagon-like peptide 1 (GLP-1) receptor agonist or dipeptidyl peptidase 4 (DPP-4) inhibitor instead of gliclazide would reduce the risk of hypoglycaemia and provide weight loss benefit

Box 68.1 (Continued)

Key principles

- Pre-Ramadan counselling should include all aspects of care and specific changes in medications that may be required.
- Consider a *mock fast* over a weekend, for example, to check that changes in medications advised suit the reality of fasting.
- Encourage safe fasting at all times, including being guided by the risk to the person with diabetes.
- Specific attention should be given to avoid hypoglycaemia and observe sick-day rules.
- Discuss the specific indications for breaking the fast, e.g. hypoglycaemia, hyperglycaemia cut-offs, and signs of dehydration.
- Advise regular glucose monitoring throughout the fast.
- Ensure good fluid intake outside of fasting hours.
- Discourage feasting habits after the fast, which will lead to hyperglycaemia and weight gain.

Review post-Ramadan (at next routine review) to ascertain the safety of current practice and plan for next year's Ramadan.

insensitivity, competing priorities, and influences pertaining to family, community, and cultural preferences restricting the inclusion of Asian subgroups into trials. Worryingly, compared to white Europeans or individuals of other ethnicities, there is a significantly higher number of South Asian people who are excluded from participation in research due to language barriers [76].

Therefore, it is of the utmost importance and urgency that researchers are trained to be culturally competent and have the essential culturally sensitive techniques to recruit and retain people from ethnic minority groups. Various strategies have been proposed to facilitate South Asian participation in clinical trials (Figure 68.3).

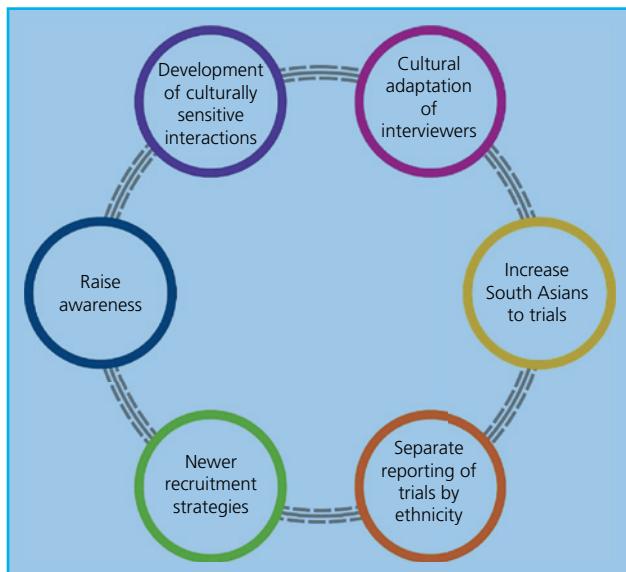

Figure 68.3 Strategies proposed to enhance participation from ethnic minority groups in clinical research trials. Source: Reproduced by permission from Hanif et al. 2021 [29].

Conclusion

Even before the impact of Covid-19 on ethnic minority groups, we appreciated that people of Black and South Asian ethnicity were at higher risk of type 2 diabetes and its complications compared to white Europeans. Recent events including the global Covid-19 pandemic have simply reminded us of the ongoing health inequalities and have continued to widen them for ethnic minority groups.

By understanding the relevance of ethnicity and culture on beliefs and daily practices, which can affect health and disease management, we can begin to appreciate the reasons for health inequalities and be better equipped to reduce health inequalities and improve health outcomes, including for people with diabetes.

The real take-home message is for us all to become culturally competent as individual healthcare providers and as healthcare systems as a whole, so that we can continue to individualize the management of people with diabetes and improve their outcomes.

Diabetes in Childhood

Jennifer M. Ikle, Ananta Addala, and David M. Maahs

Division of Endocrinology, Department of Pediatrics, Stanford University, Stanford, CA, USA

Key points

- An estimated 1.1 million children have diabetes worldwide; over 125 000 new cases are diagnosed annually and the incidence has been increasing by up to 5% annually over decades.
- Type 1 diabetes accounts for almost all cases in children younger than 10 years, for >90% among older children of European ancestry, and for 20–70% of diabetes in children older than 10 years from other ethnic groups.
- In the last decade, the incidence and prevalence of paediatric type 2 diabetes have markedly increased and should be considered in the differential diagnosis of new-onset diabetes in children and adolescents.
- The presence of two or more islet autoantibodies predicts the development of diabetes in those less than 10 years in most cases; despite an enormous research effort, prevention of type 1 diabetes is still elusive.
- Diabetes in children is diagnosed based on polyuria, polydipsia, weight loss, fatigue, and random blood glucose >200 mg/dl (11.1 mmol/l). Oral glucose tolerance testing is rarely needed.
- The classical presentation of diabetic ketoacidosis (DKA) in a thin, dehydrated child with Kussmaul breathing, abdominal pain, vomiting, and impaired neurological status is present at diagnosis in approximately 30% of cases in high-income countries.
- There are significant differences in the management of DKA in children, compared with adults, with the primary focus being on prevention of the cerebral oedema.
- After diagnosis, childhood diabetes is managed in the outpatient setting by a team including a paediatric endocrinologist specializing in diabetes, a diabetes nurse educator, a dietitian, a paediatric social worker, and/or a paediatric psychologist trained in childhood diabetes.
- Diabetes technology, such as continuous glucose monitors and insulin pumps, is associated with improved glycaemic and psychosocial outcomes, and should be considered in all children and adolescents with type 1 diabetes.

- Disparities in diabetes technology use and glycated haemoglobin (HbA_{1c}) exist by socioeconomic status and race/ethnicity.
- Telemedicine is an effective means of delivering paediatric diabetes care and can supplement in-person visits.
- In-depth initial and continuing education of parents and children in the self-management of diabetes is the cornerstone of lowering the risk of acute and long-term complications.
- Insulin pump or basal bolus multiple daily injections are the standard of insulin therapy in children.
- Nutrition planning should be based on a carbohydrate counting or exchange system; the macronutrient and micronutrient composition of the diet is similar to that for healthy children without diabetes.
- While regular exercise is recommended for all children with diabetes, it requires careful planning of insulin and nutritional management to prevent severe hypoglycaemia.
- Severe hypoglycaemia is largely preventable, but is still the most common serious complication of childhood diabetes.
- Healthcare providers should equip families with the tools necessary to avoid dehydration, uncontrolled hyperglycaemia or DKA, and hypoglycaemia during routine infections.
- HbA_{1c} levels below 53 mmol/mol (<7.0%) are the target currently recommended and achievable by most children and adolescents; the gap between recommended and actual HbA_{1c} levels is the widest among adolescents.
- Age-specific psychological care should include screening for and treatment of family dysfunction, developmental maladjustments, and communication problems, disordered eating and sleep patterns, as well as psychiatric disorders both in children and their care providers.
- All children with diabetes should be screened at an appropriate age and duration of diabetes for dyslipidaemia, microalbuminuria, elevated blood pressure, retinopathy, coeliac, and thyroid disease.

Spectrum of diabetes in children

In Europe and North America, 1 in 300 children develops type 1 diabetes by the age of 20 years [1]. There are an estimated 1.1 million children and adolescents aged 0–19 years living with type 1 diabetes, with 128 900 new cases diagnosed each year as of 2019 [2].

The incidence and prevalence rates are highest in Europe (31.1/100 000 per annum and 269.5/100 000, respectively) and the lowest in Africa (10.1/100 000 per annum and 25.8/100 000, respectively) [1]. Diabetes is a heterogeneous disease at any age. Newborn babies and infants rarely develop the disease (1 in 250 000 in those younger than 6 months) and in those cases the aetiology is not autoimmune, but usually monogenic (Chapter 20). From the age of

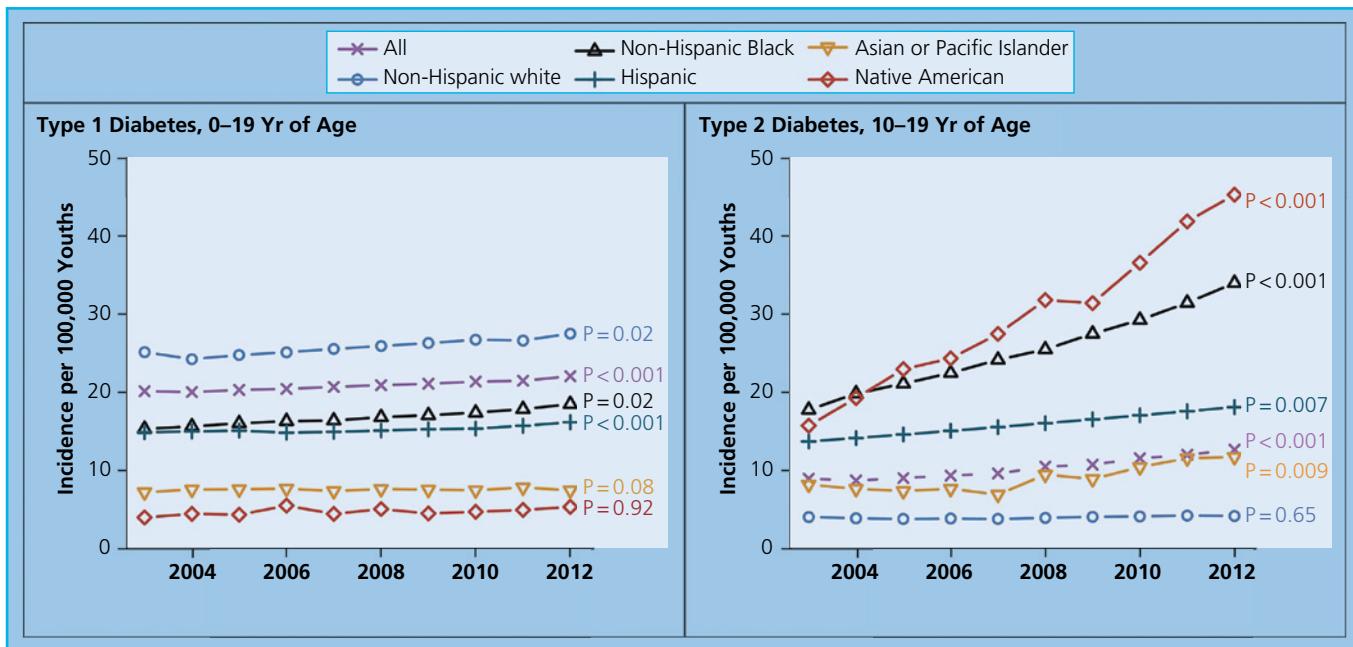

Figure 69.1 Diabetes incidence in youths less than 20 years of age. Source: Data from Mayer-Davis et al. 2017 [3].

9 months to 10 years, almost all diabetes is caused by islet autoimmunity (Chapter 14). The incidence of type 1 diabetes has been increasing in the last decade, with the greatest rise in incidence in children and adolescents from racial and ethnic minority groups. In addition to the rise in type 1 diabetes incidence, in the last decade there has been a marked rise in the incidence and prevalence of type 2 diabetes (Figure 69.1) [3]. Measurement of autoantibodies to insulin, glutamic acid decarboxylase (GAD65), islet tyrosine phosphatase 2 (IA-2), and zinc transporter 8 (ZnT8) at diagnosis and examination for signs of insulin resistance may be necessary to determine the diagnosis and long-term treatment.

This chapter focuses on the practical aspects of the management of type 1 diabetes in children, while Chapter 69 addresses management of type 1 diabetes in adolescents and transition to adult care. Management of type 2 diabetes in children is increasingly important, as the incidence and prevalence of type 2 diabetes in this age group have been increasing. In addition, greater rates of morbidity and mortality are observed in paediatric type 2 diabetes when compared to type 1 diabetes. Female, adolescent, and non-Hispanic Black youths with type 2 diabetes have excess mortality, whereas short-term excess mortality was not observed in youths with type 1 diabetes [4–6]. However, life expectancy remains 8–13 years shorter and cardiovascular disease continues to be the leading cause of morbidity and mortality in type 1 diabetes [7], and earlier age at type 1 diabetes diagnosis is associated with shorter lifespan [8, 9]. Chapters 15 and 20 provide a description of type 1b diabetes, where the clinical presentation is as in type 1a diabetes but without evidence of islet autoimmunity, and monogenic diabetes, respectively. The epidemiology and aetiology of type 1 diabetes are addressed in Chapter 4 and Chapter 14, respectively. The temporal changes in incidence rates over the last 15 years vary by country. While type 1 diabetes incidence rates continue to rise steadily in many countries, some countries, such as Finland, Norway, Sweden, Denmark, and parts of the UK, are showing signs of a slowing in the rise [10–13]. Elimination of the environmental trigger(s) responsible for this epidemic would be the most efficient approach to primary

prevention; however, there is lack of consensus about which environmental factors initiate and promote islet autoimmunity [10–14]. Efforts to prevent or delay type 1 diabetes have been recently reviewed elsewhere [15].

After the initiation of islet autoimmunity, most people have a long pre-clinical period that offers an opportunity for secondary prevention of the progression to clinical diabetes. The presence of more than one of the autoantibodies combined with susceptibility to human leucocyte antigen (HLA)-DR, DQ genotypes identifies those at high risk of developing diabetes. There may be a ‘point of no return’ in the autoimmune destruction of the islets, rendering some interventions effective only at the earlier stages of the process. In most individuals with persistence of islet autoantigens, progression to diabetes occurs within 10 years. A period of mild asymptomatic hyperglycaemia, detectable by oral glucose tolerance testing (OGTT) or glycated haemoglobin (HbA_1c) [15, 16] may precede by months or years overt insulin dependence among those with islet autoantibodies. Intervention at this *dysglycaemic* stage may also theoretically preserve endogenous insulin secretion and reduce the acute and long-term complications of type 1 diabetes. Preservation or regaining of residual insulin secretion after diagnosis of diabetes might also help, but the immunomodulatory agents used so far in tertiary prevention carry unacceptable long-term risks.

The growing understanding of the heterogeneity of paediatric diabetes in the last decade has brought new challenges to diabetes management in children. In particular, these challenges include appropriate identification of diabetes type and addressing disparities in diabetes care management and outcomes [17–20]. The modern obesogenic environment has resulted in the rising prevalence of both obesity in paediatric type 1 diabetes and the incidence of paediatric type 2 diabetes [21–24]. The rates of obesity and overweight are higher in children and adolescents with type 1 diabetes than in the general population and therefore nutritional and exercise interventions should be considered in the treatment of all paediatric diabetes [25, 26].

In the last half decade, data have demonstrated marked disparities in diabetes management and outcomes in minority racial/ethnic and lower socioeconomic groups [17–19]. The degree of these disparities varies by country, but they are present in all countries with regard to diabetes technology use, HbA_{1c}, and diabetes-related complications [17, 27]. Social determinants of health are defined as the economic, environmental, political, and social conditions in which people live that play a significant role in health outcomes and are considered to be, in part, responsible for health inequity worldwide [28, 29]. Strategies to tailor treatment of type 1 diabetes in the psychosocial context of the young person and their family include [28]:

- Understanding the role of social determinants of health in diabetes management and outcomes.
- Assessing food, housing, and the financial and legal security of the family.
- Evaluating the impact of racism and discrimination on the young person and their family.
- Being apprised of and referring appropriately to community resources.
- Providing family and youth support with lay health coaches or community workers.

Addressing these disparities along with the continued innovation of diabetes technology is an important step towards equitable care for all children and adolescents with diabetes.

Manifestation, diagnosis, and initial treatment

Clinical presentation and diagnosis

The cardinal symptoms at the diagnosis of diabetes include polyuria (96% of children, often with nocturia or bed-wetting), polydipsia, weight loss (61%), and fatigue [30]. The classic presentation of diabetic ketoacidosis (DKA) in a thin, dehydrated child with Kussmaul breathing, abdominal pain, vomiting, and impaired neurological status affects less than half of cases presenting in high-income countries today [31–33]. With the increasing community recognition of diabetes, most children present with milder hyperglycaemia of shorter duration; however, 75% of the children (63% below age 5 years) have the symptoms for more than two weeks, suggesting that the diagnosis could be made earlier in many cases. Very young children may have less specific presentations, for example with vomiting or rapid breathing, often in the setting of a concurrent illness or infection. Diabetes should always be considered in ill children; urine or blood testing for glucose and ketones leads to an early diagnosis and may prevent DKA and hospitalization. Recognition of early diabetes symptoms is critical, as many children admitted with severe DKA have missed or delayed diagnosis by other healthcare providers [30].

While insulin infusion and intravenous fluids are required for a minority of new-onset cases of diabetes, many children who are newly diagnosed may spend several days admitted to the hospital. These hospitalizations could be avoided if safe outpatient alternatives and adequate reimbursement existed for this initial care. The majority of centres in the USA continue to require a several-day hospital stay for new diabetes diagnosis, to allow for family and caregivers to acquire the necessary knowledge base and practise the daily skills involved in diabetes care [34]. However, these hospitalizations have both economic and emotional impacts – both on the healthcare system as a whole and on individual families, who may travel, need childcare, be underinsured, and so on. Because of these

considerations, some institutions have adapted alternative models of diabetes education and recent studies have shown that outpatient education results in lowering of healthcare costs without compromising medical care [35, 36].

The diagnostic criteria are the same in children and adults (Chapter 2). In a symptomatic child, plasma glucose ≥ 11.1 mmol/l (200 mg/dl) at any time of day, without regard to time since the last meal, or fasting plasma glucose ≥ 7.0 mmol/l (126 mg/dl) is diagnostic. Blood glucose results obtained using a glucose meter should be immediately confirmed in a laboratory, before the initiation of insulin treatment. By contrast, if marked hyperglycaemia and blood or urinary ketones are present, treatment is urgent; waiting another day to confirm the diagnosis may be dangerous if DKA is allowed to develop. In a well child, the diagnosis must not be based on a single plasma glucose test or borderline results obtained using a glucose meter. In such cases, it is reasonable to obtain the HbA_{1c} level; if this is normal, further monitoring of the fasting and/or two hours post-prandial blood glucose is recommended for several days. In children progressing to overt diabetes, hyperglycaemia after dinner is usually the initial abnormality detectable by self-monitoring of blood glucose at home. OGTT should not be performed if fasting, random, or post-prandial criteria are met, as it is unnecessary and excessive hyperglycaemia can result.

Hyperglycaemia detected incidentally or during acute infection, trauma, or other illness may be transient, especially if typical symptoms of diabetes are absent or equivocal. Non-diabetic causes of hyperglycaemia include stress, acute illness, and use of glucocorticoids and other medications [37]. The need for treatment or additional follow-up should be addressed on a case-by-case basis, as length, severity, and cause of hyperglycaemia will guide the next steps. There are some data suggesting that children with stress hyperglycaemia are more likely to develop diabetes in the future, but this has not been widely supported in the literature [38, 39].

The combination of antibody testing and genetics can also help to determine the diagnosis, particularly in children with mild or early presentations. Additionally, antibodies play an increasingly important role in differentiating type 1 diabetes and type 2 diabetes, as obesity is increasing and body habitus is no longer a reliable way to distinguish between these two pathologies. More than 80–90% of individuals with newly diagnosed type 1 diabetes have one or more anti-islet cell autoantibodies (islet cell antibodies, insulin autoantibodies, antibodies to the 65 kD isoform of GAD65, the IA-2 molecule, and ZnT8), and the presence of two or more autoantibodies is highly predictive of progression to overt diabetes [40, 41].

A majority of type 1 diabetes cases occur in individuals without a family history of the disease; however, individuals with a first-degree relative with type 1 diabetes have a 5% lifetime risk of developing type 1 diabetes, compared with a 0.3% lifetime risk for the general population. Monozygotic twins have a concordance rate of >50%, whereas dizygotic twins have a concordance rate of 6–10% [42, 43]. Genetic risk scores (GRS) are a growing tool to predict the development of type 1 diabetes, as well as distinguishing it from other forms of diabetes, such as monogenic diabetes or type 2 diabetes [44, 45]. Genetic factors can be complemented by environmental and other factors to improve predictability; one example of this is the combined risk score (CRS), which utilizes the GRS2 as well as family history and presence of autoantibodies and is more highly predictive of type 1 diabetes than any of those components when used alone [44, 46–49]. Improved predictability, particularly in the early stages of type 1 diabetes, will maximize the potential for intervention as potential preventive therapeutics are identified.

The possibility of other types of diabetes should be entertained in children who have negative diabetes autoantibodies and any of the following features:

- Diagnosis at <6 months of age.
- Autosomal-dominant family history of diabetes.
- Mild fasting hyperglycaemia that does not progress.
- Associated syndromic features.
- History of exposure to drugs known to cause β -cell toxicity or insulin resistance.

Impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) may also be detected in a child with islet autoimmunity progressing to overt diabetes [50]. OGTT is rarely needed in prepubertal children. In older children, especially obese teenagers with equivocal symptoms, the OGTT may have a role in the earlier diagnosis of type 2 diabetes, IGT, and IFG.

Monogenic diabetes

While type 1 diabetes and type 2 diabetes have multifactorial aetiologies, monogenic causes of diabetes are also important causes of paediatric diabetes. This includes maturity-onset diabetes of the young (MODY) and neonatal diabetes mellitus. MODY is an autosomal, dominantly inherited form of diabetes that is characterized by an early age of onset (at least one affected family member with an onset before 25 years of age) and pancreatic β -cell dysfunction [51]. Mutations in the three most commonly associated genes (*HNF1A*, *HNF4A*, and *GCK*) can account for up to 95% of all MODY cases.

Neonatal diabetes mellitus is a heterogeneous disease defined as diabetes with onset during the first six months of life, with a monogenic cause identifiable in up to 85% of cases [52]. Mutations in the genes that comprise the pancreatic adenosine triphosphate (ATP)-sensitive potassium channels, *ABCC8* and *KCNJ11*, are the most common causes of neonatal diabetes mellitus, and cases due to these mutations are often responsive to oral sulphonylureas, potentially avoiding the need for insulin therapy [53]. If clinical presentation is typical for either MODY or neonatal diabetes mellitus, especially in antibody-negative individuals, genetic testing should be performed.

Diabetic ketoacidosis

The clinical presentation of DKA includes abdominal pain, nausea, and vomiting, which can mimic an acute abdomen. The children are mildly to moderately dehydrated (5–10%), may have Kussmaul respiration, and become progressively somnolent and obtunded. DKA results from absolute or relative deficiency of circulating insulin and a corresponding increase in the levels of counter-regulatory hormones, such as catecholamines, cortisol, glucagon, and growth hormone (Chapter 41). This combination leads to a catabolic state with increased glucose production by the liver and kidneys, increased lipolysis, ketogenesis with ketonaemia, and metabolic acidosis. Absolute insulin deficiency occurs in children with previously undiagnosed type 1 diabetes or in those with an established diagnosis through omission of or inadequate insulin regimens. Relative insulin deficiency occurs during acute illness and stress if the increase in counter-regulatory hormones is not balanced by an appropriate increase in insulin dosage.

DKA is defined by the triad of ketonaemia and/or ketonuria, acidosis (serum pH <7.3 and/or serum bicarbonate <15 mEq/l), and hyperglycaemia, although DKA can occur without hyperglycaemia if the individual is pre-treated at home or in another hospital [54]. The severity of DKA is typically categorized by the degree of acidosis:

- Mild: venous pH 7.2–7.3 or bicarbonate <15 mmol/l.
- Moderate: venous pH 7.1–7.2 or bicarbonate <10 mmol/l.
- Severe: venous pH <7.1 or bicarbonate <5 mmol/l.

Diabetic ketoacidosis at diagnosis of diabetes

In the USA, an average of 28% of individuals less than 20 years of age diagnosed with type 1 diabetes presented in DKA [31]. Globally and throughout the USA rates of DKA presentation vary, ranging from 19% to 58% on initial diagnosis, and correlating inversely with the local incidence of type 1 diabetes [32, 33]. DKA is more often found among younger children and in children with lower socio-economic status who encounter barriers in accessing medical care [33, 55]. Intensive community intervention to raise awareness of the signs and symptoms of childhood diabetes among school teachers and primary care providers may help to reduce the prevalence of DKA at diagnosis.

Diabetic ketoacidosis in children with established type 1 diabetes

In two large cohorts of children with established type 1 diabetes, on average 4–7 per 100 developed DKA every year [56, 57]; however, nearly 60% of the DKA episodes occurred in 5% of children with recurrent events. Recurrent DKA was predicted by omission of insulin, suboptimal metabolic management, intercurrent gastroenteritis with dehydration, psychiatric and eating disorders, difficult family or social circumstances or limited access to medical care, and the use of insulin pump therapy. Recurrent DKA is more common in peripubertal or adolescent girls.

Treatment of ketoacidosis

Children with DKA should ideally be cared for in a unit with nursing staff trained in management of DKA in children, written guidelines for DKA management in children, and access to a laboratory capable of providing frequent and timely biochemical results. In 2020, the International Society for Paediatric and Adolescent Diabetes (ISPAD) released additional guidelines for consideration during the SARS-CoV-2 pandemic, recommending that in cases where intensive care unit (ICU) capacity may be limited, some children with mild and moderate DKA may be treated outside of the ICU without compromising care [58]. Hydration status should be assessed and fluid deficit and osmolality calculated to help guide fluid and electrolyte replacement. Serum electrolytes, glucose, blood urea nitrogen, creatinine, calcium, magnesium, phosphorous, and blood gas testing should be repeated every 2–4 hours or more frequently in severe cases. The calculations are shown in Box 69.1.

Children with DKA have a 5–10% deficit in extracellular fluid volume that has developed slowly and rapid or overzealous fluid replacement should be avoided, largely to minimize the risk of cerebral oedema. Initial volume expansion should occur over the first 1–2 hours with intravenous (IV) infusion of 10–20 ml/kg normal

Box 69.1 Calculations of anion gap, corrected sodium, and serum osmolality

$$\text{Anion gap} = \text{Na} - (\text{Cl} + \text{HCO}_3)$$

$$\text{Corrected Na} = \text{measured Na} + [(\text{plasma glucose} - 100 \text{ mg/dl}) \\ (1.6)/100]$$

$$\text{Serum osmolality} = 2(\text{Na} + \text{K}) + \text{glucose}/18 + \text{blood urea nitrogen}/2.8(\text{mOsm/l})$$

Box 69.2 Estimate of 24-hour maintenance fluid volume

Estimation based on age:

- 0–2 years = 80 ml/kg
- 3–5 years = 70 ml/kg
- 6–9 years = 60 ml/kg
- 10–14 years = 50 ml/kg
- >15 years = 35 ml/kg

Estimation based on body weight:

- 100 ml/kg for the initial 10 kg body weight, plus
- 50 ml/kg for the next 10 kg body weight, plus
- 20 ml/kg for each additional kg body weight

For example, a child weighing 30 kg needs $1000 + 500 + 200 = 1700$ ml maintenance water for 24 hours or 70 ml/h, not counting past or ongoing losses.

saline (0.9%) or Ringer solution. The bolus rarely needs to be repeated and should not exceed a total of 40 ml/kg over the first four hours of treatment. Subsequent fluid deficit replacement should occur over the next 48 hours using half to three-quarters of normal saline, in addition to electrolytes (Box 69.2). Hypotonic fluids (e.g. half normal saline) are typically used for continued fluid replacement, although a recent study found that among four arms of treatment, neither the rate of fluid repletion nor the salinity of the chosen fluids alters the risk of cerebral oedema [59].

Once blood glucose concentrations reach 250 mg/dl (14 mmol/l), 5–10% dextrose should be added to the IV solution to maintain the blood glucose concentration between 150 and 250 mg/dl (8–14 mmol/l) and avoid saline overload and hyperchloraemic acidosis.

Continuous IV insulin infusion (typically consisting of diluted regular insulin) at a dose of 0.05–0.1 units/kg/h should commence after the child has received initial volume expansion. An IV bolus of insulin is unnecessary and may increase the risk of cerebral oedema [54]. The insulin infusion should allow for a gradual decrease in blood glucose concentration by 50–100 mg/dl/h (2.8–5.6 mmol/l/h). If the blood glucose levels decrease too quickly or become too low before the acidosis has resolved, the IV dextrose concentration may be increased to 12.5% to prevent hypoglycaemia while continuing to correct the metabolic acidosis with insulin. Caution should be used when considering decreasing the infusion rate below 0.05 units/kg/h, as this is likely to prolong the time needed to suppress ketogenesis, but it may be clinically appropriate in severe or persistent hypoglycaemia. Bedside monitoring of blood ketones (β -hydroxybutyrate) is more helpful than blood gases in adjusting insulin and glucose infusion rates.

Total body potassium is usually depleted, but serum levels at presentation may be normal or high secondary to efflux of intracellular potassium into the extracellular space in the presence of acidosis. Similarly, serum phosphorus levels may be initially elevated only to fall rapidly, frequently leading to hypophosphataemia. Once the serum potassium is found to be normal or low, and urine output is confirmed, IV fluids should include 20–40 mEq/l potassium in the form of K acetate, K_2HPO_4 , or a combination of these. Clinical problems resulting from low phosphorus levels have not been substantiated; however, severe hypophosphataemia (<1 mg/dl) should be treated. No more than half of the potassium replacement should be given as K_2HPO_4 , because excessive phosphorous administra-

tion may result in hypocalcaemia and hypomagnesaemia following the suppression of parathyroid hormone. If hypocalcaemia develops, administration of phosphate should be decreased or stopped.

Severe acidosis is reversible with fluid and insulin replacement. Bicarbonate therapy may paradoxically cause central nervous system acidosis and hypokalaemia from rapid correction of acidosis and is a risk factor for cerebral oedema. Bicarbonate therapy is not recommended except in situations of cardiovascular collapse due to acidosis. If bicarbonate is considered necessary, 1–2 mmol/kg can be cautiously administered over 60 minutes in an intensive care unit setting.

Cerebral oedema

Cerebral injury is the major cause of morbidity and mortality in children with cerebral oedema, accounting for 60–90% of all deaths due to DKA while up to 10–25% of survivors have significant residual morbidity [54]. Neurological status must be monitored at frequent and regular intervals. Subclinical cerebral oedema occurs in most children with DKA. Severe clinical oedema affects 0.5–1% of the children and is fatal in over 20% [60]. Typically cerebral oedema occurs at 4–12 hours, but has been reported as late as 24–28 hours after the initiation of IV fluid treatment. Potential risk factors for symptomatic cerebral oedema in children include:

- Age <5 years old.
- More profound dehydration, hyperventilation, and acidosis at presentation.
- Bicarbonate therapy.
- Excessive and rapid fluid administration, especially if initial serum osmolality >320 mOsm/l or initial serum glucose >800 mg/dl (44 mmol/l).
- Rapid correction of glucose.
- Failure of serum sodium to rise as hyperglycaemia resolves.
- Initial IV insulin bolus or too early initiation of insulin infusion.

Signs and symptoms of cerebral oedema include headache, change in mental status or behaviour, incontinence, focal neurological findings, sudden normalization of heart rate in a previously tachycardic dehydrated child, or a worsening clinical course in a child with improved laboratory values. Bradycardia, hypertension, and irregular respiration (Cushing triad) are signs of greatly increased intracranial pressure. Early intervention is essential. Treatment includes administration of mannitol (1 g/kg over 30 min), decreasing fluid rate to 75% or less of maintenance rate, and elevation of the head of the bed. Mannitol therapy may need to be repeated. IV hypertonic saline has also increasingly been used as an alternative to mannitol, although there is variability in treatment approaches across institutions and between emergency versus critical care settings [61]. There remains a paucity of data comparing the two approaches [62, 63], but current guidelines allow for either approach [54]. Treatment should not be delayed for the purpose of imaging, and any necessary radiographic studies (such as head computed tomography [CT]), should be obtained after, rather than during, treatment of cerebral oedema [64].

Frequent monitoring of blood glucose levels should prevent hypoglycaemia. For acute hypoglycaemic episodes while on continuous insulin infusion, the insulin infusion may be temporarily discontinued for up to 15 minutes if necessary.

Transition to a subcutaneous insulin regimen

Children may be transitioned to an appropriate subcutaneous insulin regimen once DKA has resolved and they are able to eat. To prevent rebound hyperglycaemia, the insulin infusion should not be discontinued until 15–30 minutes after the first injection of

rapid-acting insulin has been administered. Long-acting insulin analogues achieve therapeutic levels sufficient to replace insulin infusion 4–6 hours after the injection. Bedside monitoring of blood ketones can help titrate insulin dose and prevent a relapse.

Hyperglycaemic hyperosmolar syndrome

Hyperglycaemic hyperosmolar syndrome (HHS) can occur in children, most often, but not exclusively, in the setting of type 2 diabetes, and is defined as follows [65]:

- Plasma glucose concentration 600 mg/dl ($>33.3 \text{ mmol/l}$).
- Venous pH >7.25 or arterial pH >7.30 .
- Serum bicarbonate $>15 \text{ mmol/l}$.
- Negative or trace urine ketones or absent to small blood ketones.
- Serum osmolality $>330 \text{ mOsm/kg}$.

Presentation of HHS can have a more insidious onset than DKA, and polyuria and polydipsia may continue until profound dehydration occurs, with approximately 50% of cases having altered consciousness or seizures. Compared to DKA, children with HHS need greater amounts of fluids to avoid intravascular collapse, which contributes to the mortality seen in HHS.

Approach to HHS treatment should include:

- Gradual decrease of sodium concentration, often by titrating the sodium content in fluids.
- Gradual decrease in glucose of 75–100 mg/dl/h (4.2–5.6 mmol/l/h) or less, after first few hours of therapy.
 - Initial treatment with bolus fluids causes a greater fall in glucose initially, but this should not persist.
 - Insulin therapy is delayed until glucose is falling less than 50 mg/dl/h (3 mmol/l/h) and should be initiated at 0.025–0.05 units/kg/h and adjusted to maintain a decrease in serum glucose of 50–75 mg/dl/h (2.7–4.1 mmol/l/h).
- Close monitoring including hourly checks of glucose, vital signs, hydration, and clinical status.
- Monitoring of serum electrolytes, blood urea nitrogen, creatinine, osmolality, and determination of intake/output balance every 2–3 hours, and phosphate and magnesium every 3–4 hours.
 - Treat hypokalaemia, hypophosphataemia, and hypomagnesaemia if they are present.
- Checking creatine kinase every 2–3 hours to monitor for rhabdomyolysis.

Complications of HHS include venous thrombosis associated with the use of central venous catheters, rhabdomyolysis, and malignant hyperthermia. Cerebral oedema is rarely seen. Children can have a mixed picture of DKA and HHS, and in these cases typically more fluids are given than usual for DKA, and insulin is started sooner than in HHS, but treatment should be based on the individual clinical presentation [54, 65].

Paediatric ambulatory diabetes care

Diabetes is primarily managed in the outpatient setting by a team including a paediatrician specializing in diabetes, a certified diabetes educator or diabetes nurse, a dietitian, a paediatric social worker trained in childhood diabetes, and/or a paediatric psychologist with knowledge of childhood diabetes and chronic illness. In communities with low population density and low prevalence of childhood diabetes, such a care team may not be available and care will primarily be provided by the child's primary care physician. In these instances, these physicians should work closely with and have access to a regional diabetes care team. When available, telemedi-

cine utilizing two-way video-computer technology and local medical staff offers a way for more efficient and effective care from afar [66–74]. Healthcare providers and the diabetes care team must always be cognizant of and sensitive to the cultural needs and barriers to care that may arise with minority children of recent immigrants. When providers do not speak the preferred language of the family, interpreters should be utilized in care delivery.

Initial education

Initial education should provide a basic understanding of the pathophysiology of diabetes and its treatment to ensure that families feel confident in providing diabetes care at home (Table 69.1).

At many institutions, initial education at time of diagnosis occurs in an inpatient setting regardless of whether or not the child presents acutely ill in DKA. In some centres with appropriate outpatient resources, initial diabetes education and initiation of insulin therapy can occur in the ambulatory setting, which has been shown to be cost-effective. The introduction of continuous glucose monitoring (CGM) shortly after type 1 diabetes diagnosis is well received by children and adolescents and their families and is associated with improvements in HbA_{1c} [76, 77]. Therefore, introduction of diabetes technology and, if possible, offering CGM shortly after diagnosis should be considered in the initial education.

Continuing education

In the first six months following diagnosis, close contact in the form of frequent outpatient visits, home visits, telephone communication, and other methods of communication is essential for addressing the frequently changing requirements during this time (Table 69.2) [75].

Diabetes education is a continuous process and must be repeated to be effective. It must be adapted and appropriate to the age of the child. Infants and toddlers often have unpredictable eating and activity patterns. There is commonly more difficulty in distinguishing normal behaviour from mood swings related to hypoglycaemia or hyperglycaemia. Needle phobia can present a significant issue with the perception of pain inflicted by the caregiver. Hypoglycaemia is more common in this age group and the prevention, recognition, and management of hypoglycaemia are a priority [78, 79]. Fear of hypoglycaemia is a well-recognized barrier to achieving optimal glycaemic targets and meeting exercise goals, thereby having impacts on long-term diabetes-related complications including cardiovascular morbidity [80]. CGM use is associated with an improvement in time spent in range without an increase in

hypoglycaemia rates [81, 82]. School-aged children will have increased understanding and involvement with their diabetes management. Providers should address school-aged children directly in addition to speaking with their parents or care providers. Education includes monitoring of blood glucose levels and injections at school, particularly during meal times, exercise, and extracurricular activities. Education should also focus on age-appropriate step-wise transition of diabetes responsibilities. This becomes particularly important in adolescence, during which there is a critical balance between promoting independent responsible management of diabetes while maintaining parental involvement.

Once treatment is established, it is common practice for children to be seen in the ambulatory setting at least every three months; visits should be more often if the child does not meet the treatment goals or intensifies treatment, for example if insulin pump treatment is initiated. During these visits, overall health and well-being are assessed, growth and vital signs are monitored, and a physical examination is performed. There should be routine screening for diabetes-associated complications and comorbidities. Blood glucose records are reviewed, including a check of HbA_{1c}, medications, and school plans. This will allow the insulin doses to be adjusted and provide a template for continued diabetes education. Age-appropriate diabetes-specific knowledge should be assessed and evaluated.

The dietitian may review dietary habits and provide ongoing nutrition education as needed. Given the rising prevalence in obesity in children and adolescents across the globe, it is recommended that age-specific healthy dietary habits are also considered in addition to the more standard carbohydrate counting review. The social worker or psychologist assesses and monitors psychosocial problems and family dynamics and the impact of diabetes care. At the conclusion of these visits, an individualized plan should be developed for each child and their family and a written copy of this plan should be provided.

The advent of new technology including downloadable glucometers, insulin pumps, and continuous glucose monitors, as well as electronic smartphone apps, has made it increasingly possible for the diabetes care team to gain insight into home management of diabetes; however, this should not replace self-monitoring and

regular review of blood glucose data at home by the child and their family.

Telemedicine delivery of outpatient diabetes care

Telemedicine delivery of type 1 diabetes outpatient care has been growing in favour, especially after the Covid-19 global pandemic. Paediatric subspecialists who treat type 1 diabetes are not distributed evenly in most countries; urban areas and academic centres tend to house paediatric diabetes subspecialists, leaving other areas in the country with sparse access to specialized diabetes care. To mitigate the financial and geographical barriers to access diabetes care, telemedicine has emerged as a solution for improving access to type 1 diabetes subspecialists. While some studies have demonstrated that telemedicine and in-person visits are comparable [69], others have suggested that telemedicine results in improved type 1 diabetes-specific and psychosocial outcomes while being equally cost-effective [70, 72–74]. Telemedicine proved to be crucial during the Covid-19 global pandemic, which required a rapid transition in how diabetes care is delivered. While data are supportive that telemedicine is clinically efficacious and cost-effective [66, 68], Covid-19 galvanized paediatric diabetes providers around the world to adopt and optimize telemedicine delivery [66, 67]. Consistent with previous studies evaluating the efficacy and utility of telemedicine, emerging observational studies are supportive of telemedicine as an effective means of delivering type 1 diabetes care during the pandemic [83–85].

Given the adaptation and acceptance of telemedicine in the delivery of paediatric type 1 diabetes care, it is anticipated that the use of telemedicine will continue as an integral part of paediatric type 1 diabetes care delivery. As such, two major components necessary to the equitable and efficacious delivery of type 1 diabetes care include the ability of children and adolescents and their family to share diabetes data with their providers, and addressing the digital divide that precludes families from accessing telemedicine. The digital divide is the gap in internet, broadband, and/or devices to sustain effective telehealth that is seen between differing socioeconomic and racial or ethnic groups [86]. Type 1 diabetes management is heavily dependent on glucose and insulin data to make appropriate insulin changes. For in-person visits, data downloads are typically carried out by the multidisciplinary diabetes team; however, with telemedicine these data are to be shared by the family with the provider care team. Current methods to download and transfer diabetes data can be cumbersome and challenging. Therefore, easy transfer of clinically relevant diabetes data is an important aspect of overcoming technology and health literacy barriers in certain populations [66].

Diabetes management in school

Children with diabetes spend a significant portion of their day in school; therefore, diabetes management in school is a critical part of their diabetes management plan [87–89]. The child has the right to receive adult support for diabetes care from school personnel during school hours, outdoor school activities, and school-sponsored events away from school. Glycaemic targets should be the same in school as outside of school, but may need to be adjusted for exams or in school fitness. School personnel must be trained to provide or supervise all diabetes care prescribed by the diabetes team, be supportive of providing diabetes care, and encourage diabetes management during school hours, including:

- Insulin administration by injection or with an insulin pump.
- Testing blood glucose in young children and older, newly diagnosed children and adolescents until they are capable of performing the task independently.

Part 11 Diabetes in Special Groups

- Identification and treatment for hypoglycaemia, both mild-moderate and severe.

The marked uptake in CGM use has modified the management of diabetes in the school setting. School personnel should receive education on the use of CGM, including alert notifications and trend arrows. It is also important that staff are made aware that fingerstick blood glucose values should be performed if the CGM readings appear inaccurate. In addition, the ability for parents to view glucose values and offer input to school personnel is an added benefit of CGM use in the school setting. For children using hybrid closed-loop systems, school personnel should also be informed on how to use and troubleshoot this equipment [87–89].

Children with diabetes should have a school health plan in place. The health plan should include contact information for the child's family as well as their diabetes care providers. It should also contain information regarding routine management of diabetes (blood glucose monitoring, insulin administration and dosing, snack times) and an emergency plan for management of hypoglycaemia and hyperglycaemia. Issues specific to insulin pumps include remembering to activate insulin bolus with food, disconnecting the pump during vigorous exercise or in the event of severe hypoglycaemia, pump failures, and pump alarms.

Extracurricular activities are an important component of a child's school experience and children with diabetes should be allowed to participate and have their needs accommodated accordingly. Field trips, field days, and overnight trips often require advanced planning, but a child's diabetes should never be a cause for exclusion from any school-sanctioned activity. Cognitive abilities of youths may be affected by hypo- or hyperglycaemia. Therefore, accommodations to allow for safe testing are important, including allowing the young person to check their blood glucose without penalty, the ability to treat dysglycaemia, and allowing the child to carry the equipment necessary to manage their diabetes in an easily accessible fashion [87–89].

Finally, it is important that children and adolescents and their families are aware that the diagnosis of diabetes confers legal protection where they are not excluded from the general education system; can access inclusive, quality, and free education consistent with their peers; and the educational environments should be maximized to support academic and social development [90].

Insulin treatment

The overarching goal of insulin replacement is to provide just enough insulin at an appropriate time to provide sufficient basal insulin levels as well as higher insulin levels after meals [91]. The choice of insulin regimen depends on the individual's age, duration of diabetes, dietary and activity patterns, ability to cope, and metabolic targets. Broadly, the three forms of insulin delivery include multiple daily injections (MDI), insulin pumps, and hybrid closed-loop insulin pumps. Hybrid closed-loop pumps, where sensor data are integrated in real time to inform insulin delivery and automatic modulation of basal insulin, have shown improvements in glycaemic indices and quality-of-life outcomes [92–99]. In general, insulin pump or hybrid closed-loop systems are associated with improved glycaemic outcomes when compared to MDI regimens. As noted earlier, children from low socioeconomic or racial and ethnic minority backgrounds are more likely to use MDI than insulin pumps. Providers should offer diabetes technology to all young

people with diabetes and family preferences should be the drivers to initiate regimens other than MDI [100–102].

Subcutaneous insulin injection regimens

A basal bolus regimen is the preferred method for MDI regimens delivered via insulin pens or syringe and vial. Approximately 40% of the total daily dose is basal insulin analogue (e.g. glargine, detemir) and multiple doses a day with rapid-acting insulin analogue (lispro, aspart, apidra) 10–15 minutes before each meal. It is preferred that the rapid-acting insulin delivered is calculated for each meal based on the insulin sensitivity factor to correct for hyperglycaemia and carbohydrate coverage. Fixed dosing of insulin per meal is not the preferred method, as it does not appropriately match the carbohydrate intake with insulin administration, resulting in an increased risk for both hyperglycaemia and hypoglycaemia after meals. It is notable that children and adolescents from minority racial/ethnic and low socioeconomic groups are more likely to be prescribed fixed dosing despite the fact that it is suboptimal [18]. Alternate forms of teaching mealtime bolus calculations or incorporating insulin pumps may be considered in place of fixed dosing. If there is concern about inconsistent basal dose administration, insulin degludec has a longer half-life than glargine (up to 72 h vs 20–24 h, respectively) and may be considered in the regimen in place of glargine or detemir.

Historically, alternative injection regimens including intermediate-acting insulin have been used, but are not recommended due to poorer HbA_{1c} outcomes. Intermediate-acting insulins include neutral protamine Hagedorn (NPH), which is often given twice daily, and have greater inter- and intra-individual variability than the long-acting insulin analogues. These regimens include:

- Intermediate-acting human insulin twice daily and soluble human insulin 20–30 minutes prior to each meal.
- Two injections daily of a mixture of short- or rapid- and intermediate-acting insulin before breakfast and before the evening meal.
- Three injections using some variation of the following: a mixture of short- or rapid- and intermediate-acting insulin before breakfast, rapid or soluble human insulin before the afternoon snack or evening meal, and intermediate or basal/long-acting insulin before bed.

Insulin types

The pharmacokinetics of insulin analogues vary by insulin type (Figure 69.2). Basal insulin analogues include glargine, which lasts for 20–24 hours; detemir, which lasts between 6 and 23 hours and is often given as twice-daily injections (Chapter 31); and degludec, which can last up to 72 hours [104]. Common rapid-acting insulin analogues include aspart, lispro, and glulisine, which are given before a meal and to treat hyperglycaemia. Faster acting insulin aspart (Fiasp) is considered an ultra-rapid-acting insulin which has a slightly faster onset of action as well as a shorter duration of action. Regular human insulin is a short-acting insulin that has a longer onset of action and later peak of action, but is still used commonly in many places around the world. Intermediate-acting insulins, such as NPH, are often mixed with soluble human (regular) or rapid-acting analogues (aspart, lispro, or glulisine). If children are using needles and syringes in place of insulin pen devices, they and their families should be taught how to mix the insulin properly to avoid contamination. It is generally taught to draw up the clear (regular or short-acting) insulin before drawing up cloudy insulin (NPH). As per the manufacturer's instructions, glargine or detemir insulins should not be mixed with any other insulin.

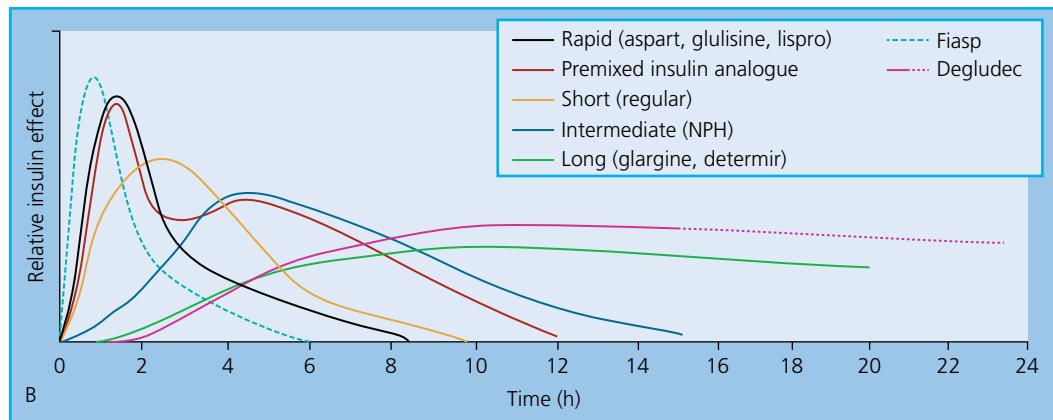

Figure 69.2 Pharmacokinetics of insulin. NPH, neutral protamine Hagedorn. Source: Data from Sperling 2020 [103].

Premixed insulins contain a mixture of regular (or rapid-acting) insulin and NPH insulin in various fixed ratios. These preparations may be useful for children who do not want to draw insulin from separate vials prior to injecting or due to cost restrictions. They may also be useful in reducing the number of injections when adherence is an issue, especially among teenagers. Premixed insulins are available for use in pen injector devices. The main disadvantage to using premixed insulin preparations is the lack of flexibility in adjusting the separate insulin doses, which is often necessary with varied food intake or during illness or exercise.

Insulin pump therapy

Insulin pump therapy is the best way to restore the body's physiological insulin profile. The pump delivers a variable programmed basal rate that corresponds to the diurnal variation in insulin needs. Prepubertal children require a higher basal rate in the early part of night, while postpubertal adolescents who experience the *dawn phenomenon* require higher rates in the morning. Two major types of insulin pumps have emerged: conventional insulin pumps (which do not incorporate CGM data) and hybrid closed-loop systems (which incorporate CGM data in real time and adjust insulin based on algorithms).

Conventional insulin pumps

The user initiates bolus doses before meals and to correct hyperglycaemia. Most pumps can receive wireless transmission of test results from glucose meters, but the child or caregiver must still manually enter the amount of carbohydrate being consumed. The pump calculates the amount of insulin needed for a meal or correction based on previously entered variables, which include insulin-to-carbohydrate ratios, insulin sensitivity factor, glycaemic target, and duration of insulin action (set at 2–8 h to estimate the duration of insulin in the body). The user may accept or override the suggestion.

Rapid-acting insulin analogues perform better in pumps than soluble human insulin, both in terms of mimicking the first-phase insulin release after meal and avoidance of post-prandial hypoglycaemia. Even with the analogues, however, insulin has to be administered at least 10–15 minutes before meals to reach effective levels to limit post-prandial glucose elevations. A longer lead time may be needed if pre-prandial blood glucose is higher than 150 mg/dl (8.3 mmol/l). Young children, picky eaters, and those with a lack of organisation may struggle with these requirements. In addition, children are often unable to predict the size of the meal. In these cases, one may administer half of the usual meal bolus in advance, with the other half, if needed, after the meal. Adherence problems

include infrequent blood glucose testing, not reacting to elevated blood glucose, incorrect carbohydrate counting, or missing boluses altogether.

Children and their families must be instructed on troubleshooting and treatment of hyperglycaemia, particularly if ketones are present, as this may be an indication of a pump malfunction. If the flow of insulin becomes interrupted, ketonaemia will develop within four hours; this is particularly dangerous at night as there is no long-acting insulin on board. Syringes or insulin pens should always be available so that insulin may be administered via injection in the event of a pump failure.

Most clinical trials have demonstrated better HbA_{1c} and less severe hypoglycaemia with pump therapy, compared with MDI. Pump therapy can improve the quality of life in children who have trouble with injections or who desire greater flexibility in their lifestyle (e.g. with sleeping in, sports, or irregular eating). Insulin pumps can be particularly helpful in young children or infants who have multiple meals and snacks and require multiple small doses of rapid-acting insulin. The newer generation of insulin pumps can deliver as little as 0.025 units/h, but higher rates using diluted insulin may be needed for uninterrupted flow. Currently the most frequent complications of insulin pump treatment include failures of insulin delivery because of a displaced or obstructed infusion set, local skin infections, and DKA. Insulin pump treatment is significantly more expensive than regimens based on injections.

Hybrid closed-loop systems

Hybrid closed-loop insulin pumps integrate CGM glucose data with insulin pumps in order to modulate the basal insulin delivered in response to glucose values and glucose trends. Excepting this incorporation of glucose data to basal rates, the remaining considerations are as discussed for conventional insulin pumps, including understanding how to give mealtime boluses, troubleshooting hyperglycaemia, and recognizing pump site failures. At present, two hybrid closed-loop systems are US Food and Drug Administration (FDA) approved and more are expected in the future. The benefits of hybrid closed-loop systems include benefits of basal modifications to increase time in range and improve HbA_{1c} [92–99]. In addition, the use of hybrid closed-loop systems is associated with improvements in quality of life and psychosocial outcomes. As more hybrid closed-loop systems are approved, the uptake and use of these system are expected to increase. Consistent with disparities seen in diabetes technology use at large, there exists concern that disparities in hybrid closed-loop systems are also emerging by race or ethnicity and socioeconomic status.

Future of insulin pumps

Fully closed-loop systems, allowing the insulin pump to be directed automatically by a CGM with minimal human input, are being tested. The goal of a closed-loop or automated insulin delivery is to allow for minimal input from the young person or parent to maintain target glucose levels. There is a particular interest in the automated system accounting for unannounced boluses in a fashion that maintains euglycaemia. Dual-hormone systems that include both glucagon and insulin in the regulation of glucose levels are being studied [105].

Nutrition

Nutritional management in children with diabetes remains a key component of diabetes care and education; a paediatric dietitian should be part of the diabetes care team. Carbohydrate counting is the foundation of nutrition education in type 1 diabetes in order to approximate insulin boluses. In addition, a key strategy should be prevention of overweight and obesity. The management does not require a restrictive diet, just a healthy dietary regimen from which the children and their families can benefit. Current guidelines target optimal glycaemic indices, reduction of cardiovascular risk, psychosocial well-being, and family dynamics [89, 106]. A thorough dietary history should be obtained, including the family's dietary habits and traditions, the child's typical meal times, and patterns of food intake. Weight loss or poor weight gain may be a sign of illness (such as infection, coeliac disease, or hyperthyroidism), insulin omission, or disordered eating [89, 106, 107].

Insulin pump and MDI therapy utilize carbohydrate counting in which the grams of carbohydrate to be eaten are counted and a matching dose of insulin is administered. This plan allows for the greatest freedom and flexibility in food choices, but it requires expert education and commitment and may not be suitable for many families or situations (e.g. school lunches, teenagers). Books and apps are now available to help calculate carbohydrate intake more accurately. Less preferred methods of accounting for carbohydrates include carbohydrate exchanges or consistent carbohydrate meal plans, as they are less flexible. Exchange planning teaches that it is not necessary to count precise grams. Exchanges are taught as either 10 or 15g servings of carbohydrate. The exchange plan can enable a more consistent daily intake of carbohydrate. The constant carbohydrate meal plan was used often in the past with insulin regimens based on NPH and regular insulin, where carbohydrate intake and the amount of insulin were kept relatively constant from day to day. It has been perceived as too restrictive and a potential source of conflict.

The concept of the glycaemic index has been shown to provide additional benefit to glycaemic management (Chapter 27). Low glycaemic index carbohydrate foods, such as wholegrain breads, pasta, temperate fruits, and dairy products, may lower post-prandial hyperglycaemia. A glycaemic load approach to predicting the post-prandial blood glucose response, based on the glycaemic index of the food and the portion size, has not been fully explored in children. With the rising rates of obesity, dietary changes to combat obesity and insulin resistance are of greater interest. However, data are limited on the impact of diets on glycaemic indices and weight management in the young person with type 1 diabetes. For example, while low-carbohydrate diets have been effective in weight management for adults with diabetes, concern exists about the impact on growth and development and they are not currently rec-

Table 69.3 Principles of dietary planning in children with diabetes.

Eat a well-balanced diet, with daily energy intake distributed as follows:
Carbohydrate 45–55% (sucrose intake up to 10% total energy)
Fat 30–35% (<10% saturated fat + trans fatty acids)
Protein 15–20%
Importance of routine mealtimes with limitations on snacking
Incorporate healthy snacks if necessary to maintain a healthy weight or prevent binge eating
Use snacks to prevent and treat hypoglycaemia, but avoid overtreatment
Snacks should be used in moderation to avoid excess calorie intake
Most children will have a mid or late afternoon snack
Modern insulin regimens reduce the need for daytime and bedtime snacks required by traditional insulin profiles
Gauge energy intake to maintain appropriate and healthy weight and body mass index
Overinsulinization, forced snacking, and excess food intake to prevent or treat hypoglycaemia promote excessive weight gain and should be avoided
Eating disorders are common in teenagers with diabetes, particularly girls
Recommended fibre intake for children older than 1 year: 3.3 g/MJ; children older than 2 years should eat (age in years + 5) g/d fibre
Avoid foods high in sodium that may increase the risk of hypertension; target salt intake to less than 4 g/d (sodium chloride)
Avoid excessive protein intake (athletes should not require protein supplements)
Protein requirements after infancy are approximately 1 mg/kg/d and 0.9 mg/g/d in adolescence
Excessive carbohydrate restriction are not recommended for children and adolescents with type 1 diabetes due to deleterious effects on growth, increased cardiovascular disease, and the risk of disordered eating behaviours
Children with diabetes have the same vitamin and mineral requirements as other healthy children; however, hypovitaminosis D is common and screening and supplementation are recommended
There is no evidence of harm from an intake of artificial sweeteners in doses not exceeding acceptable daily intakes
Specially labelled diabetic foods are not recommended because they are not necessary, are expensive, are often high in fat, and may contain sweeteners with laxative effects. These include the sugar alcohols such as sorbitol
While alcohol intake is generally prohibited in adolescents, teenagers continue to experiment with and sometimes abuse alcohol. Alcohol may induce prolonged hypoglycaemia in young people with diabetes (up to 16 h after drinking)
Carbohydrate should be eaten before, during, and/or after alcohol intake. It may also be necessary to lower the insulin dose, particularly if exercise is performed during or after drinking (e.g. dancing)

ommended in children with diabetes [108, 109]. Helpful principles foundational to a healthy diet for children with diabetes are shown in Table 69.3.

Exercise

Children with diabetes derive the same health and leisure benefits from exercise as children without diabetes and they should be allowed to participate with equal opportunities and equal safety [106]. Current guidelines recommend 60 minutes of moderate to vigorous activity for youths with type 1 diabetes, yet most children do not meet these guidelines [106]. Numerous barriers exist with regard to the dual management of type 1 diabetes and exercise, such as fear of hypoglycaemia and dysglycaemia [110–112].

Physiologically, during exercise in children without diabetes there is a decrease in pancreatic insulin secretion and an increase in

counter-regulatory hormones, resulting in an increase in liver glucose production (Chapter 28). This matches skeletal muscle uptake of glucose during exercise, maintaining stable blood glucose concentrations under most conditions. In children with type 1 diabetes, there is no pancreatic regulation of insulin in response to exercise and there may be impaired counter-regulation. These factors combine to increase the risk of hypoglycaemia and hyperglycaemia during exercise. It is helpful to keep an exercise record noting the most recent insulin dose, timing and type of exercise, blood glucose levels before and after exercise, snacks eaten, and the time of any episode of hypoglycaemia. Factors affecting the glycaemic response to exercise include exercise duration, exercise type, timing and intensity of activity, overall metabolic and glucose management, type and timing of insulin injections and its absorption, type and timing of food, muscle mass and conditioning, and degree of stress or competition [26, 106].

Preventing hypoglycaemia

There are numerous strategies to prevent exercise-related hypoglycaemia, such as order of exercise intensity, insulin adjustments, and carbohydrate intake. Blood glucose levels should be checked before, during, and after the exercise. Target glucose level before the start of exercise is >5 mmol/l or >90 mg/dl. If glucose levels are below target, it is recommended to ingest 10–20 g of carbohydrates and delay exercise until glucose values are in target [106, 107, 113].

Timing of exercise type

The timing of exercise intensity (aerobic vs anaerobic) can be one strategy to optimize glycaemic levels during exercise

(Figure 69.3) [106]. Anaerobic exercises, such as short sprints or weight lifting, are associated with a rise in glucose values during exercise followed by delayed hypoglycaemia. In contrast, aerobic exercise, such as cycling or long-distance running, results in lowered glucose values both during and after exercise. The blood glucose prior to exercise initiation can inform the order of exercise type. For example, if the blood glucose value prior to exercise initiation is above target, youths can start with aerobic exercise followed by anaerobic. If blood glucose values are in target at the start of exercise, resistance or anaerobic exercise followed by aerobic exercise is thought to optimize glucose stability during exercise.

Insulin modification

Another strategy to combat exercise-related hypoglycaemia is insulin dose modification. Reduction of basal insulin 45–90 minutes in advance of activity informed by exercise duration and intensity can be achieved in those using insulin pumps [113]. For example, 30 minutes of mild aerobic exercise can be accompanied by a 25% basal reduction, whereas heavy aerobic exercise would warrant a 75% basal reduction. In contrast, 30 minutes of intense anaerobic exercise does not warrant a pre-exercise decrease in basal insulin [113]. For those who do not use insulin pumps, the long-acting insulin should be reduced the evening before a day of intense physical activity [106, 107]. A 25–50% reduction of mealtime boluses before or after exercise can also be incorporated to prevent exercise-related hypoglycaemia. For exercise anticipated within the first hour after eating, the dose of rapid-acting insulin before the meal may need to be decreased by 25–75% (depending on the intensity of the exercise). For evening exercise, reduction of the evening meal

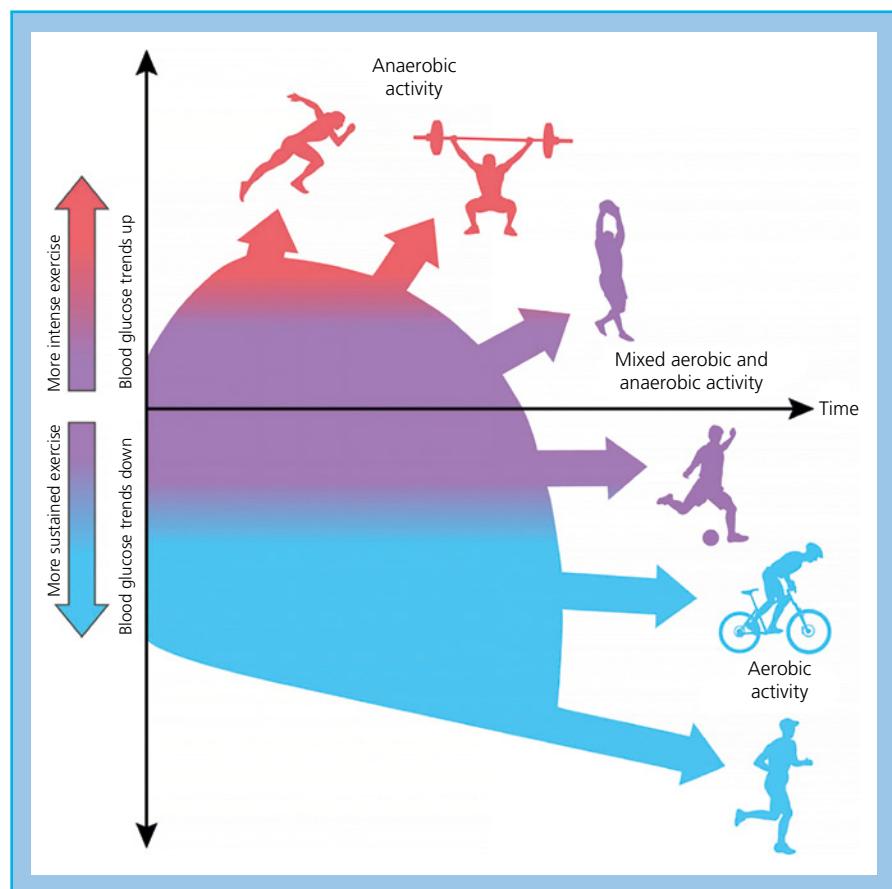

Figure 69.3 Impact of glucose trends by exercise intensity type. Source: Reproduced by permission from Adolfsson et al. 2018 [106].

Part 11 Diabetes in Special Groups

rapid-acting insulin by 25–75% as well as ingesting 10–15 g of fast-acting carbohydrate before the activity can help avoid hypoglycaemia [106, 113]. If the young person needs to disconnect from the pump in order participate in an activity, they can do one of the following:

- Bolus part of the basal insulin missed prior to exercise (particularly if the pre-exercise blood glucose level is elevated) and the remainder administered after exercise.
- Bolus half of the insulin missed while disconnected after exercise.
- Bolus all of the insulin missed while disconnected after exercise.

In general, the pump should not be disconnected for longer than two hours. If necessary, the pump should be reconnected briefly and a bolus administered prior to disconnecting again. New technologies with low glucose suspend may help with decreasing risk of hypoglycaemia during and after activity. Reduction of insulin in contrast to ingestion of carbohydrates to prevent hypoglycaemia has added benefit for weight.

The site of insulin injection should also be taken into account. Exercise increases blood flow in the part of the body being used, increasing insulin absorption if that area is where the insulin injection was administered. For example, the insulin dose should not be administered in the legs prior to running.

Carbohydrate intake Carbohydrate consumption prior to, during, and after exercise can be utilized to avoid and treat hypoglycaemia. In order to avoid unnecessary carbohydrate and calorie intake, which is associated with obesity and weight gain, insulin modification and timing of exercise intensity are more effective for weight management. For short-duration activity, sports drinks with simple sugars provide optimal absorption and usually prevent hypoglycaemia for the next 30–60 minutes. For activity of longer duration, solid foods containing carbohydrates that are digested more slowly should be consumed in addition to a liquid with simple sugars. Extra snacks should always be available to the child during exercise.

The child's coaches and teammates or other responsible adults and peers should be aware of the signs and symptoms of hypoglycaemia.

Delayed hypoglycaemia

Hypoglycaemia can occur up to 24 hours after exercise secondary to increased glucose transport into the skeletal muscle, the late effect of increased insulin sensitivity, and the delay in replenishing liver and muscle glycogen stores. Blood glucose levels must be monitored for several hours following exercise, at bedtime, and sometimes during the night on days with strenuous exercise. Utilization of CGM with exercise allows for prediction of blood glucose with trend arrows and detection of hypoglycaemia during and after exercise without finger-stick blood glucose checks. Consider a longer-lasting snack (containing a solid carbohydrate, protein, and fat) at bedtime and reducing the insulin dose, as discussed earlier.

Ketones and exercise

In situations of insufficient insulin intake or increased insulin resistance, whether it be from poor glycaemic management or from illness, exercise may be dangerous because of the effect of uninhibited action of the counter-regulatory hormones. Children with diabetes should not participate in strenuous exercise if the pre-exercise blood glucose level is high ($>250 \text{ mg/dl}$, $>14 \text{ mmol/l}$) and urine ketones (small or more) or blood ketones ($\geq 0.5 \text{ mmol/l}$) are present. Treat ketones and postpone exercise until ketones have cleared (Figure 69.4) [106].

Hypoglycaemia

Hypoglycaemia is the most common acute complication in the treatment of type 1 diabetes and severe hypoglycaemia is responsible for a significant proportion of deaths in people with diabetes

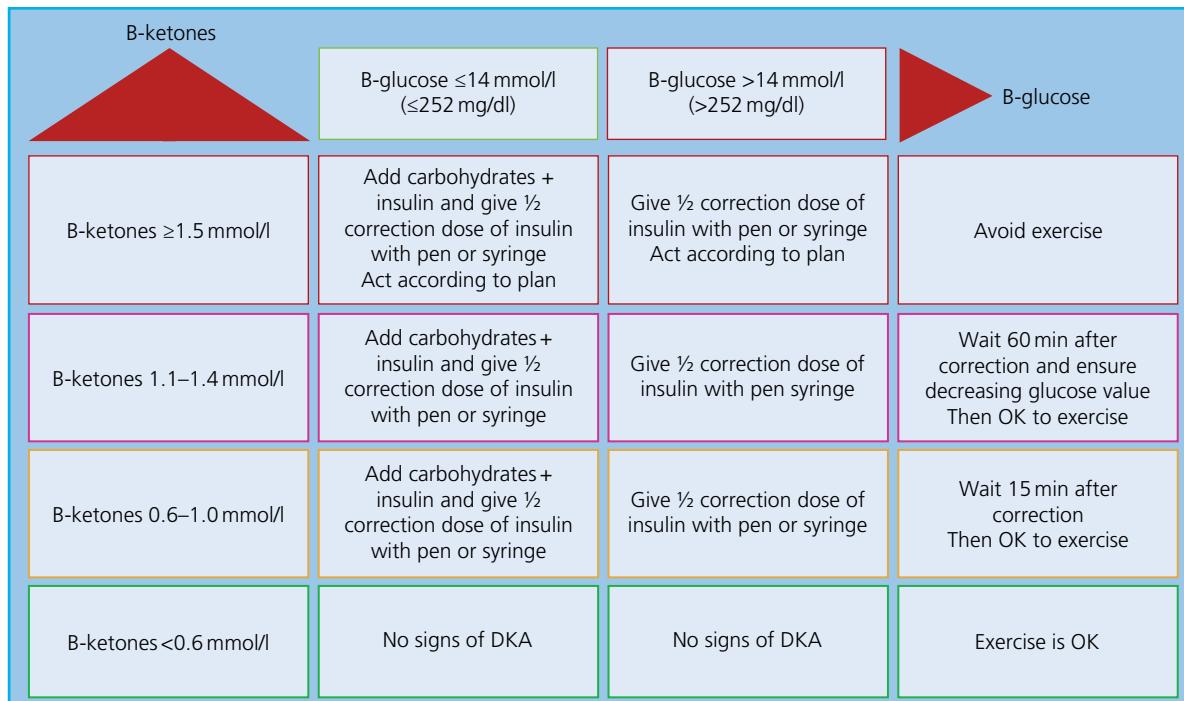

Figure 69.4 Glucose, ketone, and exercise considerations. B-glucose, blood glucose; B-ketones, blood ketones; DKA, diabetic ketoacidosis.
Source: Reproduced by permission from Adolfsson et al. 2018 [106].

aged <40 years (Chapter 40) [114]. According to the most recent guidelines published by ISPAD, hypoglycaemic events can be thought of in three tiers. At the least severe, it recommends a clinical hypoglycaemia alert threshold at 70 mg/dl (3.9 mmol/l). Treatment should be initiated at this level due to the risk of a further drop in blood glucose level. A level below 54 mg/dl (3.0 mmol/l) is considered clinically important or serious hypoglycaemia; at this level children may experience a defective response by counter-regulatory hormones as well as impaired awareness. Rather than by a specific blood glucose threshold, severe hypoglycaemia is defined by the presence of significant cognitive impairment requiring assistance from another person to administer oral glucose, glucagon, or other intervention [79, 114]. Severe hypoglycaemia occurs in approximately 6% of persons with diabetes, although less severe hypoglycaemia occurs much more frequently [115]. The largest risk factors for severe hypoglycaemia are lower socioeconomic status and race, while younger age, longer diabetes duration, lack of private health insurance, and multiple daily injections also increase the risk [115].

While lower HbA_{1c} has historically been considered a risk factor for hypoglycaemia, continuing improvements in diabetes technology, including CGM, insulin pumps, and hybrid closed-loop systems, have made it increasingly possible to maintain an appropriately intensive insulin treatment and target HbA_{1c} without significantly increasing hypoglycaemic events [97, 116–118]. Longitudinal studies in Australia and Germany showed a simultaneous decrease in both average HbA_{1c} and severe hypoglycaemic events over a 20-year period [119]. Use of CGM and automated insulin delivery systems with predicted low glucose suspend reduce time spent in hypoglycaemia [78, 98].

Signs and symptoms

Signs and symptoms of hypoglycaemia are as follows:

- *Autonomic signs and symptoms*: shakiness, palpitations, sweating, pallor.
- *Neuroglycopenic signs and symptoms*: difficulty concentrating, blurred or double vision, disturbed colour vision, difficulty hearing, slurred speech, poor judgement and confusion, problems with short-term memory, dizziness and unsteady gait, loss of consciousness, seizure, death.
- *Behavioural signs and symptoms*: irritability, erratic behaviour, nightmares, inconsolable crying.
- *Non-specific symptoms*: hunger, headache, nausea, tiredness.

Early warning signs and symptoms of hypoglycaemia are much more difficult to identify in young children.

Treatment

In mild or moderate symptomatic hypoglycaemia, after documenting a blood glucose of ≤70 mg/dl (3.9 mmol/l):

- Provide immediate oral, rapidly absorbed 5–15 g glucose or sucrose: glucose tablets, Smarties, or 100 ml of a sweet drink (juice, soda).
- Retest blood glucose in 10–15 minutes. If no response or inadequate response, repeat as above.
- As symptoms improve and euglycaemia is restored, ingest a solid snack or a meal (e.g. fruit, bread, cereal) to prevent recurrence.
- Retest blood glucose in 20–30 minutes to confirm that target glucose has been maintained.

In severe hypoglycaemia, where the child has an altered mental status and is unable to assist in their care, may be unconscious, and/or is seizing, urgent treatment with parenteral glucagon or dextrose is required.

Glucagon

Rescue glucagon is given intranasally, intramuscularly, or subcutaneously (10–30 µg/kg body weight):

- 0.5 mg for those <12 years.
- 1 mg for those >12 years or >45 kg.

Traditional formulations of glucagon were not stable in solution and thus required that the caregiver mix glucagon powder with saline prior to injection. Recently, both premixed glucagon injection pens as well as intranasal glucagon [120] have become available in the USA, making emergency administration more accessible for the average caregiver. Glucagon administration may be repeated in 5–10 minutes if the response was inadequate; however, it is likely to be ineffective after prolonged fasting. Side effects include vomiting and tachycardia.

Mini-dose glucagon

As an alternate to a full rescue dose of glucagon, typically used in settings of severe hypoglycaemia, mini-dose glucagon also has utility in some clinical scenarios. Mini-dose glucagon has the largest utility in achieving euglycaemia in the setting of mild or impending hypoglycaemia, typically in the setting of a concurrent illness (nausea, vomiting, diarrhoea) or inadequate oral carbohydrate intake or absorption [121, 122]. In such settings, mini-dose glucagon should be given as a subcutaneous injection with an insulin syringe, and can be repeated every 2–4 hours. It is estimated that 1 unit on the insulin syringe is equal to approximately 10 µg of glucagon and individuals are dosed 1 unit/year of age, with a maximum of 15 units (~150 µg) and a minimum of 2 units (~20 µg) in children <2 years of age.

Dextrose

Dextrose can be given intravenously by trained medical staff if glucagon is unavailable or recovery is inadequate in a hospital setting or by paramedics:

- Intravenous dextrose should be administered slowly over several minutes (e.g. dextrose 10% at 2–3 ml/kg).
- Rapid administration or higher concentration may result in an excessive rate of osmotic change, phlebitis, and extensive tissue damage, if extravasated.

Close observation and monitoring of blood glucose are essential because vomiting is common in response to glucagon and hypoglycaemia may recur. Severe headache and transient paresis lasting up to 24 hours are not uncommon, but generally do not require radiological work-up.

Hypoglycaemia unawareness

Hypoglycaemia unawareness occurs when there is reduced awareness of the onset of hypoglycaemia, typically due to a blunted response of counter-regulatory hormones in the setting of recurrent hypoglycaemic events. A single hypoglycaemic episode can lead to hypoglycaemia unawareness secondary to a decrease in counter-regulatory responses, but it is usually seen in children who have multiple periods of blood glucose <70 mg/dl (3.9 mmol/l). Avoiding subsequent hypoglycaemia for 2–3 weeks may reverse this loss of awareness, although these changes can persist for months or years in some individuals [123].

Prevention

Hypoglycaemia occurs more frequently:

- When the treatment regimen or lifestyle is altered (increased insulin, less food, more exercise).
- In younger children.
- With lower HbA_{1c} levels.

- With previous severe hypoglycaemia.
- When there is hypoglycaemia unawareness.
- During sleep.
- After alcohol ingestion.

Children and families should be aware of these risk factors so that glucose monitoring and insulin regimens can be changed accordingly. There is an increased risk for hypoglycaemia during, immediately after, and up to 24 hours after exercise. Untreated coeliac disease and hypoadrenalinism (Addison disease) may also increase the risk of hypoglycaemia, and should be screened for in individuals with recurrent, severe, or unexplained hypoglycaemia.

Nocturnal hypoglycaemia is often asymptomatic and should be suspected if the morning blood glucose is low and/or there are episodes of confusion, nightmares, or seizures during the night, or if there is impaired thinking, altered mood, or headaches on awakening. Nocturnal hypoglycaemia can be confirmed with blood glucose monitoring during the night and may be prevented by including more protein and fat in the bedtime snack. Care should be taken that this does not occur at the expense of high overnight blood glucose levels.

There is an association between hypoglycaemia and decrease in cognitive functioning in children with type 1 diabetes, particularly in children diagnosed before the age of 5–6 years. Recurrent severe hypoglycaemia has been associated with worsened long-term memory, attention, and verbal IQ, but studies have been inconsistent. Severe hypoglycaemia can increase worry for the parent and the person with diabetes, and lead to poor sleep, emergency room visits, hospitalizations, excessive lowering of insulin doses, and subsequent worsening of glycaemic measurements. Long-term follow-up of the Diabetes Control and Complications Trial (DCCT) participants has been reassuring that there was no evidence for permanent neurocognitive changes related to hypoglycaemia in adolescents and young adults, suggesting that the effect of severe hypoglycaemia on long-term neuropsychological functioning may be age dependent [124]. Conversely, hyperglycaemia causes changes in functional magnetic resonance imaging (fMRI) and neurological testing, further underlining the importance of optimizing time spent in euglycaemia [125, 126].

Ultimately, hypoglycaemia is frequently predictable and should be prevented. Children and their caregivers must be taught to recognize the symptoms of hypoglycaemia and treat them immediately and appropriately. Children with diabetes should always carry around a source of rapid-acting glucose and should wear identification noting that they have diabetes. The diabetes care provider should be notified if a child is having recurrent episodes of symptomatic hypoglycaemia or if there is hypoglycaemia unawareness. This will facilitate discussions to adjust insulin regimens, food intake patterns, blood glucose goals, and monitoring. CGM helps detect and avoid hypoglycaemia and the use of hybrid closed-loop insulin pumps with predicted low glucose suspend can also prevent hypoglycaemia by decreasing insulin infusion rates based on the rate and degree of blood glucose decreases [93–96, 98].

Sick-day management

Children with diabetes in good metabolic measures should not experience more illness or infections than children without diabetes; however, they will go through their share of routine infections, which can be challenging for their caregivers. In addition to routine childhood immunizations, influenza, meningococcal, and pneumo-

monia vaccines are recommended for all children with diabetes. When children with diabetes become ill, the underlying precipitating illness should be treated promptly.

Healthcare providers should equip families soon after diagnosis with the tools necessary to avoid dehydration, uncontrolled hyperglycaemia or ketoacidosis, and hypoglycaemia. Face-to-face education and written instructions are important, but most parents require telephone advice when first facing sickness in their child and some may need repeated support. Over time, most parents should be able to manage sick days independently as well as identify appropriate times to seek help from their diabetes provider or emergency services. Children and their families should immediately seek medical attention if:

- Blood glucose concentrations continue to rise despite extra insulin.
- Blood glucose concentrations remain persistently below 70 mg/dl (3.5 mmol/l).
- Blood ketones are higher than 1.5 mmol/l or ketonuria is severe and persistent.
- The child becomes exhausted, confused, dehydrated, or develops difficulty in breathing, severe abdominal pain, or a severe hypoglycaemic reaction.

Missed insulin injection, inactivated insulin, or interruption of insulin delivery from pump may lead to sick days as well, especially in older children. While treatment is essentially the same as for hyperglycaemia in the course of an infection, the differential diagnosis is important for prevention of recurrent events.

Hyperglycaemia is seen in many illnesses, particularly those associated with fever, as a result of elevated levels of stress hormones, which promote gluconeogenesis and insulin resistance. Severe illness increases ketone body production secondary to inadequate insulin action or insufficient oral intake of carbohydrates. By contrast, illnesses associated with vomiting and diarrhoea can lead to hypoglycaemia secondary to decreased food intake, poor absorption, and slower gastric emptying.

In general, during illness, blood glucose concentrations must be monitored more frequently – at least every 3–4 hours and more often when blood glucose concentrations are outside the target range (e.g. 80–200 mg/dl; 4.4–11.1 mmol/l). Urinary or blood ketones must be checked at least twice daily and more often if previously elevated or when blood glucose concentration exceeds 300 mg/dl (17.6 mmol/l). When available, blood ketones (β -hydroxybutyrate, using e.g. a Precision Xtra[®]/Xceed Pro[®] meter, Abbott Laboratories, Chicago, IL, USA) can provide more specific and timely assessment of ketosis compared to urine ketone testing:

- The presence of ketones when blood glucose concentrations are persistently elevated above 200 mg/dl (11.1 mmol/l) indicates the need for supplemental insulin and fluids.
- The presence of ketones when blood glucose concentrations are low or normal, especially during gastrointestinal illness, indicates insufficient oral intake of carbohydrates (starvation ketones). In this case, ketones do not reflect insulin deficiency, but rather a physiological response and may protect the child from severe hypoglycaemia, as β -hydroxybutyrate is the only alternative fuel to glucose for the brain. Supplemental insulin is contraindicated as it will likely cause hypoglycaemia; the correct treatment includes fluids with glucose.

Insulin therapy must never be stopped during a sick day, although the dose may need to be decreased if the child is vomiting or eating less than usual. A fasting child still requires approximately 40% of the usual daily insulin dose, as long-acting basal insulin, to cover

basic metabolic needs and prevent ketoacidosis; however, infections associated with normal food intake often require an increase of basal insulin by 10–15%. In addition, extra doses of rapid-acting insulin are usually needed to correct hyperglycaemia, prevent ketoacidosis, and avoid hospital admission. These doses may be repeated every 2–4 hours as needed based on the results of blood glucose and ketone monitoring.

An example of a typical management approach when ketonuria/ketonemia and blood glucose concentrations are greater than 200 mg/dl (11.1 mmol/l) includes:

- Usual high blood glucose correction, e.g. 1 unit of rapid-acting insulin for each 50 mg/dl (2.8 mmol/l) above 100 mg/dl (5.5 mmol/l), if blood ketones <0.6 mmol/l or urine ketones negative/small.
- Injection of rapid-acting insulin at 10% of the total daily dose, if blood ketones 0.6–1.5 mmol/l or urine ketones moderate or large.
- Injection of rapid-acting insulin at 10–20% of the total daily dose if blood ketones >1.5 mmol/l or urine ketones moderate or large.
- As acidosis is present in most children with hyperglycaemia and blood ketones >3.0 mmol/l, this warrants referral to an emergency department.

Children using insulin pumps who develop hyperglycaemia and moderate or large urine ketones (or ≥1.0 mmol/l blood ketones) must always consider the possibility of an interruption in insulin delivery. If blood glucose levels do not decrease appropriately after an insulin bolus from the pump, the correction bolus of short-acting insulin should be given as an injection and the pump infusion set should be changed. A temporary increase in the basal rate by 20% or more may be required until blood glucose concentrations begin to normalize and ketones clear.

If hypoglycaemia <70 mg/dl (<3.9 mmol/l) persists and the child is unable to tolerate any oral intake, an injection of mini-dose glucagon may reverse the hypoglycaemia and enable oral fluid intake to resume. This dose of glucagon is not to be used for the emergency treatment of severe hypoglycaemia.

Hydration status must be followed closely. Fever, hyperglycaemia with osmotic diuresis, and ketonuria all increase fluid losses. Households should maintain a supply of sugar and electrolyte-containing fluids:

- Oral water is sufficient to prevent dehydration in uncomplicated cases of hyperglycaemia.
- If there is an ongoing fluid loss from diarrhoea or vomiting, hydration liquids should contain salt in addition to water (e.g. Pedialyte®, Abbott Laboratories). These preparations contain 25–30 g/l glucose, 45–90 mEq/l sodium, 30 mEq/l bicarbonate, and 20–25 mEq/l potassium. Oral rehydration fluid can be made at home by mixing half of a flat teaspoon of salt (~3 g NaCl = ~50 mEq sodium), seven teaspoons of sugar (28 g), and (optionally) 100 ml of orange juice into 1 l water.
- If there is difficulty eating or keeping food down and the blood glucose is falling below 200 mg/dl (11.1 mmol/l), sports drinks should be administered. They contain fewer electrolytes but higher amounts of glucose (e.g. Gatorade® [PepsiCo., Purchase, NY, USA] contains 255 g/l glucose, 20 mEq/l sodium, 3 mEq/l bicarbonate, and 3 mEq/l potassium).
- If the blood glucose is falling below 100 mg/dl (5.6 mmol/l), fluids with a higher concentration of sugar are recommended (e.g. juice or non-carbonated regular soda containing approximately 70 g glucose per 100 ml). These fluids contain almost no sodium and are not appropriate in large amounts for children with diarrhoea.

The required volume of oral fluid replacement is the sum of maintenance volume, deficit, and ongoing losses. In practical terms, infants and toddlers with diabetes who have vomited more than twice or have multiple loose stools may need to be referred to an emergency department for evaluation and intravenous fluids. Those with milder symptoms can be given oral fluid therapy at home using small amounts (5 ml) of cold fluids every 5 minutes. Most children with vomiting can be successfully orally rehydrated with persistent gentle encouragement by the parents.

Use of antiemetic medication at home should be approached cautiously, especially in young children, as it may mask acute abdominal processes such as appendicitis, volvulus, or intussusception and may have significant adverse effects. Where appropriate, ondansetron can be used to contain vomiting in children who have been properly evaluated by a physician and selected older children presenting without abdominal pain.

Monitoring and goals of diabetes management

HbA_{1c} is the only measure of mid- to long-term glycaemic levels for which robust outcome data are available (Chapter 29). Elevated HbA_{1c} predicts long-term microvascular and macrovascular complications, but has its limitations. In the DCCT, an HbA_{1c} of 53 mmol/mol (7.0%) corresponded to a higher average blood glucose concentration (measured seven times a day) of 192 mg/dl (10.7 mmol/l) in the conventionally treated participants compared with 163 mg/dl (9.1 mmol/l) in those in the intensively treated group. Consequently, the same HbA_{1c} level conferred a significantly higher risk of microvascular complications and hypoglycaemia in the conventionally treated group compared with the intensively treated group. HbA_{1c} is only one of the measures of optimal glycaemic management, with other measures including documented hypoglycaemia, type of treatment, the person's age, and quality of life. Ideally, there should be 4–6 measurements/year in younger children and 3–4 measurements/year in older children.

Self-monitoring of blood glucose (SMBG) provides immediate and daily documentation of hyperglycaemia and hypoglycaemia, helps to determine immediate and daily insulin requirements, detects hypoglycaemia, and assists in its management. Blood glucose is best measured during the night, after the overnight fast, before meals, and two hours after a meal – typically 4–6 times a day. Blood glucose should also be measured in association with illness, exercise, and prior to driving a car. The frequency of SMBG is associated with improved HbA_{1c} in people with type 1 diabetes. Even with CGM, SMBG remains an important part of diabetes care.

Targets for HbA_{1c} and SMBG proposed by ISPAD [127] and the American Diabetes Association (ADA) [128] are summarized in Table 69.4.

Continuous glucose monitoring metrics

While HbA_{1c} has long been the gold standard marker of glycaemic management, there are limitations to HbA_{1c} , namely the inability to evaluate glycaemic excursions in real time and to measure glycaemic variability. While the correlation between SMBG and HbA_{1c} is established, an HbA_{1c} of 7.0% can have wide variability in mean glucose values [129]. In addition, variations in HbA_{1c} are reported by race and ethnicity. For these reasons, the time-in-range data offered by CGM are increasingly being used and are emerging as a very valuable tool in evaluating glycaemia.

Table 69.4 Biochemical targets of glycaemic management.

Targets	
HbA _{1c}	
DCCT standardized (%) ^a	<7.0%
IFCC (mmol/mol)	<58 mmol/mol
CGM	
Time in range	>70%
Hypoglycaemia	<4%
SMBG, mmol/l (mg/dl)	
Fasting or pre-prandial blood glucose	4–8 (70–145)
Post-prandial blood glucose	5–10 (90–180)
Bedtime blood glucose	6.7–10 (120–180)
Nocturnal blood glucose	4.5–9 (80–162)

These targets are intended as guidelines; each child should have their targets individually determined.

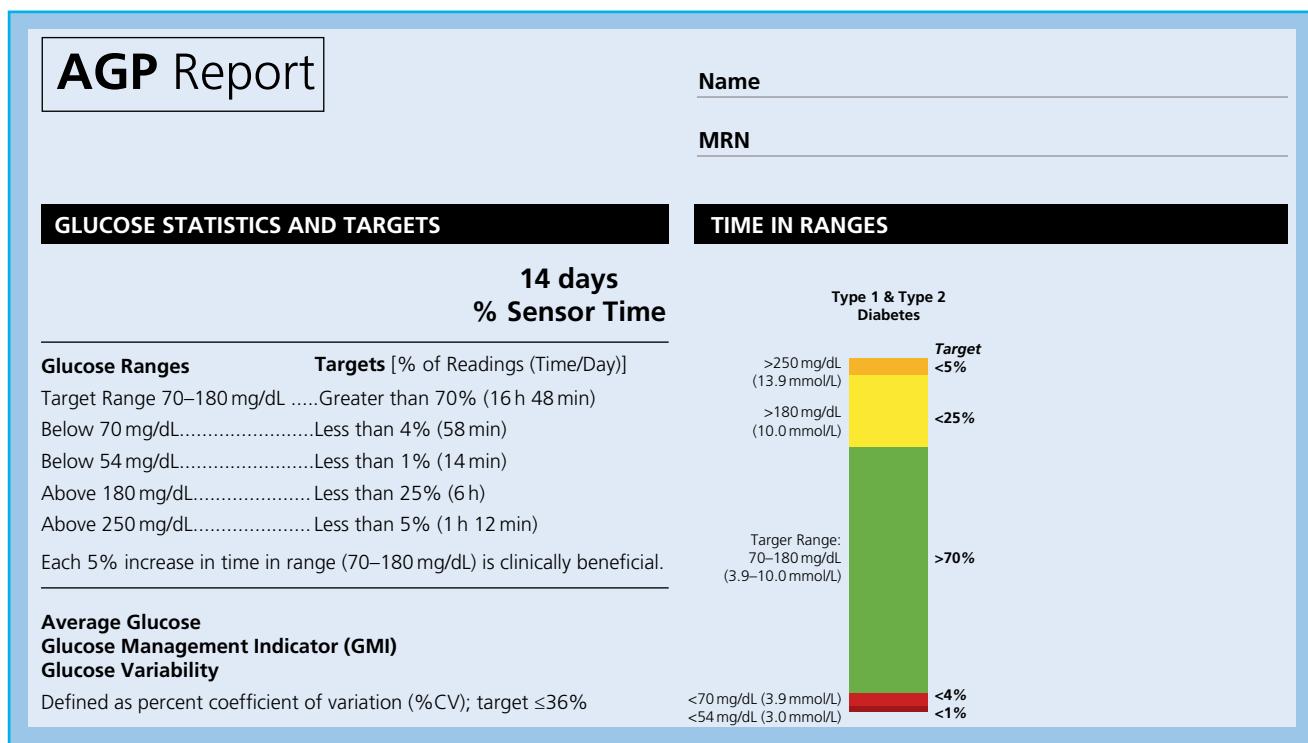

^a The DCCT conventional adult cohort had a mean HbA_{1c} value of 8.9% (74 mmol/mol). Both DCCT and Epidemiology of Diabetes Interventions and Complications (EDIC) have shown poor outcomes with this level. CGM, continuous glucose monitoring; DCCT, Diabetes Control and Complications Trial; HbA_{1c}, glycated haemoglobin; IFCC, International Federation of Clinical Chemistry; SMBG, self-monitoring of blood glucose.

crete period of time to assess glycaemic patterns and trends [128, 130]. The goal time in range (70–180 mg/dl; 3.9–10.0 mmol/l) is >70% and <4% time in hypoglycaemia (<70 mg/dl; <3.9 mmol/l) [114]. CGM targets are presented in Figure 69.5 [128]. An increase in time in range by 5% is associated with clinically significant benefit in diabetes outcomes [131, 132].

CGM is now becoming the gold standard for glucose management and is associated with improvements in diabetes-related outcomes [128, 130]. Specifically, improvements are seen in HbA_{1c} irrespective of type of insulin delivery (MDI or insulin pump) as well as a decrease in both hyper- and hypoglycaemia. In the last decade, with improvements in CGM technology including better accuracy and ease of use, CGM use has increased across the globe. However, although CGM use has increased in more-resourced countries, emerging data demonstrate disparities in CGM uptake: youths from low socioeconomic and racial and ethnic minority groups have the lowest CGM use [17, 133]. CGM uptake is lower in less-resourced countries. In these countries, meeting SMBG guidelines of ≥5 checks/day is challenging due to the limited availability of diabetes devices. For resource-limited countries, a tiered level of care to work towards establishing guidelines-based care has been published [134].

Psychological care

Psychosocial and behavioural factors play an important role in the management and outcomes of type 1 diabetes. Children and adolescents with type 1 diabetes are more frequently diagnosed with and treated for psychiatric disorders, disordered eating, and neurocognitive problems than the general population [107, 135]. In addition, many young people and their families face an increase in general and diabetes-specific stress due to the demanding nature of

type 1 diabetes management. The diagnosis of type 1 diabetes changes the lives of affected families and can pose lifelong challenges. Children with type 1 diabetes are at risk for adjustment disorder during the initial period after diagnosis (Chapter 63). For these reasons, routine and consistent psychosocial screening is recommended for all young people with type 1 diabetes to evaluate for symptoms of depression, diabetes distress, disordered eating, parental distress, and other psychosocial factors [107, 135]. In consort with standardized screening, an interdisciplinary diabetes health team, inclusive of mental health providers, should maintain regular contact with youths and their families.

Diabetes providers should be aware of diabetes-specific psychosocial concerns that can affect young people and their families, in addition to general mental health disorders such as depression and anxiety. Diabetes distress is defined as the emotional burden and worries that are inherent to the diagnosis and management of diabetes. Diabetes distress is common and persistent throughout the lifetime of an individual with type 1 diabetes and has adverse impacts on both HbA_{1c} and quality of life [136–138]. Addressing diabetes distress in addition to symptoms of depression, anxiety, and other mental health disorders is associated with an improvement in HbA_{1c} and quality-of-life measures [139–141]. Addressing psychosocial factors is also associated with an increase in diabetes technology uptake and improved diabetes self-management habits, which are independently associated with improved glycaemic and quality-of-life outcomes [107, 135, 142–144].

Finally, addressing psychosocial factors in low socioeconomic and minority race and ethnic groups who have a disproportionately larger burden of depression, diabetes distress, and other psychosocial concerns may be yet another way to bridge the disparities seen in paediatric type 1 diabetes management and outcomes.

Screening and early treatment of risk factors for complications and associated conditions

Dyslipidaemia

Cardiovascular disease is a leading cause of morbidity and mortality in adults with type 1 diabetes. Pre-clinical atherosclerosis often starts in childhood. While children with type 1 diabetes generally have a favourable lipid profile, this remains a major modifiable cardiovascular risk factor in this population. Screening for dyslipidaemia in children with type 1 diabetes should commence after diagnosis, once normoglycaemia has been established, in those older than 2 years of age [145]. If within the accepted risk level (low-density lipoprotein (LDL) $\leq 100 \text{ mg/dl}$; 2.6 mmol/l), lipids should be repeated at 9–11 years of age.

Per ISPAD and ADA guidelines [146, 147], children with LDL levels $>100 \text{ mg/dl}$ ($\geq 2.6 \text{ mmol/l}$) should optimize glucose management and follow dietary and lifestyle interventions. If LDL is 130 mg/dl ($\geq 3.4 \text{ mmol/l}$) and there is one or more cardiovascular risk factors, then statin therapy is recommended for children >10 years of age. Target LDL level is 100 mg/dl ($<2.6 \text{ mmol/l}$). Target high density lipoprotein (HDL) is $>35 \text{ mg/dl}$ ($>1.1 \text{ mmol/l}$) and triglycerides 150 mg/dl ($<1.7 \text{ mmol/l}$). Approved therapies for children include bile acid sequestrants and statins [145, 148, 149]. Bile acid sequestrants are not well tolerated and therefore the drugs are frequently not taken. Several short-term trials of statins have confirmed their safety and efficacy in children and adolescents with familial hypercholesterolaemia. If therapy with statins is under-

taken, regular monitoring of liver function and screening for symptoms of rhabdomyolysis should occur. Appropriate contraceptive advice should be given to girls receiving statins [149].

Microalbuminuria

Microalbuminuria is the first clinical manifestation of diabetic nephropathy and may be reversible with diligent glycaemic and blood pressure management [150]. Microalbuminuria is defined as any of the following:

- Albumin excretion rate $20\text{--}200 \mu\text{g/min}$, or $30\text{--}300 \text{ mg/24h}$ in 24 h urine collections.
- Albumin concentration $30\text{--}300 \text{ mg/l}$ (in early-morning urine sample).
- Albumin-to-creatinine ratio $2.5\text{--}25 \text{ mg/mmol}$ or $30\text{--}300 \text{ mg/g}$ (spot urine) in males and $3.5\text{--}25 \text{ mg/mmol}$ in females (because of lower creatinine excretion).

Screening for microalbuminuria with a random spot urine sample should occur annually in children when they begin puberty or are 10 years of age (whichever is earlier) and have had diabetes for more than five years. If values are increasing or borderline, more frequent screening should occur. For abnormal results, testing should be repeated. The diagnosis of microalbuminuria requires documentation of two abnormal samples out of three samples over a period of 3–6 months. Once persistent microalbuminuria is confirmed, non-diabetes-related causes of renal disease should be excluded and treatment started. Persistent microalbuminuria is associated with end-stage renal disease and increased risk of macrovascular disease. Treatment with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) should be started in the setting of persistent microalbuminuria, even if the blood pressure is normal [145]. Females of reproductive age should be counselled on the teratogenic effects of ACE inhibitors and ARBs and offered appropriate contraception as needed [151]. Children and their families should be counselled about the importance of optimal glycaemic management and smoking cessation if applicable. ARB blockers are not approved for use in children, but are occasionally used off-label.

Elevated blood pressure

Hypertension in adults with diabetes is associated with the development of both micro- and macrovascular disease. Treatment of blood pressure is critical in reducing these complications in adults and presumably in children and adolescents as well. Blood pressure should be checked and reviewed at each clinic visit. Hypertension is defined as systolic or diastolic blood pressure (measured on at least three separate days) above the 95th percentile for the child's age, sex, and height and target blood pressure is $<90\text{th}$ percentile. Care should be taken to ensure use of an appropriately sized cuff in children to avoid inaccurate readings. If elevated blood pressure is confirmed, non-diabetes causes of hypertension should first be excluded. Treatment includes lifestyle interventions and ACE inhibitors or ARBs if lifestyle fails [151].

Retinopathy

Adolescents have a higher risk of progression to severe non-proliferative or proliferative retinopathy compared to adults with diabetes, although there is a low risk of development <12 years of age [152, 153]. The first dilated ophthalmological examination should be obtained by a healthcare professional trained in diabetes-specific retinal examination once the child is ≥ 10 years old or at puberty (whichever is earlier) and has had diabetes for

3–5 years [147, 154]. The frequency of subsequent examination is generally every two years, but may be spaced to four years with a favourable individual risk profile and advice of an eyecare provider [151, 155].

Neuropathy

Although peripheral neuropathy is extremely rare in children with 1–2 years of diabetes, the SEARCH for Diabetes in Youth study found a 7% prevalence of peripheral neuropathy in children with type 1 diabetes [156]. Therefore children with diabetes should have an annual foot exam starting at age 10 years or the start of puberty (whichever is earlier) after the child has had diabetes for 5 years, including inspection and determination of monofilament sensation, as well as assessment of presence of neuropathic pain. This can also be an opportunity to begin to educate the young person on proper foot care [157].

Celiac disease

The prevalence of biopsy-confirmed coeliac disease in children with type 1 diabetes ranges from 1% to 10%, compared to <1% in the general population [154]. Clinical manifestations of coeliac disease can include delayed growth and puberty, decreased bone mineralization, abdominal pain, and abnormal liver function tests, which may overlap with those with persistent hyperglycaemia.

All children should be screened for immunoglobulin(Ig)A transglutaminase autoantibodies at the onset of diabetes and, if negative and asymptomatic, rescreened within two years of diagnosis and again after five years since diagnosis. Children with symptoms or a first-degree relative with coeliac disease may benefit from more frequent screening. If the transglutaminase autoantibodies are negative, but the child has symptoms and/or signs consistent with coeliac disease, other causes (e.g. hyperglycaemia, or intolerance of milk, soy, or salicylates) should be explored. If transglutaminase autoantibodies are strongly and persistently positive (radioimmunoassay index >0.5 or enzyme-linked immunosorbent assay [ELISA] >60), biopsy is recommended even in a completely asymptomatic child. By contrast, children with low to moderately positive transglutaminase antibody levels may have a false-negative biopsy and may be falsely reassured that they do not have coeliac disease and forgo further follow-up.

Untreated coeliac disease may pose problems with diabetes management, including inconsistent nutrient absorption, increased risk of hypoglycaemia, and chronic diarrhoea that is difficult to differentiate from that caused by autonomic neuropathy in adults. Gluten-free diets may prevent some of the episodes of hypoglycae-

mia. The benefit of early detection and treatment remains unproven, but is the subject of ongoing investigation.

Thyroid disease

Hypothyroidism is present in 3–8% of children with type 1 diabetes. Long-term follow-up suggests that as many as 30% of people with type 1 diabetes develop autoimmune thyroiditis. The presence of hypothyroidism has been associated with thyroid autoantibodies, which are observed more frequently with increasing age and diabetes duration and female sex. With follow-up of 20 years, 80% of people with type 1 diabetes and thyroid peroxidase (TPO) autoantibodies develop hypothyroidism. Hyperthyroidism is less common than hypothyroidism in people with type 1 diabetes, but still more common (3–6%) than in the general population.

The presence of autoimmune thyroiditis in the population with type 1 diabetes has the potential to affect growth, weight gain, diabetes management, menstrual regularity, and overall well-being. All children with type 1 diabetes should be screened for elevated levels of the thyroid-stimulating hormone (TSH) after stabilization at onset of diabetes and every 1–2 years thereafter, or sooner if symptoms of hypothyroidism or hyperthyroidism are present. TPO antibodies, anti-thyroglobulin antibodies, and free T4 may also be sent at the time of TSH screening [89]. Those with positive TPO autoantibodies and normal thyroid function should be screened on a more frequent basis (every 6–12 months). Treatment of thyroid disease in children with type 1 diabetes is the same as for the general population.

Addison disease

Addison disease affects approximately 1 in 10 000 of the general population and 1% of people with type 1 diabetes [158]. While there are currently no data to support routine screening for Addison disease, the increased risk of this disease necessitates a heightened degree of suspicion on the part of the clinician should any signs or symptoms of Addison be present, particularly in the setting of frequent, severe, or unexplained hypoglycaemia. Most children who develop disease are mildly symptomatic with decreasing insulin doses and HbA_{1c}. Adrenocorticotrophic hormone (ACTH) stimulation testing remains the gold standard for diagnosing adrenal insufficiency, although increased risk can be ascertained by the detection of autoantibodies reacting to 21 hydroxylase (21-OH). The presence of this autoantibody in the general population is very rare, in contrast to 1–2% in people with type 1 diabetes. Of those with positive antibodies, but as yet free of Addison disease, 15% develop Addison disease within a few years.

Adolescence and Emerging Adulthood: Diabetes in Transition

Charlotte W. Chen and Lori M.B. Laffel

Pediatric, Adolescent and Youth Adult Section, Joslin Diabetes Center, and Harvard Medical School, Boston, MA, USA

Key points

- The period of adolescence and emerging adulthood involves significant physical, social, and emotional growth, and presents unique challenges to those with diabetes.
- The intensive treatment required for consistent and effective diabetes care, especially for young people with type 1 diabetes, can be time-consuming and challenging for young adults with diabetes. It can be especially challenging as adolescents move towards adulthood. The degree of independence and responsibility adolescents accept for their diabetes care ideally increases as they enter older adolescence and young adulthood.
- Empowering emerging adults with a sense of self-efficacy with respect to their capacity to care for diabetes effectively is crucial to ensuring success during this transitional phase and in establishing consistent self-care habits for life.
- As the emerging adult is likely to leave the home, the supportive role originally assumed by parents and family members can be taken on by close friends and significant others.
- The process of transition followed by the actual transfer from paediatric diabetes care to an adult practice can be challenging for emerging adults with diabetes. It is imperative that parents and the paediatric diabetes team members provide the necessary training and preparation for self-care to support the transfer to an adult practice. It is recommended that parents continue to support their teenagers' diabetes care during this tumultuous developmental stage.
- Parents of teenagers along with healthcare professionals should monitor and attempt to prevent burnout from diabetes care. Inclusion of diabetes educators and mental health clinicians on the adolescent and emerging young adult's diabetes team can help reduce the likelihood of burnout and help overcome barriers to self-care acquisition.

Although this chapter focuses on the adolescent and young adult with type 1 diabetes, the commonest type of diabetes affecting this age group, many of the issues also apply to young people with type 2 diabetes. Thus, the chapter will describe the process of transition that begins during adolescence and culminates in the transfer from a paediatric care team to an adult diabetes or endocrinology practice for young people with either type 1 diabetes or type 2 diabetes. This period of transition is affected by multiple developmental changes that teenagers undergo between the ages of 13–18 years, with additional developmental issues arising during the stage of emerging adulthood, between the ages of 18–25 and 25–30 years. The chapter will examine the psychosocial and physical changes experienced by adolescents as well as the special challenges teenagers and emerging young adults with diabetes encounter as they transition from adolescence into early adulthood.

The process of transition requires the growing and developing adolescent to take on responsibilities for diabetes self-care, tasks that were previously managed by the parents. This process should be gradual, with sharing of diabetes management between parents and teenagers initially, followed by the ultimate transfer to self-care that should precede the time when the older adolescent or emerging young adult

leaves the paediatric diabetes team and receives care from a medical team that specializes in adult diabetology or endocrinology.

There is no exact age at which the young person with diabetes should perform all self-care; rather, this is a process that needs to be individualized, depending on development stage, maturity, family support, family expectation, education from the healthcare team, as well as other factors. Acquisition of self-care can begin for some youngsters in the higher primary grades or during the middle school years, although adults may continue to supervise diabetes management tasks. These may include using a continuous glucose monitoring (CGM) device or checking blood glucose levels, assessing the carbohydrate content of meals or snacks, or reading the values on food packages and participating in calculating insulin doses, or even use of an automated insulin delivery device. Participation in these management tasks is generally encouraged by parents and the paediatric diabetes team, with decreasing supervision by parents and other adults from around the ages of 12 or 13 years [1]. There is an additional need to navigate how older adolescents and young adults maintain or discontinue sharing their diabetes self-care activities with parents, especially, for example, given current opportunities for real-time CGM data sharing [2].

Direction and support provided by members of the paediatric diabetes team are imperative to promote the gradual transfer of these self-care tasks to the teenager, with the goal of maintaining optimal self-management and maximizing the opportunities for achieving target glycated haemoglobin (HbA_{1c}) values and reducing the likelihood of acute and chronic diabetes-related complications [3]. As adolescents differ in their cognitive capacity to perform diabetes tasks with increasing independence, it is imperative that healthcare professionals, parents, and the young person with diabetes work together to establish realistic goals. Helping the growing and developing teenager to develop a sense of self-efficacy in performing diabetes self-management tasks with increasing independence is critical, certainly prior to the transfer to adult diabetes clinics, where healthcare professionals expect independence in diabetes care. The eventual goal is for the adult with diabetes to have the capacity and to possess the skills to engage in full and effective diabetes self-care, having traversed adolescence without diabetes burnout [4].

Demographic information about diabetes

Currently in the USA, about 210 000 children, adolescents, and young adults (<20 years old) are living with diabetes [5]. There appears to be a significant increase in the occurrence of type 1 diabetes and type 2 diabetes in this age group. According to the SEARCH for Diabetes in Youth study in the USA from 2001 to 2012, the incidence rate of young-onset type 1 diabetes increased by 1.4% annually [6]. For type 2 diabetes, the incidence rate increased by 7.1% annually, with a high relative increase in racial and ethnic groups compared to non-Hispanic white people [6, 7]. An analysis of EURODIAB registry data from over 26 European centres found that the incidence rate of type 1 diabetes increased by 3.4% annually over 1989–2013 [8]. A paper from Lawrence et al. shows that the prevalence of type 1 diabetes and type 2 diabetes was also increasing for 2001–2017. Type 1 diabetes has a relative increase of 45.1% over 16 years, while type 2 diabetes has a relative increase of 95.3% over 16 years, and the most significant increase was noted in non-Hispanic Black and Hispanic young people [9].

Physical changes during adolescence

At the same time that there is an expectation for the teenager to take on increasing responsibility for diabetes self-management, the young teenager is undergoing substantial physical, developmental, behavioural, and emotional changes, many of which substantially affect insulin needs. The major change in diabetes management results from the recognized insulin resistance associated with pubertal growth and development (Chapter 69) [3, 10]. Regardless of the age at diagnosis of diabetes, this period of adolescence requires great vigilance to assess diabetes needs and direct management due to physical and lifestyle changes. This vigilance entails frequent blood glucose monitoring, attention to carbohydrate intake, physical activity that becomes as much therapeutic as recreational in nature, and, of course, careful attention to insulin delivery in terms of both amount and timing. Shortly after diagnosis, people with type 1 diabetes generally experience a time-limited phase known as the *honeymoon* stage, during which the pancreatic β cells continue to produce a small amount of insulin. As time

progresses, the pancreas produces less insulin, and those with type 1 diabetes experience increasing needs for exogenous insulin as the honeymoon wanes. This intensification of type 1 diabetes management can be particularly apparent for the growing and developing adolescent, whose insulin needs usually increase rapidly during puberty by up to 50% or even more [3, 10].

To manage insulin effectively for an adolescent, parents and the paediatric diabetes team need to pay close attention to changes related to puberty, weight gain, and linear growth. Insulin doses need to be increased to help ensure that the HbA_{1c} remains within the target range of <7.0% (<53 mmol/mol) set by the International Society for Paediatric and Adolescent Diabetes (ISPAD) and American Diabetes Association (ADA) [11, 12], and for those using CGM, that the glucose time in range is 70–180 mg/dl (3.9–10 mmol/l) and remains >70% without substantial hypoglycaemia [13].

Thus, while teenagers with diabetes experience increasing independence in many aspects of their lives related to school and social life, the period of pubertal growth and development requires ongoing parent involvement in diabetes management to ensure that glycaemic levels do not deteriorate. Indeed, teamwork in diabetes management between parents and teenagers is recommended at this stage. Furthermore, frequent consultation with members of the paediatric diabetes team regarding insulin adjustments, appropriate nutrition, stress management, and exercise also reduces the likelihood of hyperglycaemia, glucose variability, and the development of acute complications [3, 10].

Developmental stages

This section of the chapter will describe the normal developmental stages of adolescence and emerging adulthood, with a focus on various transitions and recommendations for optimal family management of diabetes (Table 70.1). Key developmental changes that may affect the ability of the teenager and young adult with diabetes to engage in self-care tasks independently will be reviewed (Figure 70.1). There will also be a section on empirical evidence for specific intervention and care strategies for adolescents and emerging adults with diabetes. Lastly, novel technology platforms to support optimal diabetes management will be discussed.

Adolescence (age 13–18 years)

Along with rapid physical growth, cognitive development, and pubertal maturation, adolescence is a time of increased attention to body image and sexuality. Teenagers within this age range are also forming their identities, a process that can lead to increases and decreases in taking on and accepting greater responsibility for various school and home-related tasks. Furthermore, relationships with same-age peers have a powerful influence on an adolescent's behaviour [14–16].

A tremendous number of physical, social, and emotional changes occur during the period of adolescent growth and development, often challenging the management of diabetes, their parents, and the healthcare team. The ADA and ISPAD, along with other organizations, recommend an HbA_{1c} goal of <7.0% (<53 mmol/mol) [11, 12]. These societies also recommend more stringent HbA_{1c} goals (such as <6.5%; <48 mmol/mol) for young people with type 1 diabetes and type 2 diabetes who can achieve these targets without significant hypoglycaemia or undue burden of care [12, 17]. The National Institute for Health and Care Excellence (NICE) guidelines include an HbA_{1c} goal of $\leq 6.5\%$ (48 mmol/mol) [18].

Table 70.1 Developmental stages and major developmental tasks during adolescence and emerging adulthood.

	Typical development	Diabetes-specific development	Psychosocial challenges
Early adolescence (ages 13–15yr)	Rapid growth Sexual maturation Body image concerns Changing physical activity level Social/friend interactions Interest in technologies Ongoing cognitive development Emerging alcohol and drug experimentation	Frequent alterations in glucose levels Expanding needs for self-care and sharing diabetes responsibilities between teenager and parent Body image concerns related to wearing diabetes devices Concerns regarding peer awareness and comments about diabetes Understanding exercise and diabetes needs	Diabetes-related family conflict Disordered eating Depressive symptomatology Fear of hypoglycaemia or hyperglycaemia School staff knowing what to do in an emergency Family planning
Later adolescence (ages 16–18yr)	Identity formation Sexual activity Body image concerns Changing physical activity level Social/friend interactions Interest in technologies Ongoing cognitive development Emerging alcohol and drug experimentation	Balancing type 1 diabetes care with schoolwork and social interests Greater independence and need for adult support related to diabetes care Body image concerns related to wearing diabetes devices Concerns regarding peer awareness and comments about diabetes Understanding exercise and diabetes needs	Diabetes-related family conflict Disordered eating Depressive symptomatology Fear of hypoglycaemia or hyperglycaemia School staff knowing what to do in an emergency Family planning Driving a motor vehicle
Early phase emerging adulthood (ages 19–24yr)	Education and career training Moving away from the family home Dormitory/apartment roommates Changes in emotional and financial ties with parents Wider friendship group	Possible gaps in medical insurance Making time for type 1 diabetes when with friends Negotiating performing diabetes tasks at first job or while at college Remembering to refill/reorder prescriptions Recreational substance use Negotiating self-advocacy	Diabetes-related family conflict Disordered eating Depressive symptomatology Fear of hypoglycaemia or hyperglycaemia Teachers or co-workers knowing what to do in an emergency Family planning
Later phase emerging adulthood (ages 25–30 yr)	Interest in marriage, starting a family Further career advancement Expanding social, emotional, and financial independence	Increasing awareness of the impact of diabetes care on significant others, family planning, and career development Recreational substance use Negotiating self-advocacy Remembering to refill/reorder prescriptions	Diabetes-related family conflict Health roles of close friends or significant others Lecturers and co-workers knowing what to do in an emergency Family planning

However, of all age groups, adolescents are farthest away from this target HbA_{1c} goal [19]. Along with the impact of pubertal development, physical growth, and emotional stress that most adolescents experience, diabetes, and especially type 1 diabetes, when compared to other chronic illnesses of childhood, requires the teenager to perform management tasks multiple times each day, day in and day out without any break. In addition to checking blood glucose levels, attending to food intake, administering insulin, understanding the impact of exercise on glucose levels, adolescents with diabetes and their families also must navigate the impact of acute illness on their diabetes management needs [1]. Teenagers develop emotional maturity and the ability to take on diabetes responsibilities with independence at varying rates and at various ages. However, some teenagers do not possess the emotional maturity to sustain tasks of daily self-care, and some may experience gaps in medical care, which can lead to adverse health outcomes [20].

Family support, family involvement in diabetes management, and low levels of diabetes-specific family conflict are associated with smoother transitions for adolescents as they acquire and accept more responsibilities of type 1 diabetes self-care [21–24]. While adolescents with diabetes learn to adapt to fewer adult prompts to engage in and perform self-care tasks accurately and consistently, parents are encouraged to remain involved in sharing management responsibilities. The roles and responsibilities that

parents keep versus those that they pass on to the adolescent will differ depending on the adolescent's cognitive capacity and willingness to engage in care activities. As these factors are rarely static due to ongoing maturation and situational stressors experienced by the adolescent and/or family, the roles parents and teenagers fill during this transition will frequently need to be renegotiated. Members of the adolescent's diabetes team can serve as an excellent resource in problem solving the division of responsibilities and ensuring that teenagers with diabetes are provided with a realistic number of self-care tasks. The ultimate goal is for the adolescent to possess a sense of self-efficacy and the capacity to accept and treat diabetes optimally [1].

Additional important factors for an optimal transition of diabetes management from parents to the adolescent include the establishment of self-efficacy and self-advocacy for the teenager, especially in the context of developmental and social needs. Teenagers with a strong belief and confidence that they can perform self-care and advocate for themselves in particular situations are more likely to overcome barriers to diabetes self-care. Teenagers should be empowered to speak up for their diabetes self-management needs in public settings, such as school or sports clubs, and have confidence in doing so. There are improved outcomes when there is acceptance of self-care leading to improved glycaemia [25–27]. In a 2014 study, Wiebe et al. found that adolescents who reported a decrease in

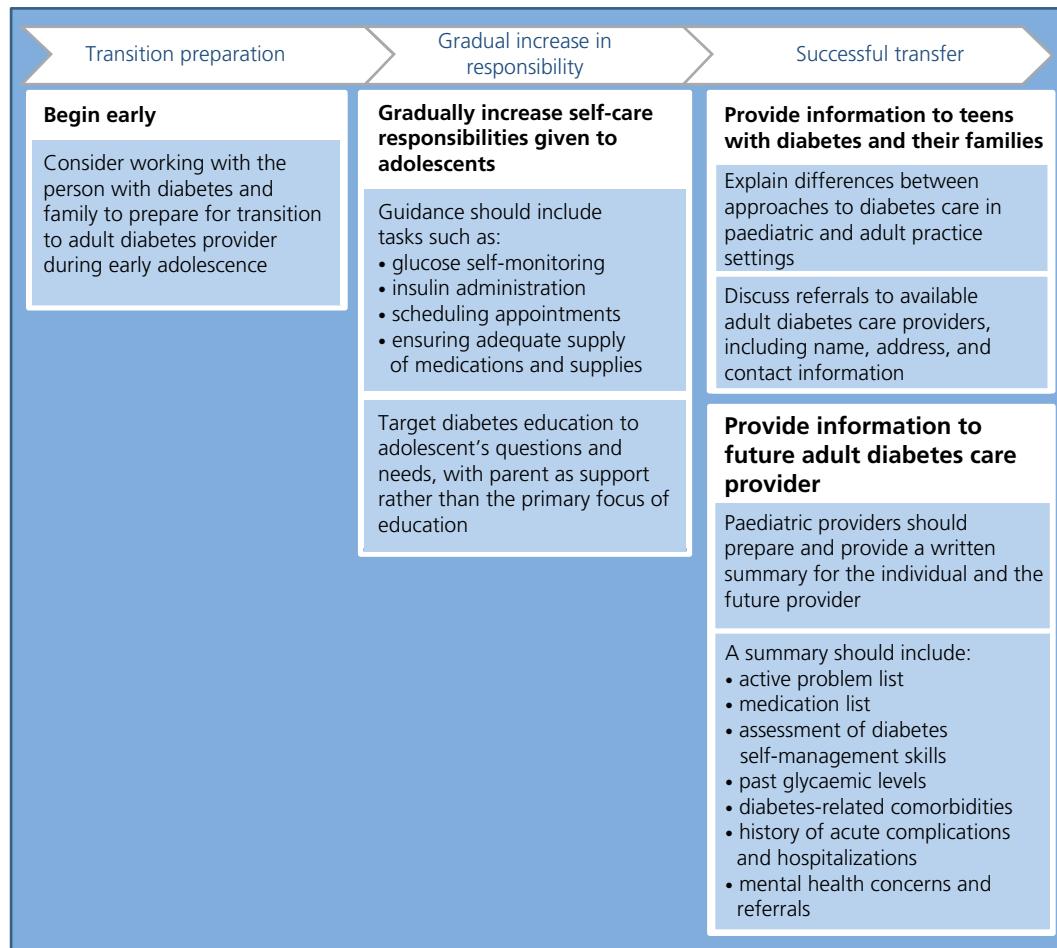

Figure 70.1 Trajectory of transition preparation, self-care acquisition, and transfer to adult care.

parental involvement for type 1 diabetes care and a high sense of self-efficacy were better able to maintain diabetes self-care than those with a lower sense of self-efficacy [28]. Those who possessed a lower sense of self-efficacy had better glycaemic levels only when a parent played a greater role in establishing self-care skills [29]. These findings support the need for the adolescent's diabetes team to consider the level of self-efficacy an adolescent possesses when increasing their self-care independence.

In addition to the impact of pubertal insulin resistance, other factors can lead to deterioration in glycaemic levels. Glycaemic targets can be challenging when teenagers have competing preoccupations, for example with athletics, academic studies, and social distractions, which can detract from self-management, leading to lower self-care and more inadequate glycaemic levels [10, 23, 30, 31].

Based on a T1D Exchange study in 2019, adolescents from 13 to 17 years old had a mean HbA_{1c} of 9.2% (77 mmol/mol), with only 17% achieving HbA_{1c} levels <7.5% (<58 mmol/mol) [19]. In the same report, a majority of the adolescents 13–17 years old (79%) disclosed missing insulin bolus doses. Furthermore, 40% of the adolescents receiving injection-based therapy reported missing basal insulin at times [19]. In 2013, Hilliard et al. analysed predictors of glycaemic deterioration in 150 adolescents with type 1 diabetes over a period of 18–24 months [32]. Approximately two-thirds of participants did not meet the requirement to check blood glucose values more than four times daily and did not achieve the

target HbA_{1c} of <7.5% (58 mmol/mol). There were both modifiable and non-modifiable factors related to the suboptimal management and glycaemic outcomes. Non-modifiable factors included ethnic minority status and unmarried caregiver status. The authors highlighted that diabetes healthcare professionals should identify these non-modifiable factors to assess a person's risk and provide timely support. The modifiable factors associated with deteriorating type 1 diabetes care and glycaemic levels included injection-based insulin regimens as well as diabetes-specific family conflict [32]. Similarly, there are factors associated with diabetes device use in adolescents with type 1 diabetes. Chen et al. found that pump and CGM users were more likely to have more favourable psychosocial, sociodemographic, and diabetes self-care characteristics compared with non-device users [33].

These observations emphasize the importance of including behavioural and mental health assessments as part of adolescent diabetes care visits to assess for and intervene in stressful parent-teen interactions and modifiable barriers related to diabetes management, while providing additional support to those with non-modifiable barriers to benefit the transition to self-care for teenagers with type 1 diabetes.

Social context can have an important impact on an adolescent's diabetes self-management. Those who are extremely peer oriented may perceive diabetes as a barrier that prevents them from engaging in peer activities [34]. Borus et al. conducted a study where,

over a 14-day period, adolescents with type 1 diabetes, aged 14–18 years, carried handheld devices that prompted them to report social context variables related to self-monitoring of blood glucose. Despite concern that many adolescents with type 1 diabetes do not check their blood glucose as often as recommended, the study demonstrated an increased likelihood of participants checking blood glucose levels when the teenagers expressed a strong desire to blend in with peers and a lower likelihood of checking blood glucose levels when the teenagers wanted to impress others. The authors suggested that these findings could help diabetes teams to encourage teenagers to check their glucose levels more frequently, as monitoring allows them to identify out-of-range glucose values promptly, thereby allowing them to avoid possible embarrassment as a result of sudden unexpected hypoglycaemia or symptomatic hyperglycaemia [35].

Adolescence is a time for experimentation and engaging in risky behaviours such as alcohol, tobacco, and substance abuse [36]. Potter et al. examined the prevalence of alcohol, tobacco, and other illicit substance use in Canadian adolescents with type 1 diabetes compared with a general adolescent population and found that the engagement of teenagers with type 1 diabetes with alcohol, tobacco, and cannabis use was similar to the control group [37]. Another published study from the T1D Exchange reported that the mean age for the first use of an illicit substance was 18 ± 5 years, 17 ± 3 years for first alcohol consumption, and 17 ± 3 years for first tobacco use [38]. Therefore, it is essential to routinely discuss and educate adolescents on the effects of alcohol, tobacco, and illicit drug use in type 1 diabetes.

There have been several family-based behavioural interventions aimed at optimizing glycaemic levels during adolescence. Two behavioural family interventions, family teamwork and behavioural family systems therapy, have reported the most consistent, lasting impact on diabetes outcome [39]. Laffel et al. performed a randomized prospective study examining the impact of a family-focus teamwork intervention on glycaemia and compared it with standard multidisciplinary diabetes care. A year later, they found that those who received the teamwork intervention were less likely to have any deterioration in glycaemic levels and more likely to maintain or increase family involvement without any negative impact on quality of life [40]. Wysocki et al. conducted a six-month behaviour intervention using Behavioural Family Systems Therapy for Diabetes (BFST-D). Participants exposed to this intervention were compared with two comparison groups (educational support and standard care); teenagers in the BFST-D group demonstrated better diabetes self-management at follow-up compared with the comparison groups [41].

Multisystemic therapy targets barriers on multiple levels, such as individual, family, and community, can also be used for adolescents with diabetes with elevated HbA_{1c}. Ellis et al. performed a randomized controlled trial (RCT) evaluating the effect of multisystemic therapy compared with weekly telephone support on glycaemic levels and insulin administration in teenagers with type 1 diabetes and type 2 diabetes. Participants in the multisystemic therapy group experienced a significant reduction in HbA_{1c} at the end of the study and 12 months after the intervention [42].

Another series of studies has focused on cost-effective, clinic-based interventions utilizing *care ambassadors* [43–45]. These care ambassadors do not possess medical training, but they provide support to individuals and families between medical visits, ensuring timely follow-up, which is particularly important when the competing needs of adolescence may impede routine diabetes visits.

Those individuals with type 1 diabetes receiving care ambassador support compared with standard care demonstrated increased ambulatory visits, reduced hospitalizations and emergency room visits, and reduced occurrence of severe hypoglycaemia. Furthermore, those with type 1 diabetes and elevated HbA_{1c} at study entry who were assigned to receive care ambassador support compared with standard care demonstrated a decrease in HbA_{1c} [43–45].

Motivational interviewing can be used to bolster an adolescent's willingness to increase self-management. Motivation interviewing involves collaborative communication between a member of the paediatric diabetes team and the adolescent in an effort to strengthen the teenager's personal motivation for change and commitment towards achieving a specific goal [46]. Channon et al. designed and implemented an RCT that studied the impact of motivational interviewing during clinic visits in 66 teenagers with type 1 diabetes, aged 14 and 17 years [47]. Findings of the 12-month study showed that, compared with control participants, those who received the motivational interviewing intervention had lower mean HbA_{1c}. Furthermore, this improvement was maintained a year after the intervention ended. Motivational interviewing may serve a role during transition as a means to motivate support for the acquisition of self-care tasks among teenagers with diabetes.

Several studies have examined the use of mobile technologies to assist adolescents in their transition to diabetes self-care. Text messaging has been studied as means of offering reminders to adolescents for self-care when they are away from their parents and other adult care providers. Markowitz et al. conducted a study where adolescents and young adults with diabetes received text messages that promoted a general healthy lifestyle and diabetes self-care [48]. Messages were tailored to assisting study participants attain personal goals regarding diabetes self-care. While self-efficacy and glycaemic levels did not change during the three-month pilot study, results indicated that text messaging was highly acceptable to participants and could be expanded in future studies [48]. A Scottish study entitled Sweet Talk sent daily automated text messages that reinforced goals that adolescent study participants had set during their diabetes clinic visit [49]. The intervention did not demonstrate consistent improvement in participants' HbA_{1c}, but results suggested that the adolescent participants developed a stronger sense of self-efficacy related to their ability to care for type 1 diabetes.

Given the general increased use of smartphones, studies have also looked at mobile applications to support adolescents' self-management skills and improve glycaemic outcomes. In 2019, Pramanik et al. created a mobile application that reminded adolescents with suboptimally managed type 1 diabetes about insulin, meals, and physical exercise. They found a reduction in HbA_{1c} in the participants who used the mobile application [50]. A similar study, undertaken in 2017 by Goyal et al., also found an increase in daily self-monitoring of blood glucose and improvement in glycaemic levels in adolescents who used *bant* (a diabetes self-management app) compared with the control group [51]. However, these studies lasted 12 months, and it is uncertain if there will be any glycaemic benefits with continued usage. It is important to note that mobile applications need to be engaging and updated to ensure durable and persistent usage by adolescents.

There is also an uptake in social media usage and many adolescents engage in these activities. A qualitative study by Malik et al. found that teenagers appeared to be interested in using social media to increase engagement with their diabetes care team and to support their self-care [52].

Part 11 Diabetes in Special Groups

Table 70.2 gives details of other clinical interventions that are being tested to improve glycaemia in adolescents with diabetes.

Emerging adulthood

To add to the challenges of transition to self-care during adolescence, another developmental stage, termed *emerging adulthood*, demands the attention of both paediatric and adult diabetes teams. This developmental stage of young adulthood has been popularized over the past 20 years in the USA and other high-income countries [56]. The concept of emerging adulthood developed from observations that many individuals in their late teens and early 20s are delaying tasks that had been traditionally associated with this age, such as

marriage, parenthood, and work. These life events now occur for many in their late 20s and early 30s. Emerging adulthood can be separated into an early phase and a later phase. Notably, health insurance coverage for young adults with diabetes has generally not been a problem in countries with universal coverage, but young adults in the USA had been at risk for gaps in health insurance coverage until reforms such as the Patient Protection and Affordable Care Act mandated coverage under parents' policies until the age of 26 years [57].

The early phase of emerging adulthood corresponds to the years immediately after secondary education or high school, between the ages of 18 and 24 years. During this phase, the emerging adult

Table 70.2 Examples of interventions under study worldwide.

Interventions	Trial	Prominent findings/ongoing trial	Country
Art	An open-label 12-wk trial of group art therapy in young adults with type 1 diabetes and type 2 diabetes (NCT02790892) Outcomes: changes in social support and diabetes distress scores	The study had poor attendance Participants who participated in group art therapy had a higher score in social support and lower in diabetes distress [53]	Canada
Behavioural	A randomized controlled trial that tests the efficacy of an emotional abilities training programme (NCT03734367) Outcomes: change of emotional skills of young people with type 1 diabetes	Ongoing	Spain
Group education	A randomized open-label trial that evaluated the impact of group diabetes education in teenagers with type 1 diabetes (NCT03147274) Outcomes: frequency of blood glucose monitoring	The intervention group demonstrated significantly improved diabetes self-delivery and transition readiness [54].	USA
Mobile	A randomized open-label trial that tests the efficacy of my MyT1DHero mobile application (NCT03521362) Outcomes: change in glycaemic levels, diabetes knowledge, and family communication	Ongoing	USA
Mobile	A randomized open-label trial that evaluated a smartphone application that can determine carbohydrate content using pictures/speech (NCT04354142) Outcomes: assessing carbohydrate counting accuracy and efficiency	Participants using iSpy demonstrated improved carbohydrate counting accuracy and positive acceptability [55]	Canada
Peer mentorship	A randomized trial to test the efficacy of peer mentorship during the transition period (NCT04247620) Outcomes: change in glycaemic levels and time to first adult visit	Ongoing	USA
Peer mentorship	A randomized open-label trial that evaluated the benefits of peer mentorship for parents with youth with type 1 diabetes (NCT03199716) Outcomes: frequency of blood glucose monitoring	Results pending	USA
Pet ownership	A randomized open-label trial that evaluated the impact of pet ownership on glycaemic control for youth with type 1 diabetes (NCT01733524) Outcomes: change in glycaemic levels and healthcare burden	Results pending	USA
Video game	An open-label trial to evaluate the contribution of a computer game (DIVE) in diabetes education (NCT03520855) Outcomes: change in glycaemic levels and self-care skills	Ongoing	France

Source: Information from <https://clinicaltrials.gov>.

may be physically moving away from home and beginning to change the degree and nature of emotional and financial ties with parents, although the emerging adult is not yet fully independent. During this phase, the young adult experiences tremendous pressures related to academic studies, occupational choices, and social commitments, while separating from the family [57]. Thus, it is not surprising that these competing needs for time, energy, and effort often detract from diabetes self-care, leading to further deterioration in insulin administration and glycaemic levels. Indeed, data from the T1D Exchange Clinic Registry in the USA indicate that HbA_{1c} reaches its peak of 9.3% (78 mmol/mol) during this phase of development [19]. Thus, paediatric and adult healthcare professionals working with emerging young adults must be aware of these competing demands and help to ensure that young adults with diabetes receive reinforcement for self-care behaviours, along with ongoing education and training in self-management, including how to fill prescriptions and make diabetes follow-up appointments [58].

During the later phase of emerging adulthood, usually occurring between the ages of 25 to 30 years, the young adult starts to assume more traditional adult roles [56]. An increasing sense of maturity leads many emerging young adults in the second phase to realize the importance of monitoring their health. Interest in getting married, raising children, and establishing a career leads many individuals to invest more effort in improving self-care and achieving better glycaemic levels [57]. It is no surprise that there is a steady decrease in HbA_{1c} to 8.0% (64 mmol/mol) by the age of 28 years [19]. Considering the young person's increased awareness of self-care needs and health outcomes, this period is ideal for the diabetes team to bolster diabetes management habits. As transfer from paediatric to adult providers likely occurs during this developmental stage, both paediatric and adult healthcare professionals should be well versed in the relevant issues [57].

Changes in family involvement

Family involvement is a critical component of diabetes management during childhood and adolescence. Additionally, parents and family members, as well as members of the paediatric diabetes team, play significant roles in helping adolescents and young adults transition to take on the primary role of managing their diabetes. Interestingly, the perceptions of parents may contrast at times with those of the paediatric diabetes team with respect to a young person's capacity to engage independently and effectively in self-care. Wysocki et al. had parents and members of paediatric medical diabetes teams complete surveys that measured their estimates of the self-care independence of young people with type 1 diabetes [59]. This study, which was conducted across multiple type 1 diabetes centres, found that compared with parents, healthcare professionals characterized young children and those in elementary school as less capable of independently monitoring and treating type 1 diabetes without the supervision of an adult caretaker. Parents of these children reported earlier mastery of skills by their children related to motor activities (e.g. blood glucose self-monitoring) and the capacity to take care of type 1 diabetes events with immediate consequences (e.g. preventing or treating hypoglycaemia). Additional results indicated that many parents of adolescents, however, reported lower levels of self-care and competence for critical skills involving

executive functions. These self-care activities included planning, anticipation, and self-regulation (e.g. preventing hyperglycaemia or adjusting insulin doses) [59].

Before 1986, no guidelines existed for the family sharing of type 1 diabetes management activities or what tasks were appropriate at different ages and stages of development. Ingwersoll et al. found that as children grew older, responsibility for type 1 diabetes tasks shifted from the parent to the growing teenager [60]. This finding matches the general developmental expectation that adolescents will require less guidance in general from teachers, for example, to write down homework assignments and fewer prompts from parents to complete homework. However, when parental involvement in diabetes management tasks decreased, specifically regarding adjusting insulin, Ingwersoll et al. reported that adolescents did not increase their independence and effectiveness in the self-care management of type 1 diabetes. Nevertheless, those who took over more responsibility for insulin adjustments were at 'advanced levels of cognitive maturity and had a stronger personal sense of control over diabetes' [60]. These findings launched a critical body of research related to family teamwork during adolescence, which has changed the paradigm of care during this stage of development and highlights the need to individualize approaches based on the individual's cognitive, emotional, and social development.

As parental involvement in type 1 diabetes care declines over time, the roles of the child or teenager and family in diabetes management rarely remain static; the growing and developing child goes from a stage of dependence on parents or other adults, to sharing tasks or a state of interdependence, prior to emerging with complete independence in self-care during later adolescence and young adulthood. To provide optimal care, paediatric diabetes providers are encouraged to be well versed in the ebb and flow of the roles of the adolescent and family members during the course of development. Normal developmental tasks of childhood and adolescence call for slowly increasing the young person's acquisition of responsibilities, personal decision making, and self-care (Figure 70.1) [61]. Division of type 1 diabetes management roles within the family is often directed by the multidisciplinary diabetes care team, which ideally provides ongoing education and psychological support for teenagers with type 1 diabetes and their families, with a need to direct diabetes education and support to both the teenager and the parent. Healthcare team members can provide anticipatory guidance and realistic expectations related to the roles of the young person and family members [3].

It is important to recognize that adolescents and emerging adults will likely differ in their capacity to perform diabetes self-management independently. The ability to manage diabetes responsibilities can be affected by executive functioning challenges, such as attention-deficit/hyperactivity disorder (ADHD), as well as short-term and working memory difficulties [62]. Several recent studies have focused on the impact that hypoglycaemia and hyperglycaemia may have on cognitive ability and executive functioning skills [63, 64]. The findings have been mixed, and deeper examination of these studies is beyond the scope of this chapter. Nonetheless, it is important to consider the impact of ADHD, short-term/working memory, executive functioning, and organizational skills on an adolescent's or emerging adult's capacity to perform diabetes self-care independently, consistently, and effectively. Dysfunction in executive functioning in young people with type 1 diabetes not only affects diabetes self-care and glycaemic levels, but also has impacts

on the health-related quality of life, especially in females [65]. The individual may benefit from carrying a discrete, step-by-step checklist or from utilizing mobile alarms as reminders or aids to perform diabetes tasks as the young person acquires increasing independence in self-care. Depending on the skill level of the teenager or young adult, the checklist or reminder can include instructions for what to do when blood glucose levels are out of range, either low or high.

To increase the likelihood that adolescents and young adults with diabetes will experience success in self-care, it is imperative that parents and members of the paediatric diabetes team monitor and take action to prevent or intervene for diabetes burnout. Research has suggested that several factors, including low self-efficacy, low self-esteem, complex treatment regimens, and longer duration of disease, contribute to burnout [66, 67]. Burnout in adolescents becomes evident when teenagers reduce their frequency of blood glucose monitoring and glycaemia subsequently deteriorates [68]. Members of the adolescent's diabetes team, specifically diabetes educators and mental health counsellors, can help parents and teenagers identify and manage diabetes burnout and ensure parents remain in supportive roles when the adolescent experiences this challenge during transition to greater self-care.

Diabetes technologies

Despite the burgeoning of new technologies to assist in managing diabetes, especially type 1 diabetes, over the past 20+ years, consistent and effective use of devices, such as insulin pumps and CGM, can be challenging for people with diabetes across the age range. Insulin pumps can offer ease of insulin delivery throughout the day and night. Several closed-loop or hybrid closed-loop systems on the market can adjust specific aspects of insulin delivery to help the user achieve glycaemic target levels, such as Control IQ (Tandem Diabetes Care, San Diego, CA, USA) and MiniMed™ 770G (Medtronic, Northridge, CA, USA). A large multicentre RCT in 2019 showed that using a closed-loop system was associated with a greater percentage of time spent in range and reduced hypoglycaemia in adolescents and young adults compared with a sensor-augmented insulin pump [69, 70].

CGM devices can enable people with diabetes to monitor trends in glucose levels and to receive alerts and alarms when glucose values fall out of range [71, 72]. In the USA, Dexcom CGM version G5 and higher (Dexcom, Hudson, OH, USA) is approved for non-adjunctive use [73]. In addition, there is even an implantable CGM system called Eversense® (Senseonics, Germantown, MD, USA) that can last up to 90 days [74].

However, such devices all require input and vigilance to ensure proper functioning. Thus, the additional effort needed to use these advanced diabetes technologies may impede uptake or lead teens and emerging adults to discontinue them. Published data have identified characteristics related to the underuse of these advanced technologies, such as lower socioeconomic status and adolescence [75]. Adolescents and young adults have the highest rate of insulin pump discontinuation compared with other age groups in the T1D Exchange Clinic Registry [76]. The commonest reasons for discontinuation included problems with wearability and disliking the pump [76]. The healthcare team can help by providing families, adolescents, and emerging adults with realistic expectations and ongoing education and support regarding using these technologies to maximize

their update and durability of use. This support should include discussions regarding the optimal timing of initiation of these devices. Similar approaches will likely be needed for soon to be available automated insulin delivery in an artificial pancreas, as human input will remain critical for proper functioning and surveillance of such systems.

Type 2 diabetes in adolescence and transition

Unlike type 1 diabetes, where pancreatic β cells cease to produce insulin, individuals with type 2 diabetes have a combination of reduced insulin sensitivity and defective insulin secretion [77]. Although type 2 diabetes was generally considered a disorder associated with middle or older age, the increased occurrence of childhood obesity over the past few decades has led to a substantial increase in the number of young people diagnosed with type 2 diabetes [78]. Published data show that developed countries such as China and the USA have the highest prevalence of young-onset type 2 diabetes, with 520 cases per 100 000 people and 212 cases per 100 000 people, respectively [78]. Studies from the USA and UK found an increased incidence of young-onset type 2 diabetes among certain race and ethnic groups, including Black, Hispanic, Asian/Pacific Islander, and Native American people [7, 79]. It is particularly concerning that young people diagnosed with type 2 diabetes are at increased risk for more severe diabetes complications (diabetic kidney disease, retinopathy, and peripheral neuropathy) compared with those with type 1 diabetes [80]. In addition, young people with type 2 diabetes have a more accelerated decline of β -cell function at ~20–35% annually compared with older individuals with type 2 diabetes [81, 82].

Treatment for young-onset type 2 diabetes should encompass lifestyle modifications, pharmacological treatment, and diabetes self-management education. Even though lifestyle modification is essential, it is often inadequate in achieving and maintaining glycaemic targets [77]. Therefore, it is important to add pharmacological intervention early on. The Treatment Options for Type 2 Diabetes in Adolescents and Youth (TODAY) study is the largest clinical trial examining the management of young people with type 2 diabetes [81]. This study enrolled 699 participants, aged 10–17 years old, with recent-onset type 2 diabetes. After a run-in period during which metformin was used to attain an $\text{HbA}_{1c} < 8\%$ (64 mmol/mol), participants were randomized to treatment with metformin alone, metformin with a lifestyle intervention, or metformin with rosiglitazone. About half of the participants experienced the primary outcome of loss of glycaemic control (defined as $\text{HbA}_{1c} \geq 8\%$ [64 mmol/mol] for six months or metabolic decompensation requiring treatment with insulin), over an average follow-up of about four years. Loss of glycaemic control occurred at approximately equivalent rates in the metformin alone and metformin plus lifestyle groups, while the group receiving rosiglitazone in addition to metformin had superior outcomes, with a ~25% reduction in the proportion of participants randomized to that group reaching the primary outcome. This was a significant finding, which highlighted the need for treatment of young people with type 2 diabetes with more than one anti-diabetes agent; however, rosiglitazone and other thiazolidinedione drugs are not approved by the US Food and Drug Administration (FDA) for use in children.

Recently, a study by Tamborlane et al. found that liraglutide, a glucagon-like peptide-1 (GLP-1) receptor agonist, with metformin

is efficacious at improving glycaemic levels in children with type 2 diabetes aged 10–16 years old [83]. As a result, it has been FDA approved for use in children with type 2 diabetes aged 10 years or older. Currently, ongoing clinical trials are evaluating the safety and efficacy of adult-approved therapies, such as sodium-glucose cotransporter 2 (SGLT-2) inhibitors and dipeptidyl peptidase 4 (DPP-4) inhibitor for children with type 2 diabetes [84].

Studies of type 2 diabetes medical care have focused on including a short-term diabetes educational component. The TODAY study provided standardized diabetes education during which teenagers with type 2 diabetes received education not only about pathophysiology, how medications work, and lifestyle guidelines, but also about how to improve their diabetes self-care with focused goal setting. Participants were closely monitored with regard to dosages of injected medication and/or oral medication(s) for diabetes. As this chapter is about ensuring the transition from paediatric diabetes care to adult care and increasing the likelihood that adolescents and emerging adults will establish consistent self-care practices, it is important to acknowledge that all participants in the TODAY study had to complete a 2–6-month run-in period successfully prior to randomization. During this period, which could include a minimum of 6 to a maximum of 12 clinic visits, participants were required to demonstrate $\geq 80\%$ medication taking for at least six weeks, miss no more than two run-in visits, and maintain an HbA_{1c} of $< 8\%$ (64 mmol/mol) for at least two months [85]. In order to fulfil these requirements, participants were provided with a significant amount of support, including appointment reminders and follow-up phone calls or text messages from study staff. Despite this support, 24% of the young adults who were screened for the study did not fulfil the requirements of the run-in period and thus were excluded from randomization into the main trial.

It is also important to consider the inclusion of family-based behavioural lifestyle intervention focusing on weight loss or prevention of continued weight gain during the transition process. Several international guidelines recommend a multidisciplinary approach to treating young-onset type 2 diabetes [11, 86]. Hannon and Arslanian reviewed the importance of a multidisciplinary team that could include the individual with diabetes, family, physician, nurse educator, dietitian, behavioural specialist, and personnel from the adolescent's school [87]. Although the authors did not go into detail regarding the emerging adults' transition from paediatric to adult diabetes care, they emphasized that the focus should be geared towards individualized therapy, family-based interventions, and pharmacotherapy with the objective of weight loss or prevention of continued weight gain, while optimizing diabetes management and glycaemic levels [87, 88]. The importance of family support was illustrated further in a study looking at barriers to oral diabetes medication for young people with type 2 diabetes. The most commonly cited barrier was forgetting with no reason named (39.3%), and interestingly, the most commonly cited strategy to improve medication taking was family support [89].

The transfer of older teenagers and emerging adults to adult diabetes care may offer a unique opportunity to overcome clinical inertia and revisit a young adult's diabetes treatment regimen by adding another medication to the care plan. This transition period can also be a time full of multiple changes in the young adult's life. The SEARCH for Diabetes in Youth study found that while a majority (57%) of young adults with type 2 diabetes transferred from paediatric to adult care after 18 years old, a substantial portion of them (15%) reported no medical care. Those who reported no medical care were more likely to be uninsured [90]. Similarly, a study looking

at healthcare visits pre- and post-transition from paediatric to adult care in young adults with type 2 diabetes versus type 1 diabetes in Manitoba, Canada, found that only 76% of those with type 2 diabetes attended any diabetes-related medical visit in the two years post-transition. Pundyk et al. also saw that diabetes visits attended during the pretransition period predicted the number of visits post-transition in those with type 2 diabetes. In addition, only 45% of those with type 2 diabetes met the criteria for successful transition compared with 70% of young adults with type 1 diabetes [91]. This highlights the need to develop a specific transition plan for young adults with type 2 diabetes focusing on the unique characteristics of young-onset type 2 diabetes and their specific needs.

Family planning and the possibility of pregnancy are of major importance in women with diabetes. As part of the TODAY study, all female participants received counselling on birth control, and were required to use some form of contraception (including abstinence) to participate in the study. Despite that, 10% of female participants became pregnant during the study. Of the pregnancies that were not electively terminated, 26.4% ended in miscarriage, stillbirth, or intrauterine demise, and 21.5% of the live-born infants had major congenital anomalies [92]. Another Canadian study found that girls with type 2 diabetes were more likely to become pregnant during the transition period compared with girls with type 1 diabetes [91]. The transition period and transfer to adult care present a unique opportunity for more exploration and counselling on this topic in order to decrease the frequency of poor maternal and fetal outcomes.

Acute and chronic complications in young adults diagnosed with diabetes in childhood

The commonest acute complications for adolescents and young adults with type 1 diabetes are hypoglycaemia and diabetic ketoacidosis (DKA). Severe hypoglycaemia is associated with cognitive dysfunction and abnormalities in young children with type 1 diabetes [93, 94]. In addition, recurrent hypoglycaemia may lead to hypoglycaemia unawareness (Chapter 40). Diabetes devices may help address this issue, as demonstrated in a study by Ly et al. in which the epinephrine response to hypoglycaemia in adolescents with type 1 diabetes was greater after the use of CGM with hypoglycaemia alarms [95].

Gaffney et al. studied the incidence of DKA during 'emerging adulthood' between 1998 and 2014 and found that the DKA rate increased during emerging adulthood in both the USA and Manitoba, Canada [96]. DKA rates were higher among those of a lower socioeconomic status and adolescent girls [96].

The ADA recommends assessment of the history of acute complications, along with continued education on the prevention of recurrence of acute complications [11]. Adolescents and young adults with type 1 diabetes are at risk for various psychiatric disorders, including depression and eating disorders, and diabetes teams should attend to identifying and intervening for such problems to avoid worsening, particularly at the sensitive time of transition. In addition, the problematic usage of alcohol, tobacco, and illicit drugs at this age can increase the risk of diabetes complications such as DKA [97]. Finally, chronic vascular complications, such as retinopathy, nephropathy, neuropathy, and cardiovascular disease, can begin in childhood and continue or worsen in young adulthood. There is a greater vascular complication risk in those developing diabetes before or during puberty compared with after

puberty [98]. Many organizations regularly publish guidelines regarding screening for such complications [11, 99].

Young people with type 2 diabetes are also at risk of acute complications such as DKA and hyperosmolar hyperglycaemia [100]. In addition, there is an increased risk of a variety of chronic complications and comorbidities, including hypertension, dyslipidaemia, nephropathy, retinopathy, non-alcoholic fatty liver disease (NAFLD), polycystic ovary syndrome (PCOS), depression, and binge eating [100]. The TODAY study found that hypertension, dyslipidaemia, and microalbuminuria were present at baseline and increased by the end of the study [101]. This study group recently published a 10-year follow-up study examining the occurrence of diabetes-related complications in participants in the main trial. More than half of the cohort of young adults (mean age 26.4 ± 2.8 years) had developed at least one complication. The risk factors for developing complications included minority race or ethnic group, hyperglycaemia, hypertension, and dyslipidaemia [102]. This study shows the importance of early aggressive management of hyperglycaemia for young people with type 2 diabetes to preserve health and prevent complications [102]. Young adults with type 2 diabetes may also be at risk for mental health problems, such as depression, decreased quality of life due to early complications, and disordered eating behaviour [77, 103, 104].

What is transition?

Transition is the reorientation that people experience in response to a change. While change is situational, such as moving to a new town or changing jobs, transition is the way in which people respond to the changes they encounter in their lives [105]. Transition is the movement people make through such a disruptive life event in order to continue to live with a coherent, albeit evolving, sense of themselves [106]. Transfer refers to the physical change in the ministration of responsibilities from one individual to another; in this case, the paediatric endocrinologists or diabetologists end their relationships with the person with diabetes, who begins meeting with an adult physician. Transition is a process in which the adolescent or young adult with diabetes prepares for self-care and the future change in diabetes team, while transfer is the actual transfer event. If these activities are managed poorly, failure to engage with adult services decreases the likelihood of regular attendance at diabetes medical centres and increases the likelihood of emergency department use and hospitalizations [107, 108].

Within paediatric healthcare, transition has often been defined as the time when an adolescent or young adult makes a purposeful, planned movement from paediatric to adult care services. It is a multiyear process that should begin in early adolescence. The goal is to optimize health and well-being. To accomplish this, several factors need to be present, including:

- Transition preparation.
 - Engagement in chronic disease self-management.
 - Actual transfer of healthcare from paediatric to adult systems [4].
- The moment of transfer requires a hand-off approach between providers. Successful transition from paediatric to adult services involves the family, and is affected by demographic characteristics, diabetes history, glycaemic levels, self-management, and a sense of self-efficacy and transition preparation [109]. Transition is considered successful when an emerging adult demonstrates the ability to self-manage diabetes, meet with members of the diabetes healthcare

team at recommended intervals, maintain glycaemic levels, and avoid acute complications [4]. Figure 70.1 provides a schematic of tasks during the period of transition and for the ultimate transfer between providers.

Problems with transition

Emerging adults with diabetes and their healthcare team encounter various issues during the transition from a specialized paediatric diabetes clinic to an adult endocrinology, diabetology, or primary care practice (Box 70.1). Notably, the topic of transition has continued to garner substantial interest from diabetes clinical and research communities for several reasons: first, there are more young people with type 1 diabetes and type 2 diabetes who need to undergo transition; and second, there is a deficiency of efficacious intervention research aimed at guiding the transition process and optimizing health outcomes of emerging adults with diabetes [57, 110–112].

One difficulty with transition is that the emerging adult must part with a long-term, familiar relationship with a group of paediatric healthcare professionals. In addition, there are fundamental differences in healthcare delivery between paediatric and adult settings [57]. Shulman et al. surveyed the Ontario Paediatric Diabetes Network regarding transition readiness and found that some paediatric providers perceived that adult diabetes clinics were less likely to have multidisciplinary holistic models of care, were less friendly to young adults, and had an infrastructure that made it more difficult to book appointments [113]. The longstanding relationship with the paediatric diabetes team had been family centred and

Box 70.1 Challenges for older teenagers and young adults with diabetes during the transitional period

- Diabetes self-care often loses priority to competing demands related to social, emotional, educational, and occupational interests and needs.
- Emerging adults with diabetes are at high risk for chronic hyperglycaemia.
- Mental health issues (i.e. depression, anxiety, disordered eating behaviours) are common at this age.
- Issues around sexual and reproductive health become paramount.
- Risk-taking behaviours around alcohol, smoking, and drug abuse typically increase in this age group.
- There is increased risk of acute complications (i.e. diabetic ketoacidosis and severe hypoglycaemia) for transitioning young adults.
- There is a risk of missing screening opportunities for eye and kidney complications and cardiovascular risk factor identification.
- Paediatrics and adult healthcare professionals employ different approaches to diabetes care.
- Loss to follow-up is a common problem at time of transition/transfer.
- Developing chronic diabetes complications may present in older adolescence and young adulthood and may go under-detected and untreated.

holistic with respect to paediatric and adolescent developmental needs. Adult visits tend to be shorter in duration and tend to focus more on medical treatments [57]. Adult medical providers tend to focus the visit almost exclusively on the young adult rather than the family, with the belief that the individual is capable of making independent decisions regarding care and treatment [57]. Adult care providers often assume that the person with diabetes possesses the skills and capacity to perform diabetes care independently, which could be problematic if the emerging adult was ill-prepared by the paediatric team to assume the necessary responsibilities for their diabetes self-care. In turn, the emerging adult may feel unsupported and vulnerable following the transfer [109]. In some instances young adults may choose to reject adult care, limiting their openness to the medical provider's recommendations. These factors contribute to the frequent loss to follow-up care experienced by many emerging adults [57].

Indeed, more than one-third of older teenagers and emerging adults transferring care between paediatric and adult providers experience gaps in care exceeding six months [57]. Risk factors for gaps in care include a high number of stressful life circumstances, no college degree, and fewer than three paediatric diabetes visits in the year before transition [109, 114]. These gaps in care and loss to follow-up can lead to acute complications and the emergence of chronic complications that go undetected and untreated.

Unsuccessful transition is more likely to occur when emerging young adults lack skills for independent decision making, especially when they do not feel ready to handle such responsibilities [4, 57]. For example, a small sample of pre-transition teenagers with type 1 diabetes with an $\text{HbA}_{1c} > 9\%$ (75 mmol/mol) reported a lack of formal preparation for transition, with a preference to defer being 'serious' about the transition process [115]. Furthermore, there are many age-appropriate social, emotional, educational, and work-related activities that compete for the attention of older teenagers and emerging adults, often superseding self-care and attendance at healthcare visits [109]. Many of these older teenagers and young adults may also feel uncomfortable disclosing their chronic medical condition to others, especially when entering a new school or work environment, making it challenging for those with diabetes to perform management tasks consistently [116]. The successful balance of diabetes self-care demands with these competing needs requires self-efficacy and self-advocacy. Transition preparation should include attention to these areas.

Gaps in care or loss to follow-up care results in elevated HbA_{1c} and glucose variability and places the emerging adult at increased risk for medical complications in both the short and long term [117]. The short-term complications are related to extreme glucose fluctuations (i.e. severe hypoglycaemia or hyperglycaemia) and can lead to emergency room use or hospitalization, especially in the absence of routine care. Further, persistent hyperglycaemia increases the risk for long-term microvascular and macrovascular complications [118]. Transition preparation from the paediatric team should include discussion of chronic diabetes complications, pregnancy planning, and routine screening for clinical evidence of early kidney and eye changes and risk factors for macrovascular complications. Otherwise, some emerging young adults may opt to avoid follow-up adult care rather than be suddenly faced with discussions regarding complications when they have been ill prepared [4].

There are several behavioural, psychosocial, and psychiatric challenges that can confront the older teenager and emerging adult with diabetes during the transition: these include diabetes distress,

fear of hypoglycaemia, fear of hyperglycaemia, burnout, depressive symptoms, depression, anxiety, and disordered eating behaviours, among others. These challenges can interfere with effective self-care and consistent diabetes follow-up, leading to a vicious cycle of discouragement and burnout, which, in turn, may further diminish attention to diabetes self-care. Data in teenagers and emerging adults with type 1 diabetes identify psychosocial risk factors associated with reduced diabetes self-management and burnout [31, 114, 119, 120].

The coexistence of psychiatric conditions (Chapter 65), specifically depression and anxiety, brings considerable challenges to the management of diabetes during adolescence and emerging adulthood, having substantial impacts on self-care and consistent follow-up with medical providers [4]. Although such conditions are common in the general population, rates of depression and anxiety are higher in those with diabetes, especially during these developmental stages [121]. Collaborative care from professionals, including psychologists, social workers, and psychiatrists, versed in depression and anxiety disorders, including their impact on diabetes, is necessary to aid in the management of these conditions. Depressive symptoms and frank depression, associated with reduced motivation, often lead to reduced attention to diabetes self-care, yielding hyperglycaemia. For example, a study conducted in Singapore found an association between anxiety and depression before transition in both type 1 diabetes or type 2 diabetes and suboptimal glycaemic levels during follow-up visits [122].

Furthermore, the symptoms of depression and persistent hyperglycaemia can overlap with intensification of fatigue. Anxiety disorders also complicate living with and managing diabetes, in particular related to fear of needles or injections or fear of extremes of glucose levels. Fear of hypoglycaemia is more common than fear of hyperglycaemia, but some may fear the latter due to extreme concerns about the development of diabetes complications. Extreme anxiety can trigger panic attacks at times. Additionally, symptoms of hypoglycaemia and anxiety may overlap, further complicating management and generally leading to poor self-management [57].

Disordered eating behaviours and eating disorders, especially common in females, complicate diabetes management during the period of transition [57]. Cecilia-Costa et al. found that two of every five teenagers had moderate or high levels of disordered eating behaviour in their sample of 178 teenagers with type 1 diabetes [123]. A unique manifestation of eating disorders in diabetes is the purposeful restriction or omission of insulin. The deliberate underdosing of insulin serves as a very potent but dangerous weight loss strategy [124]. Many specific elements of type 1 diabetes and its treatment have been linked to the development of disordered eating behaviours and eating disorders, specifically the following:

- Initial loss of weight at the onset of the disease followed by weight gain on initiating insulin replacement.
- Occasional weight gain associated with intensive insulin therapy.
- Focus on diet as part of the diabetes treatment plan.
- The need to eat often without hunger, due either to peaking insulin action or hypoglycaemia [104, 125].

Factors associated with disordered eating behaviours include female sex, obesity, suboptimal glycaemic levels, presence of depressive symptoms, and executive dysfunction [123]. A recent publication also highlights associations between executive dysfunction and disordered eating behaviours in adolescents with type 1 diabetes; the former remains an area of ongoing investigation due to the importance of executive function in self-care in

type 1 diabetes [126]. Furthermore, disordered eating and eating disorders, particularly with insulin restriction or omission, can lead to deterioration in glycaemic levels and subsequent complications, even premature mortality [127–129]. It is crucial that teenagers and emerging adults with disordered eating behaviours or eating disorders receive specialized care, typically coordinated by the diabetes treatment team; however, this can be problematic if care for the affected person falls between the paediatric and adult healthcare systems [57].

In addition to the challenges already enumerated, there is a lack of empirically validated programmes to promote transition readiness, well-defined criteria to determine transition readiness, and methods to ensure a smooth transfer between paediatric and adult healthcare systems. Recently, questionnaires have been developed to assess transition readiness, such as Readiness Assessment of Emerging Adults with Type 1 Diabetes Diagnosed in Youth (READY), Transition Readiness Assessment Questionnaire (TRAQ), and Readiness for Independent Self-Care Questionnaire-Adolescent (RISQ-T) and Parent (RISQ-P) [24, 130, 131].

Still, many older teenagers and young adults with diabetes experience gaps in care on transfer, deterioration of glycaemic levels, increased risk for acute complications, and the unrecognized emergence of chronic complications. Finally, there may be a component of reticence and even ambivalence regarding transition and transfer from paediatric providers. Many paediatric diabetes providers have known the individuals with diabetes for years and may have difficulty discharging them to adult providers, as they worry about how the individuals with diabetes will adjust to different models of care. Thus, there is a need for coordinated efforts between paediatric and adult providers to ease transition and transfer for individuals with diabetes and families as well as for the providers.

Existing transition programmes/interventions

Transition programmes do exist in the USA and other countries. However, there is no documented gold standard approach that has been empirically proven to yield optimal outcomes with respect to engagement, follow-up, medical outcomes, and psychosocial outcomes. The literature includes descriptions of structured and unstructured transition programmes, with structured programmes generally resulting in better outcomes. This section will describe published approaches to transition programmes along with suggestions for future directions.

There are three main approaches to developing transition programmes: clinics dedicated solely to emerging young adults, clinics focused on transition planning, and clinics that incorporate care coordination (care ambassadors or *diabetes navigators*) to ensure timely follow-up [4, 112]. In dedicated young adult clinics, there are specific days and times reserved for the care of young adults within the diabetes clinics. These focused clinics tend to be staffed by adult healthcare professionals who have a particular interest in the care of the emerging young adult.

Outcome results from care in young adult clinics have been variable, with some studies yielding no effect on glycaemic levels [132], while others have demonstrated superior outcomes with lower HbA_{1c} and reduction in hospital admissions [133, 134]. One study found high satisfaction levels in parents and young adults who participated in half-day transition clinics [135]. The differing results are likely to reflect the different designs and features of each of these programmes.

The second type of transition programme is related to transition preparation, which provides paediatric diabetes teams, individuals with diabetes, and families with a more structured and purposeful approach to transition planning aimed at creating a successful transfer. Cadario et al. retrospectively examined two groups who were transferred from paediatric to adult diabetes care in different ways [136]. The first group was sent a letter with information about their medical history and a scheduled appointment with an adult team. The second group participated in a structured transition programme, which included transition planning during the last year of paediatric care and discussions about what to expect following the transfer. Additionally, both paediatric and adult physicians participated in the last paediatric clinic appointment and first adult clinic appointment, with the paediatrician providing a medical summary to the adult doctor and the person with diabetes at the last paediatric appointment. Those in the second group showed more optimal outcomes, with a shorter time between last paediatric and first adult clinic appointments, better clinic attendance in the first year post-transfer, and improved HbA_{1c}. Furthermore, the second group reported satisfaction with the transition process [136]. More rigorous, prospective studies are needed.

The third type of transition programme utilizes a care coordinator who works closely with the older teenagers or young adults as they transition from paediatric to adult care. Van Walleghem et al. studied an intervention called the Maestro Project, which assigns a care coordinator to provide consistent contact and ensure access to diabetes care for the person with diabetes during the transition process [136]. In addition to care coordination, this programme offers a website, newsletter, meeting groups, and educational events. People with diabetes in this programme had greater retention in care, while the coordinator helped recapture individuals who had been previously lost to follow-up care. Other studies of care coordination have shown varied results; one demonstrated improved glycaemic levels and reduced hospitalizations [133], while another study comparing usual care with outreach by phone revealed no difference in outcomes [137]. Again, varying results may reflect differences in programme features or implementation.

Campbell et al. performed a systematic review of care transition among many chronic diseases of childhood, including type 1 diabetes, and compared the effectiveness of different interventions aimed at improving the transition of care for adolescents [112]. Four different interventions were reviewed: transition preparation training delivered in a two-day workshop, a web- and text message-based educational intervention, a one-hour one-on-one teaching session led by a nurse, and a comprehensive transition programme with a transition coordinator. Results indicated slight improvements in transition readiness, disease knowledge, and self-efficacy, especially in the technology-based intervention and with one-on-one teaching sessions. However, no major conclusions were drawn from the review, and it remains clear that there is a need for more prospective, longitudinal research [112].

In addition to these transition programmes housed within either paediatric or adult diabetes clinics, there may be opportunities to support older teenagers and young adults within a support group setting. Our team at the Joslin Diabetes Center in Boston examined the utility of monthly support groups for young adults with type 1 diabetes [116] and found that after five months of participation, self-reported diabetes burden had decreased and two-thirds of the participants had improved HbA_{1c}; there was a trend for improved self-care. Another report described a programme that combined aspects of many of those listed earlier, including transition planning,

coordinated transfer visits, an extended intake appointment with the adult diabetes staff, and group support sessions [138]. Those who participated in this programme had improved HbA_{1c}, decreased hypoglycaemic episodes, and greater diabetes-specific knowledge compared with those who received standard care. In addition, the Hemsley type 1 diabetes transition Let's Empower and Prepare (LEAP) programme provided pre-transition adolescents with type 1 diabetes with additional diabetes education, dietitian support, case managers, and the option of transferring to the young adult clinic and joining private social network groups. Compared with usual care, participation in the programme was associated with better glycaemic levels and psychosocial well-being [139]. Another multicentre RCT in Canada showed that young adults with type 1 diabetes who attended a transition programme with a transition coordinator showed an initial increase in clinic attendance, more satisfaction with care, and less diabetes-related distress than standard care [140].

Other innovative methods to help ease the transition process in youths with type 1 diabetes include using technology and group education. In a focus group for young people with type 1 diabetes in transition, the participants talked of a lack of communication technology during the transfer from paediatric to adult care [141]. Albanese-O'Neill et al. designed transition education for young adults with type 1 diabetes using group telehealth. Young adults with type 1 diabetes were recruited to attend five 30-minute videoconferences over eight weeks. Even though there was no statistically significant difference in diabetes self-efficacy or diabetes-related

distress, they found that group videoconferencing was a feasible method to deliver diabetes education for young people with type 1 diabetes [142].

Other investigations are ongoing worldwide to design, implement, and evaluate transition programmes, given the increasing numbers of older teenagers and emerging adults with diabetes in need of improved systems of care and better health outcomes.

Conclusion

Significant physical, social, and emotional growth occurs during the adolescent years. The extra burden of diabetes adds further challenges at this time. Teenagers with diabetes have often developed a strong relationship with their paediatric diabetes care team, and the transfer to a new adult diabetes care team disrupts an established bond. Adolescents and young adults must develop increasing independence and responsibility for their diabetes care. This could be a time of crisis or a time of opportunity. By approaching this transition equipped with information about normal developmental stages and the unique challenges of diabetes self-care at this time, parents and diabetes healthcare providers can help older adolescents and young adults make this transition, empowering them to negotiate the transition and transfer as seamlessly as possible to preserve health and prevent the emergence of diabetes complications.

David R. McCance and Laura Cassidy

Regional Centre for Endocrinology and Diabetes, Royal Victoria Hospital, Belfast, Northern Ireland

Key points

- Pregnancy outcomes were transformed by the discovery of insulin in 1922 and the subsequent realization of the importance of optimal glycaemic management, close obstetric surveillance, and dedicated multidisciplinary care.
- The aim is to optimize blood glucose levels both before and during pregnancy through education and maternal empowerment, so that pregnancy may proceed as normally as possible and result in the birth of a normal baby at near term.
- Data registries indicate that congenital malformation and perinatal mortality rates remain 2–5-fold higher in pregnant women with diabetes than the background obstetric population.
- The benefits of pregnancy planning and pre-pregnancy care in improving outcomes are clear, but only a minority of women plan their pregnancy and education remains a key priority.
- Optimizing glycaemic levels is challenging for both the woman and clinician and must be balanced against the risks of hypoglycaemia.
- Randomized controlled trials suggest that insulin aspart and detemir are safe to use and have some benefits over conventional insulins; safety and efficacy data on very fast-acting analogues are awaited.
- Recent advances in insulin delivery and glucose sensing and their integration into hybrid closed-loop systems offer promise, but elucidation of their relative roles is urgently needed.
- Prevalence rates of type 2 diabetes, compounded by obesity, are being translated into pregnancy and now exceed type 1 diabetes in some populations, with similarly poor pregnancy outcomes.
- Consensus recommendations for the diagnosis of hyperglycaemia in pregnancy have generated a uniformity of approach, but individual variation remains across countries, and the risk, costs, and benefits of intervention are the subject of continued debate.
- Glycated haemoglobin ($\text{HbA}_{1\text{c}}$) or fasting plasma glucose (or other assessment of blood glucose) should be measured in early pregnancy to diagnose previously unrecognized type 2 diabetes and pre-diabetes and to identify women with severe hyperglycaemia.
- Metformin (in conjunction with dietary modification) is being used increasingly to supplement or replace insulin in the management of women with gestational diabetes mellitus (GDM) and type 2 diabetes, especially in those who are overweight; metformin crosses the placenta, and some international bodies still recommend insulin as first choice.
- Early postnatal visits in women with GDM are a unique opportunity to screen for and treat cardiometabolic risk factors, prevent or postpone the future risk of type 2 diabetes, and remind women of the need for contraception and future pregnancy planning.
- The adverse long-term implications of hyperglycaemia during pregnancy for both mother and offspring must be incorporated into cost-economic analyses.

The transformation of diabetic pregnancy outcomes following the discovery of insulin in 1922 was one of the outstanding medical success stories of the twentieth century [1]. Prior to insulin, these mothers ‘gave birth astride a grave’ [2] and the prospect of a viable fetus was negligible. By the middle of the last century, maternal mortality had declined significantly but the fetal outlook, even up to the early 1950s, remained very poor, with perinatal mortality rates of 20–25% [3]. During the next two decades pioneering work in centres including the Joslin Clinic in Boston, King’s College Hospital in London, and Rigshospitalet in Copenhagen established the critical roles of optimal glycaemic management in mid to late pregnancy and of early delivery in reducing perinatal mortality [1, 3]. Along with this came increasing recognition of the need for multidisciplinary integrated care in units specializing in diabetic pregnancy [3]. In the 1980s, the advent of self-monitoring of blood

glucose, glycated haemoglobin ($\text{HbA}_{1\text{c}}$), and insulin pen devices together with advances in obstetric surveillance helped to make pregnancy a more positive experience and further improved pregnancy outcomes. During recent decades, several randomized trials have offered new insight into the role of insulin analogues and oral anti-diabetes drugs in pregnancy.

Despite these advances, the goal of the Saint Vincent Declaration [4], that the outcome of diabetic pregnancy should approximate that of pregnancies of women without diabetes, has not been realized, and congenital malformation and perinatal mortality rates are still 2–5-fold higher than in the background obstetric population. Optimizing glycaemic levels remains challenging for both the woman and her physician, and efforts to intensify management must constantly be balanced against the risk of maternal hypoglycaemia. Despite these caveats, pregnancy outcomes for

most women are successful and this undoubtedly reflects improved obstetric surveillance and better management of maternal hyperglycaemia. Recent advances in continuous subcutaneous insulin infusion (CSII), continuous glucose monitoring (CGM), and hybrid closed-loop systems have aroused considerable interest; however, their relative roles need to be elucidated, and it is uncertain what impact these devices will have on perinatal outcomes and overall patient satisfaction. The cost of this technology is likely to restrict its use to selected, educated, motivated women in experienced centres receiving dedicated supervision.

Over recent decades, the global pandemic of type 2 diabetes has been translated into pregnancy and now exceeds the proportion of women with type 1 diabetes in some populations, with similarly poor pregnancy outcomes. As the care of women with type 2 diabetes is predominantly community based, there is an urgent need to increase awareness among family doctors of the importance of contraception and pregnancy planning. Excessive maternal weight, a recognized factor for poor obstetric outcomes, frequently coexists with type 2 diabetes, and adds to the complexity of management.

While the association of overt diabetes during pregnancy with adverse pregnancy outcomes is clearly established, the relevance of minor degrees of hyperglycaemia to adverse outcomes has been surrounded by confusion and controversy. This situation eventually provided the catalyst for several landmark observational studies and randomized trials, which confirmed the continuum of risk and facilitated an international diagnostic consensus; however, variation still exists, and the glucose thresholds for diagnosis remain the subject of active debate. Recent follow-up studies showing independent associations of maternal hyperglycaemia with adverse metabolic and cardiovascular outcomes in the mother and offspring make a convincing case for early postnatal diabetes and cardiovascular risk screening, and such data must be included in cost-economic models of care.

Epidemiology

The seventh edition of the International Diabetes Federation (IDF) *Diabetes Atlas* estimated that 20.4 million or 15.8% of live births to women in 2019 had some form of diabetes in pregnancy [5]. Of these, 84% were due to gestational diabetes mellitus (GDM), 7.3% were the result of diabetes detected prior to pregnancy, and 8.5% were due to diabetes (including type 1 diabetes and type 2 diabetes) first detected in pregnancy. The vast majority of cases (87%) of hyperglycaemia in pregnancy are seen in low- and middle-income countries where access to antenatal care is often limited.

Between 1996 and 2010 the incidence of diabetes (GDM, type 1 diabetes, type 2 diabetes) during pregnancy doubled, affecting almost 1 in 10 pregnant women aged 30 years [6]. The numbers of pregnancies complicated by type 1 diabetes and type 2 diabetes increased by 33–44% and 90–111%, respectively, in Sweden and Scotland over a 15-year period since 1998 [7, 8].

A UK Confidential Enquiry into Maternal and Child Health (CEMACH, 2002–2003) of 3000 women with type 1 diabetes and type 2 diabetes in England, Wales, and Northern Ireland estimated the frequency of type 1 diabetes to be 1 in 364 (0.27%) and for type 2 diabetes 1 in 955 births (0.1%) [9]. A UK national report in England and Wales in 2015 estimated that approximately 1500 babies were born to women with type 1 diabetes, accounting for 0.21% of all live births [10].

The use of differing screening methods and diagnostic criteria both between and within countries makes comparative epidemiology difficult [11–13]. For example, within the UK the estimated crude prevalence of diabetes is 22.8% of live births, with an age-standardized prevalence of 19.9% (5.1% attributable to overt diabetes) [14]. By contrast, the prevalence estimated by the National Institute for Health and Care Excellence (NICE) in England and Wales using differing diagnostic thresholds was 5.0% (87.5% GDM, 7.5% type 1 diabetes, 5% type 2 diabetes) [15]. One retrospective study found a 30% increase in the incidence of GDM by the International Association of Diabetes and Pregnancy Study Groups (IADPSG) criteria compared with the 2015 NICE criteria [12]. The increase in GDM is compounded by obesity, which now affects about one in five women who give birth [16]. Despite the varying diagnostic criteria, there has been a progressive rise in the prevalence of GDM and overt diabetes during pregnancy over recent decades [17–19].

Physiology

Maternal metabolism adapts during pregnancy to ensure fetal growth and development. This involves a greater fall in plasma glucose and amino acids, and a greater rise in free fatty acids to overnight fasting than in the non-pregnant state (*accelerated starvation*). These changes are accompanied by hepatic insulin resistance, which ensures that maternal glucose is available to the fetus between meals [20].

Fasting glucose levels decrease from around 8 weeks' gestation and reach a nadir by the end of the first trimester due to insulin-independent glucose uptake by the fetus and placenta. From approximately 22 weeks' gestation, there is a progressive rise in post-prandial glucose and its associated insulin response, resulting from decreased insulin sensitivity, which parallels the growth of the fetal placental unit and rapidly reverses after delivery. In late pregnancy, maternal-to-fetal glucose transfer in the fasting state is also enhanced by maternal lipolysis, with free fatty acids becoming the main maternal fuel substrate. The inability of insulin to suppress lipolysis via inhibition of hormone-sensitive lipase in adipose tissue occurs at a time when maternal free fatty acid release and fatty acid oxidation are increased in parallel with reduced carbohydrate oxidation [21, 22]. The enhanced lipolysis [23] is attributed to the actions of human placental growth hormone and other placental hormones [24–27]. This *facilitated anabolism* brings about appropriate changes in carbohydrate, amino acid, and lipid metabolism and ensures adequate nutrients for the developing fetus.

The precise mechanism underlying the insulin resistance of late pregnancy is uncertain, but it appears to be related to a combination of increased hormone concentrations (human placental lactogen, progesterone, oestrogen, prolactin, and cortisol), increased free fatty acid concentrations, and changes to various cytokines elaborated by the placenta (tumour necrosis factor α , TNF- α), adipocyte fatty acid-binding protein, and leptin [28]. Maternal weight gain provides a source of calories for the fetus and mother, but increased visceral deposits contribute to insulin resistance.

Pathophysiology and its implications

To maintain glucose tolerance, maternal β cells compensate for the fall in insulin sensitivity by an approximate threefold increase of both the first- and second-phase insulin responses by the last

trimester [29], together with marked β -cell hypertrophy and hyperplasia [30].

Women who lack the necessary β -cell reserve, either absolutely as in type 1 diabetes or relatively as in type 2 diabetes or GDM, will have abnormal adaptation of carbohydrate, protein, and fat metabolism. Pregnant women with type 1 diabetes require sufficient insulin to compensate for increasing caloric needs, increasing adiposity, decreasing exercise, and increasing anti-insulin hormones. Insulin doses to maintain normoglycaemia and prevent maternal ketosis may increase up to threefold during pregnancy in type 1 diabetes. Women with type 2 diabetes will usually require insulin treatment in pregnancy, often at high doses, because of their obesity and physical inactivity. The increase in insulin resistance and requirements induced by the feto-placental unit reverses within a few hours of delivery, although requirements related to excessive maternal weight gain in pregnancy persist. An understanding of the underlying pathophysiological mechanisms is necessary for the successful clinical management of these women during pregnancy.

In GDM, the rise in glucose mostly results from a relative failure to increase insulin secretion in the face of chronic insulin resistance (primarily the result of obesity) that is accentuated in pregnancy and often compounded by excessive gestational weight gain. Women who develop GDM show decreased β -cell function [31, 32] similar to that of type 2 diabetes, and hence similar management strategies are appropriate.

The hypothesis that maternal hyperglycaemia accelerates fetal growth through provision of excessive glucose to the fetus at a time when the fetal pancreas can respond by increasing its production of insulin, an important fetal growth factor, was first proposed by Jorgen Petersen over 60 years ago [33]. Immunoreactive insulin is detectable in the human fetal pancreas by the seventh week after conception, with evidence of functional fetal β cells by the end of the first trimester [34]. The hypothesis is supported by animal and epidemiological data and has provided a basis for the concept of fetal programming. Other maternal fuels are likely to be implicated. More recently a *fetal glucose steal* phenomenon was suggested as an explanation for adverse neonatal outcomes despite seemingly satisfactory glycaemic levels in later pregnancy. This envisaged the early establishment of fetal hyperinsulinaemia, resulting in a lowering of fetal glycaemia, leading to an increased glucose concentration gradient across the placenta and hence glucose flux to the fetus. Such a hypothesis would have implications for pregnancy planning, and the need to optimize glucose levels in early pregnancy to prevent the establishment of fetal hyperinsulinaemia. An exaggerated glucose steal, by attenuating maternal glucose levels during an oral glucose tolerance test (OGTT), might provide an explanation for why some mothers with all the characteristics of diabetic fetopathy have *normal* glucose tolerance [35].

HbA_{1c} values tend to fall during normal pregnancy, possibly due to a combination of reduced fasting blood glucose levels and reduced red blood cell survival [36]. A small increase in late pregnancy may relate to developing iron-deficiency anaemia [37]. Alternative upper-limit reference ranges of 26 mmol/mol in the first and second trimesters and 40 mmol/mol in the third trimester have been suggested [38].

Classification

The World Health Organization (WHO) and IDF currently advise that hyperglycaemia in pregnancy can be classified as either GDM or diabetes in pregnancy [5, 39–42] (Table 71.1).

Table 71.1 Classification of diabetes in pregnancy.

Type of diabetes
Diabetes preceding pregnancy
• Type 1 diabetes
• Type 2 diabetes
Monogenic diabetes (e.g. <i>GCK</i> , <i>HNF1A</i>)
Secondary diabetes (e.g. cystic fibrosis)
Hyperglycaemia first detected in pregnancy
• Gestational diabetes
• Overt diabetes ^a

^aOvert diabetes defined by oral glucose tolerance test (OGTT)/glycated haemoglobin (HbA_{1c}) criteria outside of pregnancy.

Source: Based on International Diabetes Federation 2019 [5], International Association of Diabetes and Pregnancy Study Groups Consensus Panel et al. 2010 [41], and World Health Organization 2013 [42].

GDM is diagnosed for the first time during pregnancy and may occur at any time during pregnancy, most commonly after 24 weeks [41]. Diabetes in pregnancy, which may occur at any time including the first trimester [40, 41], applies to pregnant women who have previously diagnosed diabetes, or have hyperglycaemia that was first diagnosed during pregnancy and meets WHO criteria for diabetes in the non-pregnant state. Most women with *overt diabetes in pregnancy* will have previously unrecognized type 2 diabetes (suggested by higher HbA_{1c} and features of the metabolic syndrome), but between 3% and 10% of those with newly recognized diabetes during pregnancy have type 1 diabetes. The diagnosis of type 1 diabetes may be suspected where the blood glucose levels are unusually high and in the absence of obesity. Some of these women may be able to stop insulin postnatally, even with apparent remission, but relapse typically occurs [43]. Serological tests for islet cell autoimmunity are usually strongly positive [44]. Approximately 75–90% of cases of hyperglycaemia in pregnancy are GDM.

A form of type 1 diabetes with rapid onset was first described in Japan in 1987, but subsequently reported in women from Southeast Asian countries [45]. The presentation is usually abrupt with severe diabetic ketoacidosis (DKA), often preceded by a short history of flu-like and abdominal symptoms. Investigations reveal raised serum pancreatic enzymes and hyperglycaemia, but normal HbA_{1c} , consistent with the acuteness of the presentation [45]. The condition most frequently occurs in late pregnancy or immediately postpartum, with high perinatal mortality rates [46].

Cystic fibrosis diabetes is now being encountered more often during pregnancy as survival into adulthood is common. Around one-third will have developed diabetes by the age of 20–30 years. In keeping with their longer life expectancy, the women are usually less ill with better pulmonary function, higher body mass index (BMI), and a lower prevalence of diabetes [47].

The diagnosis of monogenic diabetes may antecede pregnancy, but a small percentage of women initially considered to have type 1 diabetes or type 2 diabetes during pregnancy have genetic diabetes (most commonly *GCK* or *HNF1A* mutations or mitochondrial diabetes). Such a diagnosis is prompted by fasting hyperglycaemia but normal one- and two-hour values on OGTT screening among women with a normal BMI. Recognition is important given the risk of accelerated fetal growth depending on whether or not the mutation has been inherited [48].

Adverse pregnancy outcomes

Women with type 1 diabetes have a 2–5-fold increased risk of adverse pregnancy outcomes including congenital anomalies, stillbirth, and perinatal mortality [6, 7, 49–54]. A 2013 review of 12 population-based studies published within the previous 10 years comparing 14 099 women with type 1 diabetes with 4 035 373 women from the background population [52] reported as follows:

- Congenital malformations, 5.0% vs 2.1% (relative risk [RR] 2.4).
- Perinatal mortality, 2.7% vs 0.72% (RR 3.7).
- Preterm delivery, 25.2% vs 6.0% (RR 4.2).
- Large for gestational age (LGA) infants, 54.2% vs 10.0% (RR 4.5).

In the 2016 UK National Diabetes in Pregnancy Audit (NDIPA), almost one in two babies had complications related to maternal diabetes [53]. Outcomes are similar in mothers with type 2 diabetes [54–57].

Risk factors for mother and baby

Risk factors for poor pregnancy outcomes are well recognized, but modified by the type and duration of diabetes, glycaemic levels, and diabetes-related vascular complications [15]. These include:

- *General risk factors*: age, parity, weight, hypertension, smoking, and drug abuse.
- *Obstetric risk factors*: previous miscarriage, multiple pregnancy, nutritional deficiency, late booking, and poor obstetric history.
- *Maternal risk*: miscarriage, accelerated retinopathy and nephropathy, hypoglycaemia and hypoglycaemic unawareness, DKA, pre-eclampsia, hydramnios, operative delivery, and infection.
- *Fetal risk*: stillbirth, perinatal mortality, congenital anomalies, Small for Gestational AGE (SGA), Large for Gestational Age (LGA), preterm delivery, operative delivery, shoulder dystocia and birth injury, neonatal hypoglycaemia, polycythaemia, hypocalcaemia, and respiratory distress syndrome.

Rationale for pregnancy planning

Optimizing glycaemic levels before pregnancy and early during the first trimester is associated with improved outcomes, reduced congenital anomalies, and lower perinatal mortality [15, 58–60]. A meta-analysis [59] reported that implementation of pre-pregnancy care is associated with an RR of 0.25 (95% confidence interval [CI] 0.16 to 0.37) and number needed to treat (NNT) of 19 (95% CI 14 to 24), for congenital malformations, and an RR of 0.34 (95% CI 0.15 to 0.75) and NNT of 46 (95% CI 28 to 115) for perinatal mortality. It is important for the woman to realize that these benefits occur with any improvement in HbA_{1c} [61, 62], but the average reduction in HbA_{1c} of 13 mmol/l (1.2%) was achieved at the expense of an increased risk of hypoglycaemia during the first trimester (RR 1.51; 95% CI 1.15 to 1.99) [59].

There is a critical need for the healthcare professionals to embrace every opportunity to educate women and adolescents of reproductive age about the risks of unplanned pregnancies and the improved outcomes resulting from pregnancy planning [60, 63, 64], including cost benefits [65].

Components of a prepregnancy service

There are two separate components to reproductive health education for women with type 1 diabetes: preconception counselling and prepregnancy care [63].

Preconception counselling is the education of, and discussion with, women of reproductive age about pregnancy and contraception. Beginning at the onset of puberty or at diagnosis, and utilizing appropriately customized resources [66], it should take place at regular intervals during a woman's reproductive years and include education and discussion on the following:

- The use of contraception and assessment of risks for each method until a woman is prepared and ready to become pregnant [15, 60, 63].
- Increased risks of adverse outcomes associated with hyperglycaemia.
- Nature of preconception care and how it can improve pregnancy outcomes.
- Risks of smoking and alcohol consumption during pregnancy.
- Avoidance of statins and renin–angiotensin system (RAS) inhibitors during early pregnancy [15, 60].

Prepregnancy care is the additional care required to prepare a woman with diabetes for pregnancy [15, 60, 63, 67]. Ideally, this should be delivered by a multidisciplinary team, who will care for her during pregnancy, and should begin at least six months before conception. The aim is to optimize glycaemic management before conception (Table 71.2).

Challenges associated with prepregnancy care

Prepregnancy care recommendations and, particularly, glycaemic targets are demanding and many women are unable to achieve them. Despite the clear advantages of prepregnancy and coordinated pregnancy care in improving outcomes [68, 69], not all women with type 1 diabetes attend. Such women are more likely to be younger, with no third-level education, and not married or in a relationship [70]. Awareness of the rationale for prepregnancy care in women with type 1 diabetes has increased in recent years, even among non-attenders. In one study, the commonest reason for not attending was a pregnancy that was not fully planned or conception occurring more quickly than expected (45%). Other reasons for non-attendance were fertility concerns (31%), negative relationships with healthcare professionals (21%), complex emotional issues (17%) including fear of being disappointed and wanting a normal pregnancy, and logistical or financial concerns (10%) [71].

Behaviour patterns frequently coexist and so women with sub-optimally managed diabetes are also more likely not to use regular contraception, to have unplanned pregnancies, to smoke cigarettes, to present late to pregnancy clinics, and to have more diabetes complications [9, 68, 72]. Consequently, those women who would probably benefit most from rigorous pregnancy counselling are least likely to receive it, and this may be one of the greatest challenges.

Adverse fetal outcomes

Congenital malformations

Recognition of the increase in congenital malformations in infants of women with diabetes dates back to observational studies in the 1960s [73], when odds ratios (OR) of up to 7.9 were reported;

Table 71.2 Aims of prepregnancy care for women with diabetes.

Contraception	Document use of effective contraception Continue contraception until optimum glycated haemoglobin (HbA _{1c}) achieved
Optimize glucose levels	Aim for HbA _{1c} as close to normal range as possible without significant hypoglycaemia Advise blood glucose monitoring before and 1 h post-prandial, and occasionally during the night: <ul style="list-style-type: none">• Pre-meal glucose <5.3 mmol/l• Post-meal glucose (1 h) <7.8 mmol/l Stop oral anti-diabetes agents and initiate insulin if suboptimal glucose levels Consider metformin if improved glycaemia outweighs potential risks Advise on management of hypoglycaemia
Diet, exercise, and structured education	Refer to dietitian for education on regular basis Advise small to moderate portions of low glycaemic index carbohydrates Education about weight loss if body mass index (BMI) ≥27 kg/m ² Encourage regular exercise Provide smoking and alcohol cessation advice Prescribe folic acid supplements Supplemental dose: 5 mg/d (dose may vary)
Review other medications	Stop angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor antagonists, statins, and diuretics Treat hypertension with methyldopa or labetalol Screen for diabetes-related complications Assess for retinopathy at initial visit (if not assessed in previous 6 mo) and then annually. If retinopathy is present, consider referral to ophthalmologist If proteinuria or reduced glomerular filtration rate (GFR) is present, refer to nephrologist Assess cardiac status and consider referral to cardiologist. Screen for rubella immunity Counsel on risks of pregnancy with diabetes and obesity To fetus: miscarriage, malformation, stillbirth, neonatal death, macrosomia To pregnancy: eclampsia, premature delivery, caesarean delivery Progression of diabetes-related complications Consider referral to obstetrician or diabetes specialist midwife Assessment of obstetric risk Further education and support

Caudal regression is rare, but relatively specific to diabetic pregnancy [80] (RR 26). The relative risk for heart and central nervous system defects is about twofold higher, although with some exceptions.

Most abnormalities occur in the teratologically sensitive period till the seventh gestational week, adding to the importance, and challenge, of family planning and preconception management. It is hypothesized that tissue-specific developmental control genes are regulated at specific times in embryonic development by glucose metabolism, or that maternal diabetes, possibly through epigenetic changes, reduces the precision of gene regulation [81].

Increased BMI is positively associated with congenital malformations in the general population. A meta-analysis showed a significant dose-response relationship between BMI and neural tube defects (OR 1.20 for overweight and 1.87 for obesity) [82], and similarly for congenital heart defects (OR 1.08 for overweight; 1.23 for obesity, 1.39 for severe obesity) [82, 83].

Folic acid supplementation in the periconception period prevents the occurrence of neural tube defects (overall RR 0.28) and a preventive effect on other congenital malformations has been suggested but not confirmed [84]. Guidelines recommend periconceptional supplementation with folic acid of at least 400 µg daily [60] or higher doses of 4–5 mg daily [15, 60].

Miscarriage

Fertility is usually normal in women with type 1 diabetes, although delayed menarche in girls diagnosed before puberty is common, especially if glycaemic management is suboptimal [85]. Miscarriage rates among women with diabetes appear to be similar to those in the general population (12–15%), although the risk is increased 3–4-fold when hyperglycaemia occurs in early pregnancy [86] and may relate to non-viable congenital malformations. Maternal obesity is associated with reduced success with *in vitro* fertilization and may be a risk factor for first-trimester miscarriage [87].

Stillbirth

Antenatal death *in utero* (defined as fetal loss after 24 completed weeks' gestation) remains the most feared of all outcomes for women with type 1 diabetes and their clinicians. In the UK CEMACH study, the rate was 4.7-fold greater than the general antenatal population (5.7/1000 births) and similar in type 1 diabetes (25.8/1000) and type 2 diabetes (29.2/1000 births) [9]. A population-based study in 2013 reported the risk to be approximately three times higher than the background population, affecting 1 in 100 pregnancies in the UK between 2009 and 2011 [88], with little change over the previous 10 years [9, 10]. Fetal death is likely to be multifactorial [89] and includes congenital anomalies, chromosomal abnormalities, infection, placental vascular problems (associated with an increased risk of pre-eclampsia and renal and macrovascular disease), cigarette smoking (up to 19% of women in one study) [90], and third-trimester maternal hyperglycaemia [61, 91]. Increased maternal age and significantly raised BMI are also risk factors for stillbirth, both with and without diabetes, and may explain comparable rates in type 1 diabetes and type 2 diabetes [57, 92]. Compared with normal fetuses, macrosomic fetuses (birth weight above the 90th centile) with increased oxygen requirement [93], mild acidaemia, and borderline placental vascular supply may be particularly at risk. Approximately one-quarter of stillbirths are unexplained [94]. A systematic review of four studies of adverse pregnancy outcome in type 1 diabetes and type 2 diabetes found increased perinatal mortality associated with

congenital malformations were quickly linked with maternal periconceptional hyperglycaemia [58, 59, 74–77]. The relationship was further defined by the advent of HbA_{1c} measurement, which forms the basis of current recommendations [62, 63]. The absolute risk rises from approximately 3% when the periconceptional HbA_{1c} is 50 mmol/mol to 10% when it is 100 mmol/mol, although with wide confidence intervals limiting the certainty of prediction (Figure 71.1) [62].

Since the 1990s, the rates have been 1.6–2.7 times higher than background [49, 56, 78, 79] with no apparent improvement over time with the exception of a Canadian study [6], which reported a 23% reduction in relative risk from 1996 to 2010. More recently, registry data have reported similar malformation rates in women with type 2 diabetes to type 1 diabetes (RR 1.19), even when first-trimester HbA_{1c} were lower [9, 56, 57, 60, 62, 74].

The most frequent anomalies in offspring of women with diabetes are cardiac defects (3–4-fold higher), followed by neural tube, musculoskeletal, and genitourinary defects [49]. Multiple anomalies are present in up to 20% of malformed infants (RR up to 12) [9, 49].

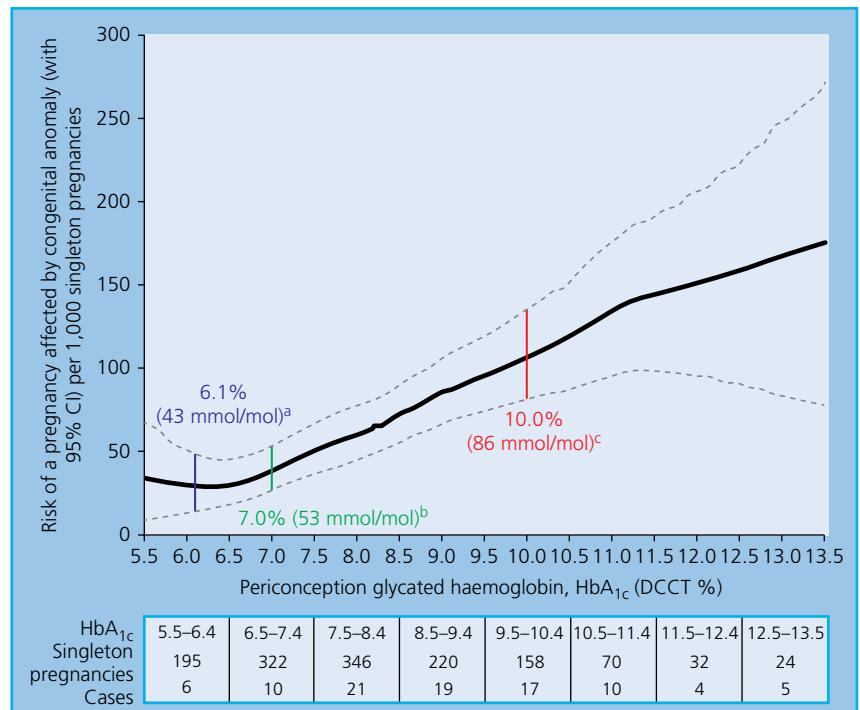

Figure 71.1 Association between periconception glycated haemoglobin (HbA_{1c}) in women with pre-existing diabetes and the risk (with 95% confidence intervals [CI]) of a pregnancy affected by major congenital anomaly. To convert values from HbA_{1c} in % into mmol/mol, subtract 2.15 and multiply by 10.929. DCCT, Diabetes Control and Complications Trial. Source: Data from Bell et al. 2012 [62].

hyperglycaemia (pooled OR 3.23; 95% CI 1.87 to 4.92 [95], although the studies had methodological limitations.

Marked oscillations in maternal glycaemic levels may explain the accelerated fetal growth and fetal compromise seen in some pregnancies with apparently excellent diabetes management [96]. When fetal death occurs it is usually after 32 weeks [9, 10, 92, 97] and frequently in the context of hyperglycaemia, polyhydramnios, and/or accelerated fetal growth [98]. By contrast, women with diabetes and vasculopathy and/or pre-eclampsia may develop intrauterine growth restriction (IUGR), and fetal demise, as early as the second trimester, probably related to placental vascular disease. Amniotic erythropoietin, a marker of chronic fetal hypoxia in late pregnancy, is higher in diabetic than non-diabetic pregnancies, and in one study of women with type 1 diabetes correlated inversely with cord blood pH and partial pressure of oxygen (pO₂) at birth [93].

Current recommendations to deliver women from 37+0 weeks' gestation, or even earlier if there are specific maternal or fetal risks [15], reflect this concern, but studies have shown that the risk of stillbirth in offspring of women with pre-existing diabetes occurs from as early as 32 weeks' gestation [92].

Accelerated fetal growth

The intrauterine diabetic milieu promotes an excess of body fat, an increase in muscle mass, and organomegaly, particularly liver and heart, without increased brain size. The excess fat is rapidly lost and by 6 months of age these babies are indistinguishable from babies of mothers without diabetes.

Birth weight, although routinely and almost universally measured at birth, is a crude estimate of fetal growth, as short-fat and long-thin newborns may have similar weights, but different *in utero* exposures and neonatal risks. Various definitions of accelerated fetal growth are used, including birth weight over 4000 g or 4500 g, or birth weight over the 90th centile or two standard deviations above the mean weight for gestational age and sex. The latter

measure is preferred, as it allows identification of premature newborns with excessive fetal growth, but even this does not characterize the selective organomegaly seen in the infants of women with diabetes. Accelerated growth can be detected on routine fetal abdominal circumference ultrasound measurement at 28 weeks' gestation [99]. Although characteristic, this finding is not specific, as it can result from maternal obesity and excess gestational weight gain. Fetal liver length measurements may be more specific to hyperglycaemia, but are technically challenging [100].

The UK CEMACH survey reported that 21% of singleton babies of women with diabetes weighed over 4000 g compared with 11% in the general population [9]. Other studies have reported babies of mothers with diabetes to be 1.8–5.2 times more likely to be above the 90th centile compared with the background population [9, 49, 52, 101], with 49–63% being LGA and 20–25% having a birth weight more than 4000 g [49, 50, 102], with similar rates in type 2 diabetes. The rate of macrosomia was 52% in the recent UK cohort [57]. Maternal obesity (increasing in women with type 1 diabetes) and gestational weight gain may contribute to these persistently high rates of fetal overgrowth [103].

Growth acceleration may start as early as 18 weeks' gestation [104]; however, growth potential of fetuses seems to be determined by prevailing maternal glycaemia before then, and excessive growth can continue despite optimal glycaemic levels in later pregnancy [105]. Higher maternal age, height, parity, BMI, presence of diabetes, gestational age at delivery, and male fetal sex are all significantly related to macrosomia [106]. Other factors include placental size, uterine blood flow, hypertension, and cigarette smoking.

The influence of genetic factors on fetal growth patterns is illustrated by the variable effects of GCK and HNF4A mutations depending on whether the mother and fetus have inherited the mutation (Chapter 20) [48, 107–109]. Certain mutations and polymorphisms have also been identified in genome-wide association studies [110].

The clinical significance of macrosomia pertains to the risk of complications presented by delivery of a large infant, such as shoulder dystocia, obstructed labour, perinatal hypoxia–ischaemia, and birth injury (e.g. brachial plexus injury and fractured clavicle or humerus) [9, 111].

Shoulder dystocia

Shoulder dystocia occurs when the baby's anterior shoulder becomes lodged behind the mother's pubic bone following delivery of the head. Precise definitions differ and are variously based on the time delay between delivery of the head and shoulders (e.g. one minute), or where excessive downward traction or special manoeuvres are needed to deliver the shoulders.

The reported rates of shoulder dystocia in women with pre-existing diabetes in the UK are 7.9% (over twice the rate in the general population) and are directly related to birth weight (<1% for birth weight <2.5 kg vs 43% for birth weight >4.5 kg) [9]. Brachial plexus injury (Erb's palsy) of 4.5/1000 births is infrequent, but occurs at 10 times the rate of the general population, while the fracture rates (usually of the clavicle and humerus) is 7/1000 births [9]. Another study of women with type 1 diabetes [112] reported an incidence of Erb's palsy of 2%. Although most babies with brachial plexus injuries recover with no long-term sequelae, the most serious damage occurs in the largest babies [113]. Given the high rate of preterm delivery and caesarean section in this cohort, the complication rate would likely be even higher if there were more normal deliveries at term. SGA infants of women with diabetes appear to be at even greater risk of adverse outcome, especially of neurodevelopmental sequelae, often compounded by preterm delivery. Delivery must be planned at an appropriate unit, as specialist neonatal care is likely to be required.

Neonatal hypoglycaemia

Neonatal hypoglycaemia, if severe and prolonged, can cause brain injury, poor neurodevelopmental outcome, and even threaten survival [114]. Infants at risk include those born to a mother with diabetes, those SGA or LGA, and late preterm deliveries [115]. Glucose is the principal energy substrate for the fetus, with fetal blood glucose levels typically corresponding to 60–80% of maternal levels [116]. Neonatal hypoglycaemia is attributed to fetal hyperinsulinaemia, which occurs in response to maternal (and subsequently fetal) hyperglycaemia during pregnancy.

Rates of neonatal hypoglycaemia vary depending on the definition of hypoglycaemia, maternal diabetes type, antenatal glycaemic levels, and infant birth weight [117]. In general, 30–50% of infants born to mothers with diabetes will have hypoglycaemia during routine testing in the postnatal period [118, 119]. The definition of neonatal hypoglycaemia is difficult, as glucose levels can fall to below 2.0 mmol/l in the first two hours of life in healthy babies [120, 121]. Even in the absence of food intake, blood glucose rises during the first three hours of life, so earlier monitoring is not informative. Blood glucose monitoring should be done before the feed to detect a nadir in blood glucose level.

Pathological hypoglycaemia is persistent hypoglycaemia beyond the first few hours of life. Although there is no consensus on the numerical value, guidelines recommend screening of at-risk infants and maintaining blood glucose at ≥ 2.6 mmol/l (47 mg/dl) [115].

If neonatal hypoglycaemia is suspected, the plasma or blood glucose concentration should be determined by using a laboratory enzymatic method, such as glucose oxidase, hexokinase, or the dehydrogenase method [115], as capillary blood glucose readings have poor precision at low values.

The main objective of glycaemic management during labour is to avoid maternal hyperglycaemia and minimize the risk of neonatal hypoglycaemia and fetal acidaemia [122]. Maintenance of maternal blood glucose between 4 and 8 mmol/l during labour and delivery [15] appears optimal. Delivery results in an abrupt cessation of maternal glucose supply to the infant, which in the setting of hyperinsulinaemia will result in hypoglycaemia.

Most cases of neonatal hypoglycaemia occur in the first 24–48 hours after delivery [115, 118] and last a maximum of a few days. Therefore, if a baby is clinically stable, and has no evidence of clinically significant hypoglycaemia, blood glucose monitoring may be discontinued when laboratory-measured glucose levels are persistently above 2.0 mmol/l. Ideally, breastfeeding should start immediately after delivery and be offered every 3–4 hours, or more frequently if the baby demands. In the absence of clinical signs, NICE guidelines [15] recommend that two consecutive (usually 2–4 hours apart) blood glucose levels below 2.0 mmol/l, at least 3–4 hours after delivery, that cannot be raised by oral or tube feeding require intervention, aiming to raise the blood glucose level to >2.5 mmol/l [15, 121]. Management of hypoglycaemia with abnormal clinical signs, for instance reduced level of consciousness or convulsions, is a medical emergency necessitating full clinical evaluation and transfer to the neonatal intensive care unit (NICU). Intravenous glucose (10% dextrose) must be given immediately starting at 5 mg/kg/min (equivalent to 3 ml/kg/h) and an increase may be needed as indicated by frequent blood glucose monitoring. Intramuscular glucagon (200 µg/kg) is useful if there are clinical signs and a delay in achieving intravenous access; glycogen will be broken down to release glucose, but the effect is transient, lasting less than one hour.

Other neonatal complications

Infants of mothers with diabetes commonly have a raised haemocrit, possibly due to fetal hyperinsulinaemia and chronic tissue hypoxia [123], but not strongly related to birth weight or late maternal HbA_{1c} [124]. Values are lower in babies born by caesarean section. Offspring are at increased risk of respiratory distress syndrome [125], most likely related to prematurity and delivery by caesarean section (recognized risk factors for respiratory morbidity) [126]. Jaundice is more common in babies who are LGA and is likely to be multifactorial in origin, including birth trauma, erythrocytosis, haemolysis, and immature hepatic bilirubin conjugation. Transient hypertrophic cardiomyopathy is characterized by ventricular septal hypertrophy that obstructs the left ventricular outflow tract and occurs in 30–80% of babies of mothers with diabetes [127]. It may be sufficiently severe to present with congestive cardiac failure and can cause fetal or neonatal death, but usually has a benign course, resolving with one month without any clinical sequelae. Transient neonatal hypocalcaemia, possibly related to glycaemia and less frequently hypomagnesaemia, can occur, but is rarely of clinical significance unless the baby has other complications, such as perinatal hypoxia–ischaemia, and routine screening is not required.

Maternal diabetes complications

Maternal hypoglycaemia

Hypoglycaemia is defined as a blood glucose level <4.0 mmol/l (70 mg/dl) and is an almost inevitable consequence of trying to achieve near-normal maternal blood glucose levels. In one study of 108 women with type 1 diabetes, 45% experienced severe hypoglycaemia during pregnancy, which was 3–5 times more frequent in

early pregnancy compared with immediately prepregnancy [128]. Predictors of severe hypoglycaemia, requiring external assistance, include impaired hypoglycaemia awareness, a past history of severe hypoglycaemia, long duration of diabetes, low HbA_{1c} in early pregnancy, fluctuating glucose levels, and excessive use of supplementary insulin between meals [128–130]. Impaired hypoglycaemia unawareness, which appears to result from the loss of the counter-regulatory response to hypoglycaemia, is accentuated in pregnant women with diabetes [131] and presents an additional clinical challenge.

The UK CEMACH study reported that 61% of women with type 1 diabetes had recurrent hypoglycaemic episodes during pregnancy and 25% had severe hypoglycaemia [9]. Moreover, 21% of women with type 2 diabetes also had recurrent episodes of severe hypoglycaemia, but neither recurrent nor severe hypoglycaemia was associated with poor pregnancy outcome (OR 1.1; 95% CI 0.7 to 1.7 and OR 1.3; 95% CI 0.7 to 2.3, respectively). Follow-up studies have shown no apparent long-term consequences of maternal hypoglycaemia on the offspring up to 5 years of age [132].

The major risk of hypoglycaemia seems to be to the mother and includes loss of consciousness, seizures, hospital admission, and death [50, 132, 133]. One study suggested that this risk can be reduced by a focused intervention including education of caregivers and women [134].

Diabetic ketoacidosis

Historically, DKA prevalence rates of 1–2% during pregnancy were reported [135, 136], and recent evidence suggests that these have not diminished (2.7% in the 2016 UK NDIPA [10]). Although DKA is typically associated with type 1 diabetes, it also occurs in women with type 2 diabetes and has been reported in GDM. It is important to note that glucose levels at presentation are often lower than anticipated due to utilization of maternal glucose by the fetus and placenta [137, 138], and therefore the possibility of DKA should be considered in women with all types of diabetes who present unwell during pregnancy, even if blood glucose is normal or low.

DKA occurs in the setting of absolute or relative insulin deficiency. Insulin deficiency leads to hyperglycaemia and a rise in plasma glucagon, which in turn stimulates hepatic gluconeogenesis and lipolysis, with subsequent ketogenesis. The physiological changes that occur during pregnancy can increase the risk of ketosis and subsequent acidosis, although the precise factors that are most detrimental to the fetus remain poorly understood [139].

Protocols for the rapid diagnosis of DKA in pregnant women are similar to those in non-pregnant women, although care is needed to avoid overhydration. Precipitants such as infection, systemic illness, hyperemesis, dehydration, insulin omission, and medications (e.g. tocolytics and corticosteroids) need to be urgently identified and treated. Particular vigilance is required for the effects of vomiting and starvation arising as a result of hyperemesis, gastroparesis, eating disorders, and gastroenteritis.

Fetal mortality rates of 9–35% have been reported in studies over the last 20 years, although current rates are likely to be lower [140]. The worst outcomes occur when diagnosis and treatment are delayed [135, 136]. Women with type 1 diabetes should be prescribed ketone strips and receive education on DKA prevention and detection as part of the sick-day rules.

Retinopathy

Pregnancy is a risk factor for progression of diabetic retinopathy [141], although these changes often regress postpartum without increased long-term risk [142]. The mechanism of retinopathy progression is

unknown, although multiple theories exist related to hormonal, haemodynamic, metabolic, and immunological changes during pregnancy. The risk of progression of retinopathy during pregnancy is greatest in women with moderate to severe retinopathy who enter pregnancy with hyperglycaemia and experience a rapid improvement in their glucose levels during the first trimester. In a prospective cohort study of 155 women with diabetes [143], retinopathy developed in 10.3% of those with no retinopathy, 21.1% with microaneurysms only, 18.8% with mild non-proliferative retinopathy, and 54.8% with moderate to severe non-proliferative retinopathy at baseline. Proliferative retinopathy developed in 6.3% of women with mild and 29% with moderate to severe baseline retinopathy. The risk of progression to sight-threatening retinopathy is approximately 20–30% for those with moderate to severe retinopathy before pregnancy, but ≤2% for those with minimal disease or no retinopathy.

In the Diabetes Control and Complications Trial (DCCT), 80% of participants with a fall in HbA_{1c} of ≥35 mmol/mol (3.2%) during pregnancy had some deterioration, compared with no overall change in retinopathy when the HbA_{1c} fall was ≤17 mmol/mol (1.6%) [142]. The benefits of improved glycaemia to the fetus, however, outweigh any risk to the mother, and women with no or minimal retinopathy at baseline are at minimal risk.

The common practice of instituting tight glycaemic management at the onset of pregnancy confounds our ability to conclude that pregnancy *per se* is the cause of retinopathy, because rapid tightening of glycaemia levels has been associated with an acute deterioration in retinopathy outside pregnancy [144, 145]. Diabetic retinopathy may be associated with diabetic nephropathy and hypertension, with the latter being reported as a risk factor for progression and thus meriting careful monitoring and treatment during pregnancy [146]. Hormonal changes are also suspected of exacerbating retinopathy. For example, the characteristic progesterone surge of pregnancy with upregulation of intraocular vascular endothelial growth factor (VEGF) [147], together with other placental hormones such as placental growth factor (PGF; the concentrations of which increase 15–20-fold between 8 and 32 weeks' gestation), may contribute to increased retinal capillary leakage and neovascularization [148]. PGF appears to regulate maternal insulin-like growth factor I (IGF-I), which in turn may promote retinal neovascularization by supporting VEGF induction of endothelial cell proliferation [149]. Other possible mechanisms for retinopathy progression include increased blood volume and cardiac output resulting in a hyperdynamic retinal capillary blood flow, and inflammation resulting in retinal vascular dysfunction from leucocyte adhesion to the retinal vasculature [150, 151].

The risk of retinopathy progression during pregnancy continues into the postpartum period [152], requiring ongoing monitoring; however, pregnancy does not generally alter the natural course of diabetic retinopathy [142] and baseline retinopathy status would seem to be the most important independent factor for progression [153].

Hypertension

Hypertension complicates 10% of pregnancies in women without diabetes [154], while up to 40% of women with diabetes are reported to have a blood pressure exceeding 140/90 mmHg during pregnancy [155]. The combination of hypertension and diabetes results in a higher number of adverse maternal fetal outcomes than either alone [156].

In type 1 diabetes, additional risk factors for hypertensive disorders of pregnancy include diabetes duration, high HbA_{1c} and diabetic

nephropathy, or early-pregnancy proteinuria [157–159]. The impact is generally less among pregnant women with type 2 diabetes due to lower rates of pre-eclampsia, although fewer studies have been reported [160]. Compared with type 1 diabetes, pregnant women with type 2 diabetes tend to be older, have more obesity (resulting in more chronic/essential hypertension), with shorter duration of diabetes and greater multiparity. Proteinuria is more common in type 2 diabetes, but is less predictive of pre-eclampsia [160]. Obesity is also a significant risk factor for pre-eclampsia (including severe pre-eclampsia), and may help explain the increasing levels of blood pressure in pregnancy in recent decades [161].

There are four hypertensive disorders (defined by severity, time of onset, and associated features) as detailed in Table 71.3 that can occur during pregnancy, all of which are more common in women with diabetes and increase the risk of adverse pregnancy outcomes.

Table 71.3 Classification of hypertensive disorders of pregnancy.

Chronic hypertension	Blood pressure (BP) ≥ 140 mmHg or ≥ 90 mmHg prior to pregnancy or before 20 weeks' gestation; or hypertension diagnosed for the first time during pregnancy without resolution postpartum. In women with diabetes, some centres regard BP $>135/85$ mmHg or even $>130/80$ mmHg as an indication for treatment [60, 155]	The greatest risk is with early-onset pre-eclampsia and the lowest with gestational hypertension.
Gestational hypertension	BP ≥ 140 mmHg systolic or ≥ 90 mmHg diastolic first detected after 20 weeks' gestation without proteinuria or other features of pre-eclampsia Retrospective diagnosis of transient hypertension is made if BP returns to normal by 12 weeks postpartum, while diagnosis of chronic hypertension if raised BP persists [162]	Chronic hypertension is associated with an increased risk of fetal loss, superimposed pre-eclampsia, preterm birth, intrauterine fetal growth restriction, and neonatal morbidity [163]. In addition, women with chronic hypertension are at risk of developing severe hypertension ($\geq 160/110$ mmHg), pre-eclampsia, and stroke during pregnancy. In mild cases, gestational hypertension is not associated with pregnancy complications; however, progression to pre-eclampsia (10–50%) or to severe hypertension ($\geq 160/110$ mmHg) occurs, with a comparable risk of severe pregnancy complications as in women with pre-eclampsia [163]. The diagnosis of pre-eclampsia is problematic in women with pre-existing microalbuminuria or nephropathy, and may alternatively be defined by worsening hypertension and a doubling of proteinuria (or albuminuria along with other end-organ features). This distinction is important, as the majority of these women are likely to develop end-organ disease manifestations (thrombocytopenia [$<150 \times 10^3/\text{mm}^3$], elevated liver transaminases [plasma aspartate amino transaminase >40 U/l], elevated creatinine, headaches or visual symptoms, pulmonary oedema) or fetal problems with pre-term delivery [162].
Pre-eclampsia	BP ≥ 140 mmHg systolic or ≥ 90 mmHg diastolic and proteinuria ($\geq 1+$ on a sterile urine dipstick or $\geq 300\text{mg}/24\text{h}$) after 20 weeks' gestation [154]; pre-eclampsia may further be classified into early-onset (<34 weeks' gestation) and late-onset pre-eclampsia (≥ 34 weeks' gestation) Severe pre-eclampsia is defined by any one of: <ul style="list-style-type: none">• Severe hypertension (systolic blood pressure ≥ 160 mmHg or diastolic blood pressure ≥ 110 mmHg, or both)• Cerebral or visual disturbance• Epigastric or right upper quadrant pain• Oliguria• Pulmonary oedema• Cyanosis• Impaired liver function• Thrombocytopenia• Intrauterine growth restriction Eclampsia is defined as new-onset grand mal seizures in women with pre-eclampsia; some women do not have diagnosed pre-eclampsia and some may present with eclampsia in the postpartum period	Pre-eclampsia complicates 7–20% of pregnancies in women with type 1 diabetes, an approximately fivefold higher risk compared with women without diabetes. Pre-eclampsia is associated with hyperglycaemia in both early and late pregnancy [90, 91] and occurs most frequently in women with pre-existing hypertension and proteinuria due to diabetic nephropathy [91, 159]. Severe (early-onset) pre-eclampsia is associated with a significant risk of adverse maternal fetal outcomes, including impaired fetal growth, placental abruption, eclampsia, coagulation abnormalities, abnormal liver function, and even maternal death, with attendant needs of instrumental delivery and neonatal intensive care [158]. Early delivery is the most effective treatment, but adds to the morbidity from prematurity.
Chronic hypertension with superimposed pre-eclampsia	Women with hypertension in early pregnancy developing new-onset proteinuria (as detailed above) In women with diabetic nephropathy and proteinuria in early pregnancy, the development of pre-eclampsia is defined by a sudden increase ($\geq 15\%$) in systolic or diastolic blood pressure, or a sudden 2–3-fold increase in proteinuria and/or thrombocytopenia (platelets $<100\,000$), and/or an increase in aspartate aminotransferase or alanine aminotransferase	Blood pressure recommendations include a target of 140/90 mmHg and even below 135/85 mmHg before and during pregnancy in the hope of reducing the risks of pregnancy-induced hypertension, pre-eclampsia, and preterm birth [155, 164, 165]. Treatment of severe hypertension ($\geq 160/110$ mmHg) is needed to reduce the risk of maternal intracerebral haemorrhage and maternal death [165]. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are contraindicated in the second and third trimesters due to reports of severe impairment of renal development and function, oligohydramnios, limb contractures, lung hypoplasia, IUGR, and death [166, 167]. A meta-analysis, however, concluded that the risk of congenital malformations observed with ACE inhibitors (RR 1.78) was similar to that of other antihypertensive drugs (RR 1.45), and the risk of their use in the first trimester would therefore appear not to increase the risk of malformations additional to that of hypertension itself or other antihypertensive drugs. The common practice is to discontinue these drugs when pregnancy is confirmed rather than planned, as it may be equally hazardous to risk losing control of blood pressure and albuminuria.

Diabetic nephropathy

The prevalence of diabetic nephropathy in pregnant women with diabetes is 3–15% and 5–11% have microalbuminuria [155, 168]. Most studies relate to type 1 diabetes, but clinical findings are similar in women with type 2 diabetes [169]. Diabetic nephropathy affects the outcome of pregnancy by two main mechanisms:

- Development of severe maternal hypertension necessitating termination of pregnancy and thereby preterm delivery.

- Impaired placental development leading to fetal growth restriction and risk of stillbirth.

The pregnancy risk increases with the degree of renal impairment. The development of pre-eclampsia is the greatest hazard of diabetic nephropathy. Reported rates in women with type 1 diabetes are 6–10% with normal urinary albumin excretion, but increasing to 42% in women with microalbuminuria and 64% when diabetic nephropathy is present before or in early pregnancy [155, 157, 158].

The glomerular filtration rate (GFR) normally increases by 50–100% during pregnancy. In women with nephropathy, the GFR may increase only slightly during pregnancy, but there can be dramatic increases in protein excretion, especially in late pregnancy. After delivery, albumin excretion can remain high for a few weeks, but usually then falls to prepregnancy levels.

Pathophysiological factors in the development of pre-eclampsia in women with type 1 diabetes and diabetic nephropathy/microalbuminuria include endothelial dysfunction and impaired maximal vasodilatory capacity, activation of the RAS system, cardiac overload, and anti-angiogenic factors [169]. The majority of these factors can be modulated by antihypertensive treatment, in relation to both blood pressure and urinary albumin excretion.

It is important to screen for the development of pre-eclampsia in all pregnant women with diabetes. In women with underlying renal dysfunction, it may be reasonable to initiate antihypertensive treatment at lower thresholds and to focus on the level of albumin excretion [60] (target <140/90 and even 130/85 mmHg). In some centres this seems to be associated with improved pregnancy outcomes and fewer preterm deliveries [155], with similar results in type 2 diabetes [168, 169].

In general, pregnancy outcome is favourable, and there is no deterioration during pregnancy with modest elevations of serum creatinine (<124 µmol/l [1.4 mg/dl]), proteinuria <1 g/24 h, and normal blood pressure in early pregnancy, when tight antihypertensive management is achieved. By contrast, a serum creatinine above 176 µmol/l (2.0 mg/dl), severe hypertension or proteinuria in the nephrotic range (above 3 g/24 h), and/or pre-existing cardiovascular disease are associated with a high risk for poor maternal and fetal outcome [169].

Antihypertensive drugs

Methyldopa (a centrally acting α-adrenergic agonist), with over 40 years' experience, remains one of the most widely used drugs for the treatment of hypertension in pregnancy, with no apparent adverse effects on fetal well-being.

Other suitable agents include labetalol, a non-selective β-blocker with vascular α-receptor blocking capabilities, and calcium channel blockers, among which nifedipine has been the most extensively investigated. Nifedipine, labetalol, metoprolol, methyldopa, captopril, and enalapril are regarded as safe during breastfeeding [15, 60, 169].

In addition, NICE recommends that women with more than one moderate risk factor for pre-eclampsia should take 150 mg of aspirin daily from 12 weeks until the birth of the baby. As well as diabetes, moderate risk factors include first pregnancy, age 40 years or older, pregnancy interval of more than 10 years, BMI of $\geq 35 \text{ kg/m}^2$ at first visit, and a family history of pre-eclampsia or multiple pregnancy [15, 60]. This recommendation is not entirely consistent with evidence from the major clinical trials in which no benefit for aspirin was seen [60], and may explain why the recommendation is not promoted by all diabetes societies.

Supplementation with antioxidants (vitamins C and E) does not reduce the prevalence of pre-eclampsia in women with type 1 diabetes and is not generally recommended [90].

Renal transplantation

The first report of a successful pregnancy following renal transplantation for diabetic nephropathy was in 1986 [170]. Transplant registries suggest that successful pregnancies are now common [170, 171], but these data fail to distinguish pregnancy outcomes specific to diabetes. The reported incidence of diabetes during pregnancy in women with renal transplants ranges from 5% to 12% and the rate of hypertension prior to pregnancy from 40% to 72%, which may reflect pre-existing conditions leading to transplantation and/or to the side effects of required immunosuppressive drugs [172]. Pregnancy should be delayed for at least one year following transplantation to allow greater stability in graft function (serum creatinine <133 µmol/l, minimal proteinuria $\leq 500 \text{ mg/24 h}$) and maintenance immunosuppressive drugs, and women should be managed by a multidisciplinary team [15, 172]. Perinatal survival in these pregnancies is almost 75%, but a large percentage of pregnancies will be associated with increased maternal and perinatal complications, including miscarriage (15–20%), pre-eclampsia (30–35%), preterm delivery (50–55%), urinary tract infection (2–5%), fetal growth restriction (5–10%), rejection during pregnancy (35–40%) and graft rejection within two years after delivery (30–50%) [171, 172]. Management of these women is similar to diabetic nephropathy, with preconception care, frequent perinatal care, optimal glycaemic and blood pressure management, intensive fetal testing, and timely delivery being the keys to successful outcome [169, 172].

Neuropathy

Pregnancy does not affect the progression of peripheral or autonomic neuropathy, but severe gastroparesis due to autonomic neuropathy with variable nutrition, fluctuating insulin requirements, and frequent vomiting may present a major management challenge, resulting in pregnancy loss, maternal malnutrition, and higher rates of ketoacidosis in women with type 1 diabetes [173].

Ischaemic heart disease

Ischaemic heart disease in pregnancy is rare, but prevalence rates have increased in recent years. Ischaemic heart disease is now the commonest cause of cardiac death associated with pregnancy in the UK [15]. The risk is increased by a combination of maternal diabetes, obesity, and increasing age, with the highest rates occurring among those with longer duration of diabetes and type 2 diabetes.

Non-pregnant women with type 1 diabetes aged 35–45 years have a 15-fold higher risk of a major cardiovascular event, while women with type 2 diabetes aged 35–54 years have a fivefold increase of a myocardial infarction compared with women without diabetes of a similar age [174, 175]. Pregnancy increases the risk of an acute myocardial infarction 3–4-fold, with the greatest risk being peripartum [176].

Mortality rates from acute myocardial infarction in pregnancy in women with diabetes have declined, but the prognosis is poor, and such women require intensive management similar to that outside of pregnancy.

Bariatric surgery

Fertility increases following bariatric surgery [177], but women should preferably wait one year post-surgery before conception. The risk of hypertensive disorders of pregnancy [178] and GDM is

reduced following bariatric surgery and offspring are at lower risk of LGA but at higher risk of SGA. In a study from the Swedish Medical Birth Register involving 670 singleton pregnancies, a lower risk of GDM (1.9% vs 6.8%; OR 0.25; 95% CI 0.13 to 0.47; $p < 0.001$) and LGA infants (8.6% vs 22.4%; OR 0.33; 95% CI 0.24 to 0.44; $p < 0.001$) compared with BMI-matched women from the general population was reported [178]. Women should be monitored throughout pregnancy for micronutrient deficiency. Given that women may develop surgical complications during pregnancy, involvement of a bariatric surgeon is advisable.

Management of diabetes in pregnancy

There is broad consensus among the international bodies [15, 60, 179, 180] and the importance of pregnancy planning has been emphasized, as pre-pregnancy counselling improves outcomes. The key elements include optimizing glycaemia before conception, folate administration, smoking cessation, review of potentially teratogenic drugs, and management of diabetic complications. A multidisciplinary team, comprising an obstetrician, diabetologist, diabetes specialist midwife, diabetes specialist nurse, and diabetes specialist dietitian, within a secondary or tertiary care setting has been recommended for the care of pregnant women with type 1 diabetes, starting before pregnancy [15].

The overall aim of joint antenatal diabetes care is to allow the woman to have an enjoyable experience of pregnancy and delivery of a normal and healthy baby. This is best achieved by attendance for prepregnancy care, referral for specialist care immediately on diagnosis of pregnancy, two-weekly multidisciplinary reviews during pregnancy, and clear postnatal plans for contraception, with early referral back to her usual diabetes team [15]. Pregnancy care is designed to advise on the topics listed in Table 71.4.

Glycaemic targets before and during pregnancy

Elevated HbA_{1c} in the periconceptual period and first trimester increases the risk of pre-eclampsia, perinatal or neonatal death, and congenital malformations [9, 15, 60]. HbA_{1c} results during the second and third trimesters of pregnancy should be interpreted more cautiously, given altered red blood cell turnover, but high levels are associated with pre-eclampsia, preterm delivery, LGA, and NICU admission [91]. The level of risk increases with HbA_{1c} levels above 48 mmol/l [91].

International bodies recommend that women should test their capillary blood glucose fasting, pre-meals, onehour post-meals,

Table 71.5 Glucose targets in the treatment of diabetes during pregnancy.

Organization	Target fasting glucose	Target 1 h post-prandial glucose	Target 2 h post-prandial glucose
NICE [15]	<5.3 mmol/l	<7.8 mmol/l	<6.4 mmol/l
ADA [50]	<5.3 mmol/l	<7.8 mmol/l	<6.7 mmol/l
Diabetes Canada [180]	<5.3 mmol/l	<7.8 mmol/l	<6.7 mmol/l
ADIPS [181]	≤ 5.0 mmol/l	≤ 7.4 mmol/l	≤ 6.7 mmol/l

ADA, American Diabetes Association; ADIPS, Australasian Diabetes in Pregnancy Society; NICE, National Institute for Health and Care Excellence.

and at bedtime during pregnancy, aiming if possible to achieve the glycaemic targets detailed in Table 71.5. These targets are demanding and many women do not reach them. The 2013 UK NDIPA [10] highlighted that only 13–15% of pregnant women with type 1 diabetes had target HbA_{1c} (<48 mmol/mol) in early pregnancy, rising to 35% in late pregnancy. In women with HbA_{1c} levels >48 mmol/mol after 24 weeks, preterm delivery, LGA, and NICU rates exceeded 50%, compared with 30% in women with levels <48 mmol/mol after 24 weeks [10].

The importance of achieving optimal glycaemic levels before and during pregnancy should be balanced against the risks of hypoglycaemia. Women with type 1 diabetes have an increased risk of hypoglycaemia in the first trimester and have an altered counter-regulatory response in pregnancy that may decrease hypoglycaemia awareness. Women with diabetes and family members need to be educated about the prevention, recognition, and treatment of hypoglycaemia before, during, and after pregnancy to help prevent and manage these risks.

In recognition of this, all guidelines advocate that targets should be relaxed if there is *undue* hypoglycaemia or impaired hypoglycaemia unawareness. Limited evidence suggests that moderate glucose levels (fasting glucose 5.0–6.5 mmol/l) are not inferior to lower levels [182]. In a large observational study, the risk of some adverse outcomes (macrosomia, pre-eclampsia, early delivery, and neonatal hypoglycaemia) was elevated only when the 26-week HbA_{1c} was ≥48 mmol (6.5%) [91].

Relation of glycated haemoglobin and pre- and post-prandial glucose levels to maternal fetal outcome

While the benefits of near-normal glycaemia both before and during pregnancy are universally recognized [142], the optimal means to achieve this is unknown. The relevance of post-prandial glucose excursions to adverse maternal outcomes is supported by two randomized trials, which reported that effectively managing post-prandial glucose levels was more likely to be associated with a successful pregnancy outcome than controlling fasting glucose levels [183, 184]. In addition, spikes of high glucose values (>11 mmol/l) are a strong predictor for LGA/macrosomia [185].

Continuous glucose monitoring systems in pregnancy

CGM systems highlight the fluctuation of glucose levels, including nocturnally, which may not be appreciated by conventional pre- and post-prandial capillary blood glucose monitoring [186, 187].

Table 71.4 The components of pregnancy care.

- Rapid referral to a joint antenatal diabetes clinic
- Blood glucose targets and the rationale for excellent glycaemic management
- Cessation of any potentially teratogenic medications
- Folic acid usage: 5 mg/d (NICE and ES) or 0.6 mg/d (ADA)
- Measurement of HbA_{1c} to assess risk of fetal abnormalities
- Detection, monitoring, and management of diabetes-related complications
- Accurate pregnancy dating and ultrasound detection of fetal abnormalities
- Determination of the most appropriate time and mode of delivery
- Management plan for blood glucose levels post-delivery

ADA, American Diabetes Association; ES, Endocrine Society; HbA_{1c}, glycated haemoglobin; NICE, National Institute for Health and Care Excellence.

Improved sensors, together with an evolving consensus on the interpretation of CGM, have resulted in this technology gaining acceptance as a valid clinical measure of blood glucose, and being accepted as an endpoint in clinical trials [188].

Pregnant women with type 1 diabetes using standard pumps and pens spend only 12 h/d with near-normal glucose levels (50% time in target during pregnancy). They spend 10 h/d above the NICE recommended glucose target 3.9–7.8 mmol/l (40% of the time too high), and 2 h/d below target (10% of the time too low) [189]. By the third trimester maternal hyperglycaemia improves only slightly, even with frequent antenatal clinic visits.

A randomized controlled trial (RCT) evaluating CGM with or without conventional glucose monitoring every 4–6 weeks between 8 and 32 weeks' gestation, in 46 women with type 1 diabetes and 25 with type 2 diabetes, showed an improvement in mean HbA_{1c} in late pregnancy (5.8% vs 6.4% [40 mmol/mol vs 48 mmol/mol]; p = 0.0007), with lower LGA rates (35% vs 60%) compared with conventional monitoring [190]. By contrast, a subsequent Danish RCT of intermittent real-time CGM (RT-CGM) versus self-monitored plasma glucose seven times daily showed no improvement in glycaemic levels or pregnancy outcomes in women with pregestational diabetes. However, both groups of women had low HbA_{1c} at conception (6.6 vs 6.8% [49 vs 51 mmol/mol]), and in 60% use of RT-CGM was intermittent [191].

A recent multicentre trial (Continuous glucose monitoring in pregnant women with type 1 diabetes, CONCEPTT) showed that those randomized to RT-CGM compared with standard care had a reduction in HbA_{1c} (0.19% [2 mmol/mol], p = 0.021), more time in range (TIR) (68% vs 61%; p = 0.003), and less time hyperglycaemic (27% vs 32%; p = 0.028), although with no difference in severe hypoglycaemic episodes [192]. In addition, there was a lower incidence of LGA (OR 0.51; p = 0.021), fewer NICU admissions lasting more than 24 hours (OR 0.48; 95% CI 0.26 to 0.86; p = 0.016), fewer incidents of neonatal hypoglycaemia (OR 0.45; 95% CI 0.22 to 0.89; p = 0.025), and one day shorter length of hospital stay (p = 0.009). There was no apparent benefit of CGM in women planning pregnancy.

An observational cohort study that evaluated the glycaemic variables reported using CGM found that lower mean glucose, lower standard deviation, and higher percentage of TIR were associated with a lower risk for LGA births and other adverse neonatal outcomes [193].

These studies support a role for CGM in the management of pregnant women with type 1 diabetes, possibly in preference to pump therapy, given the lack of difference between pump and multiple daily injection groups. Trials are in progress to evaluate closed-loop insulin delivery systems compared with conventional methods; however, preliminary data suggest that TIR during the day is no greater with these devices than with CGM, and greater emphasis may be needed on very fast-acting insulin analogues to reduce post-prandial glucose excursions. Adverse reactions (particularly skin) from CGM devices are high and may limit usage or even the reliability of readings [194].

The international consensus on TIR [195] endorses pregnancy target ranges and goals for TIR for women with type 1 diabetes including those using CGM, as reported on the ambulatory glucose profile:

- Time in range (3.5–7.8 mmol/l [63–140 mg/dl]; goal >70%).
- Time below range (<3.5 mmol/l) [<63 mg/dl]; goal 4%).
- Time below range (<3 mmol/l [54 mg/dl]; goal <1%).
- Time above range (>7.8 mmol/l [>140 mg/dl]; goal <25%).

Use of CGM-reported mean glucose is superior to the use of estimated HbA_{1c}, glucose management indicator, and other calculations to estimate HbA_{1c} given the changes to HbA_{1c} that occur during pregnancy [196]. TIR can be used to assess glycaemia in women with type 1 diabetes, but it does not provide actionable data to address fasting and post-prandial hypoglycaemia or hyperglycaemia. Universally, the cost of this technology is likely to restrict its use to selected, educated, motivated women in experienced centres receiving dedicated supervision. There are no data to support the use of TIR in women with type 2 diabetes or GDM. NICE has recently advised that CGM should be offered to all pregnant women on insulin therapy, and particularly to those with problematic severe hypoglycaemia (with or without impaired hypoglycaemic awareness) or who have unstable blood glucose levels (to reduce variability), or to gain information about glucose variability [15]. The American Diabetes Association (ADA) recommends CGM for selected women such as those with hypoglycaemic unawareness [60].

Monitoring of diabetes-related complications

Monitoring of diabetes-related complications is important to identify those women at risk of retinopathy progression and because of the association of nephropathy with pre-eclampsia and fetal growth retardation.

Retinal assessment

All guidelines recommend that any necessary treatment for retinopathy is completed and the clinical condition is stable before embarking on pregnancy. NICE guidance recommends retinal photographic screening at booking and at 28 weeks' gestation in all women with pre-existing diabetes, with more intensive follow-up at 16–20 weeks in those with any retinopathy at booking [15]. The ADA similarly recommends that women with no or minimal retinopathy on initial screening should have follow-up retinal examination in the third trimester, that those with mild retinopathy be evaluated every trimester, and that those with more advanced retinal disease should be evaluated at intervals determined by the ophthalmologist [60]. The Endocrine Society recommends ocular assessment soon after conception and then 'periodically as indicated', implying more intensive follow-up in women with established retinopathy [179].

Proliferative retinopathy should be treated with scatter or pan retinal photocoagulation as per routine guidelines. Occasional reports of intraocular anti-VEGF during pregnancy have been reported with no adverse events, but the safety of these agents during pregnancy is unknown and there are theoretical concerns regarding the deleterious effects of anti-VEGF drugs on fetal vasculogenesis and worsening of pre-eclampsia. Women with GDM are not at increased risk for diabetic retinopathy during pregnancy and do not require additional ophthalmic evaluation.

Hypertension/nephropathy

In women with pre-existing diabetes, NICE recommends that renal assessment should occur at booking if not undertaken in the previous 12 months [15]. If the serum creatinine is abnormal ($\geq 120 \mu\text{mol/l}$), the urine-to-albumin creatinine ratio is $>30 \text{ g/mol}$, or the total protein excretion exceeds 2 g/d , referral to a nephrologist should be considered. Women with known renal disease should be carefully monitored with regular blood pressure, urine albumin/protein excretion measurements, and serum creatinine. A rising serum creatinine has serious implications. Suitable antihypertensive

agents should be started with target blood pressure <130/85 mmHg [60]. NICE suggests that thromboprophylaxis should be considered for women with proteinuria >5 g/d [15, 169].

Drug cessation

Teratogenic drugs, such as ACE inhibitors and ARBs, should be discontinued before contraception, or as soon as pregnancy is confirmed, and alternative antihypertensive agents suitable for use during pregnancy should be substituted [15]. Statins should be discontinued before pregnancy or as soon as pregnancy is confirmed [15, 60]. Smoking cessation should be encouraged.

Obesity

NICE recommends that women with diabetes with a BMI >27 kg/m² who are planning to become pregnant should be advised to lose weight.

Autoimmune disease

Up to one-third of women with type 1 diabetes have serological evidence of hypothyroidism, and up to half of these develop post-partum thyroiditis [197]. The Endocrine Society and ADA recommend pre- or early pregnancy screening of women with type 1 diabetes with thyroid-stimulating hormone (TSH) and thyroid antibody tests, with consideration also of testing for vitamin B₁₂ deficiency. NICE makes no specific recommendation [15].

Insulin management

The physiology of pregnancy necessitates frequent titration of insulin to match changing requirements and emphasizes the importance of daily and frequent self-monitoring of blood glucose [198, 199]. During the first trimester, a time of enhanced insulin sensitivity and lower glucose levels, women may have lower insulin requirements (frequently compounded by pregnancy-associated sickness and altered hypoglycaemic awareness). From around 16 weeks, insulin resistance increases and total daily insulin doses increase linearly at approximately 5% per week until 36 weeks' gestation. This usually results in a doubling of the daily insulin dose compared with pre-pregnancy requirements and is closely related to weight gain [192, 198]. In women using continuous insulin infusion pumps, both basal and bolus doses increase, but the proportionate increase is greater for bolus doses [199, 200]. Insulin requirements usually level off towards the end of pregnancy; however, a rapid reduction in requirements can indicate the development of placental insufficiency and may merit early delivery [201]. Following delivery, insulin requirements rapidly fall, with doses in women with type 1 diabetes averaging two-thirds of the prepregnancy insulin dose or one-third of the dose at the end of pregnancy by the third postpartum day, and being similar to prepregnancy by the end of the first postpartum week [201]. In the majority of women with type 2 diabetes and GDM where insulin was started during pregnancy, it can be stopped after delivery.

Insulin regimens

None of the currently available insulin human preparations has been demonstrated to cross the placenta [60]. A recent Cochrane systematic review was unable to recommend any specific insulin

regimen over another for the treatment of diabetes in pregnancy [202].

Most women with insulin-treated diabetes before pregnancy are using a multiple-dose insulin (MDI) regimen comprising a short-acting prandial insulin and an intermediate or long-acting insulin up to three times daily. Safety and efficacy data of analogue insulins have largely come from observational studies, but a large RCT of insulin aspart versus regular soluble insulin in type 1 diabetes showed similar efficacy, with a tendency to lower rates of hypoglycaemia and without apparent toxicity [203].

All guidelines now recommend a quick-acting insulin analogue, such as aspart or lispro, for mealtime coverage. There is less consensus about the choice of basal insulin. NICE recommends isophane insulin as the first choice, while the ADA prefers insulins studied in RCTs [15], but the Endocrine Society recommends that women already using insulin detemir or glargine continue these agents throughout pregnancy [179]. An RCT of 310 women with type 1 diabetes randomized to insulin detemir or neutral protamine Hagedorn (NPH) insulin (both with mealtime insulin aspart) revealed non-inferior HbA_{1c} values [204] and lower fasting glucose at 24 and 36 weeks with detemir (US Food and Drug Administration and European Medicines Agency approved) than with NPH, but pregnancy outcomes did not differ. The safety of insulin glargine data come from post-marketing surveillance. The recommendation is that women with diabetes successfully treated with the long-acting analogues preconception continue with this therapy.

The pharmacokinetic properties of faster insulin aspart (onset of appearance in bloodstream 4 min) and insulin degludec (half-life 25 h) analogues have a particular conceptual appeal in pregnancy, with their potential to reduce post-prandial glycaemic excursions and hypoglycaemia. In non-pregnant adults with type 1 diabetes, prandial faster insulin aspart was associated with improved one-hour post-prandial glucose levels versus standard aspart and significantly reduced HbA_{1c}, while a 12-month RCT of degludec/aspart versus glargine/aspart was associated with significant reductions in nocturnal hypoglycaemia and HbA_{1c} compared with glargine. Faster insulin aspart is deemed safe in pregnancy. A further study comparing insulin degludec to insulin detemir, together with insulin aspart, in pregnant women with type 1 diabetes is ongoing.

Continuous subcutaneous insulin infusion

CSII may be of use for selected women, such as those with a pronounced *dawn phenomenon* or recurrent hypoglycaemia, but there is little evidence supporting its routine use in pregnancy [205–207]. A meta-analysis of six studies (107 CSII vs 106 MDI) showed comparable glucose levels and pregnancy outcomes [208], although these studies were in the pre-analogue era, lacked power to detect differences in neonatal outcomes, and were likely to be confounded by selection bias. The UK NDIPA showed no difference in glycaemic levels or maternal fetal health outcomes between standard pump users (30% of women with type 1 diabetes) and pens (70%). Both groups had elevated mean HbA_{1c} (pump 51 mmol/mol vs pen 52 mmol/mol) after 24 weeks [57]. There are also some risks, which include hyperglycaemia or ketoacidosis in the event of pump failure and increased costs. Women whose diabetes is well managed with CSII before conception usually choose to continue it during pregnancy.

The expectation that closed-loop technology calibrated for pregnancy fasting and post-prandial glycaemic targets might offer

additional benefits to existing delivery systems during pregnancy was examined in a recent open-label, crossover study. Women with overnight closed loop were in target range (3.5–7.8 mmol/l) for 75% of the time overnight compared with 60% with sensor-augmented pump therapy [209]. There was also a reduction in hypoglycaemia and high TIR (closed loop 66%, sensor-augmented pump therapy 57%) when both day and night periods were included. These devices may reduce hypoglycaemia and allow more aggressive prandial target dosing [60].

Sick-day rules

All women should be advised on contingencies when they are not eating and drinking because of illness. Advice includes the following key reminders:

- Continue fluid intake if possible.
- Never stop taking their insulin.
- Frequent need for supplementary insulin doses as guided by intensive home blood glucose monitoring.

Emergency 24-hour access to diabetes team members is essential and there should be a low threshold for hospital admission. Both NICE and ADA recommend that women with type 1 diabetes should be issued with ketone strips to use if they become ill and/or hyperglycaemic [15, 60]. Women who are unable to eat often require 10% dextrose with an insulin drip to meet adequately the higher carbohydrate demands of the placenta and fetus in the third trimester to resolve their ketosis.

Type 2 diabetes versus type 1 diabetes

Type 2 diabetes in pregnancy was uncommon until the 1980s, but is being encountered with increasing frequency [210]. The IDF figures suggest that prevalence estimates range from 2% in 20–24-year-olds up to 7% in 40–44-year-olds [5]. The prevalence of type 2 diabetes in 10–19-year-olds rose by 30% over a 10-year period [210] and this was accompanied by increasing rates of obesity, including at younger ages, and of women choosing to delay pregnancy when their risk of type 2 diabetes was increased at the time of pregnancy. This has resulted in a change in the proportion of women with type 1 diabetes and type 2 diabetes during pregnancy. For example, in the UK in 2002–2003, type 2 diabetes accounted for 27% of pregestational diabetes [9]; in 2014 this increased to 47% [10]; and it was 50% in the most recent report in 2021 [57].

Compared with women with type 1 diabetes, pregnant women with type 2 diabetes tend to be older, have higher rates of obesity and comorbidities, greater ethnic diversity, and greater socioeconomic deprivation. In addition, they frequently present late to diabetes services and have lower rates of referral and attendance for prepregnancy counselling. While women with type 2 diabetes have lower glucose concentrations, fewer preterm births, fewer LGA babies, and fewer caesarean sections [7, 57], adverse pregnancy outcomes (congenital anomaly, still birth, neonatal death) [49, 50, 54] are at least similar to women with type 1 diabetes [7, 49, 57], with some reports suggesting higher perinatal mortality (OR 1.50; CI 1.15 to 1.96) [57].

A report of the first five years of the NDIPA across 172 maternity clinics in England, Wales, and the Isle of Man [57], involving

17 375 pregnancy outcomes in 15 290 pregnant women (50% type 1 diabetes; 50% type 2 diabetes), showed that women with type 2 diabetes had:

- Higher rates of preterm delivery (42% vs 23%; $p < 0.001$).
- Higher rates of LGA (52% vs 26% respectively; $p < 0.001$).
- Similar rates of congenital anomaly (44.8/1000 vs 40.5/1000; $p = 0.17$)
- Similar rates of still birth (10.4/1000 vs 13.5/1000; $p = 0.072$).
- Higher rates of neonatal death (7.4/1000 type 2 vs 11.2/1000 type 1; $p = 0.013$).

Independent risk factors for perinatal death were third-trimester HbA_{1c} deprivation quintile, and having type 2 diabetes; maternal glycaemia and BMI were key modifiable risk factors.

The different contributions of risk factors to obstetric complications and adverse pregnancy outcomes in women with type 1 diabetes or type 2 diabetes are unclear. For the latter, the NDIPA highlighted lower rates of folic acid use and lower rates of prepregnancy counselling indicating problems with pregnancy planning, with most of women with type 2 diabetes having community-based diabetes care. At diagnosis, 6–7% of women with type 2 diabetes have microalbuminuria, up to 20% have retinopathy, up to 70% dyslipidaemia, 80% have obesity, and around one-third have hypertension, in large part due to the metabolic syndrome [211]. Vascular complications are more common in type 2 diabetes and are related to adverse outcomes.

The management of type 2 diabetes in pregnancy is similar to that of type 1 diabetes. Many women are taking oral anti-diabetes drugs (e.g. metformin, sulfonylureas, or other agents) and cardiovascular drugs at the time of conception. The majority (>95%) of women with type 2 diabetes need insulin, often in high doses because of obesity. With the exception of metformin, all other oral anti-diabetes agents should be stopped, as their safety has not been determined. A large Canadian RCT examined the addition of metformin or placebo to standard insulin therapy in 502 women with type 2 diabetes. The results showed reduced maternal weight gain and insulin dosage, improved glycaemic levels, lower adiposity and infant size measurements (resulting in fewer large infants), but a higher proportion of SGA infants and no difference in a composite neonatal outcome between the two groups [212]. Currently NICE guidance approves metformin for use during pregnancy and breastfeeding [15]. The ADA guidelines, by contrast, suggest that insulin is the preferred medication to achieve glycaemia during pregnancy [60].

Type 2 diabetes is often associated with obesity. Recommended weight gain during pregnancy for women with overweight is 7–11 kg and for women with obesity is 4.5–9 kg [213] (Table 71.6). There are no adequate data on optimal weight gain versus weight maintenance in women with $\text{BMI} > 35 \text{ kg/m}^2$.

Obstetric surveillance

The goal of obstetric surveillance is to identify the fetus at risk, in order to intervene in a timely and appropriate fashion to reduce perinatal morbidity and mortality. Accurate dating of the pregnancy is an imperative and is best achieved by ultrasound examination at 8–10 weeks. Fetal monitoring in women with diabetes is as per routine antenatal care and includes a 20-week anomaly scan and fetal cardiac scan. The UK guideline [15] recommends ultrasound monitoring of fetal growth and amniotic fluid volume every

Table 71.6 Institute of Medicine recommendations for weight gain during pregnancy [213].

Weight category (pregnancy or <10 weeks' gestation)	Body Mass Index (BMI; kg/m ²)	Recommended range of total weight gain (kg)	Recommended rate of weight gain in 2nd and 3rd trimesters (mean/range; kg/week)
Underweight	<18.5	13–18	0.45 (0.45–0.59)
Normal weight	18.5–24.9	11–16	0.45 (0.36–0.45)
Overweight	25.0–29.9	7–15	0.25 (0.23–0.27)
Obese (grade 1)	30.0–34.9	5–9	0.23 (0.18–0.27)
Obese (other)	≥35.0	<5	<0.20

Calculations assume a 0.5–2.0 kg weight gain in the first trimester.

Source: Based on Institute of Medicine and National Research Council 2009 [213].

four weeks from 28 to 36 weeks and individualized monitoring of fetal well-being for women at risk of IUGR, and those with macrovascular disease or nephropathy. Tests of fetal well-being before 38 weeks (such as performing a biophysical profile and Doppler studies) are not recommended unless there is a risk of IUGR.

Additional appointments for obstetric visits requiring ultrasound examination should be determined on an individual basis, but virtual (remote) contact by telephone/email in uncomplicated pregnancies is likely to reduce unnecessary clinic visits. More frequent face-to-face reviews are needed towards the end of pregnancy to monitor for pre-eclampsia and to discuss the timing and mode of delivery. Women with problematic glycaemia, diabetes-related complications, and fetal growth abnormalities need more intense surveillance.

Labour and delivery

The primary objectives are to avoid fetal death *in utero* and the hazards of obstructed labour or shoulder dystocia associated with fetal macrosomia. Caesarean section rates for women with pregestational diabetes in most parts of the world are over 50% (65% in the 2013 NDIPA [10]) and are similar in type 1 diabetes and type 2 diabetes [57]. The rates of preterm birth (delivery at <37 weeks' gestation) are 2–3-fold higher among women with pregestational diabetes than among women without diabetes. The majority of this increase is due to elective preterm delivery (6–7-fold higher than in women without diabetes), but spontaneous preterm delivery is also increased (~50% higher). Iatrogenic prematurity has resulted in high rates of admission to the NICU in type 1 diabetes.

Given the increased risk of preterm delivery, LGA, and perinatal mortality, close surveillance of both mother and baby by an experienced obstetrician is needed during delivery. The timing and mode of birth should be discussed with the woman during her antenatal appointments. An individualized approach is required, with particular consideration to fetal well-being, estimated size, glycaemic management, diabetes complications, and past obstetric history. NICE guidelines advise that women with type 1 diabetes should be offered an elective delivery between 37 + 0 and 38 + 6 weeks gestation, assuming that no other significant factors have developed before this time. An elective birth before 37 + 0 weeks should be

considered if significant metabolic or any other maternal or fetal complications occur [15].

Nulliparity, progression of nephropathy, pre-eclampsia, and HbA_{1c} ≥53 mmol/mol (7%) at delivery are all strongly associated with preterm delivery, as is poorer maternal mental health [214]. Preterm delivery is associated with significant neonatal morbidity, particularly neonatal hypoglycaemia and respiratory distress syndrome [215].

Preterm labour can be particularly hazardous for infants of women with diabetes. β-sympathomimetic agents used to suppress uterine contractions, and corticosteroids used to accelerate fetal lung maturation, may result in significant and prolonged maternal hyperglycaemia, and even ketoacidosis, and the need for supplementary insulin must be anticipated. Several algorithms to guide glycaemic management during steroid therapy have been developed [216, 217]. Admission to hospital and close supervision are essential.

The management of labour should follow standard practice. Given the desire not to prolong pregnancy unduly, induction of labour is widely utilized and usually involves a combination of prostaglandins initially followed frequently by oxytocin. Careful monitoring of progress is facilitated by a partograph and continuous electronic fetal monitoring by cardiotocography.

Management of diabetes during labour should follow an established protocol adapted for time and mode of delivery in a dedicated centre with a NICU equipped and staffed to deliver the most sophisticated level of care (Table 71.7). Women with type 1 diabetes who use CSII should have the opportunity to discuss glycaemic management during labour in advance of delivery with their physician, and an individualized plan should be clearly documented in their chart. NICE guidelines recommend maintenance of maternal blood glucose between 4 and 7 mmol/l during labour and delivery

Table 71.7 Intradelivery protocol and method of delivery.

Elective caesarean section
Women with type 1 diabetes should be placed first on the operating list and admitted either the previous day or early on the morning of surgery
Women should fast from 22:00 the evening before surgery
Long-acting insulin is taken as normal prior to a light supper
Rapid-acting insulin should be withheld on the day of surgery
1–2 h prior to surgery, hourly monitoring of blood glucose begins; and a glucose insulin infusion is commenced, if necessary, to maintain blood glucose between 4 and 7 mmol/l
Insulin dose and/or rate are adjusted in response to maternal/capillary glucose
Induction of labour
Women should continue their current insulin regimen until labour is confirmed
Often an early-morning breakfast is consumed with their normal morning insulin dose
Once labour is confirmed and the woman is fasting, glucose-insulin infusion is commenced as per protocol, unless delivery is imminent
Maternal blood glucose levels should be monitored hourly
Blood glucose levels should be maintained between 4 and 7 mmol/l
Insulin dose and/or rate are adjusted in response to maternal blood glucose
Spontaneous labour
Following admission in spontaneous labour, the woman is fasted
Blood glucose level should be taken on admission and hourly thereafter
Once labour is confirmed, a glucose-insulin infusion is commenced as per protocol
Capillary glucose levels should be maintained between 4 and 7 mmol/l
Insulin dose and/or rate are adjusted according to the local protocol in response to maternal blood glucose

to reduce the incidence of both neonatal hypoglycaemia and fetal distress [15, 217]. Hourly capillary glucose measurements provide a ready guide to the success of management and the need for insulin adjustment. Commonly used regimens (in the absence of a consensus) involve a constant glucose infusion with insulin being infused separately by an infusion pump. Women who are using CSII may continue their basal infusion during labour, but it is essential that whatever regimen is used, midwifery and anaesthetic staff are familiar with it.

Management of diabetes postpartum

Insulin sensitivity increases in the immediate postpartum period, normalizing over the following 1–2 weeks. Once the cord is cut, any insulin infusion should be reduced by 50%, with regular capillary blood glucose measurement and administration of intravenous fluids until the mother is eating normally. This should be done with close supervision by the diabetes care team and insulin titration as required. The women should be encouraged to eat a small snack before breastfeeding to avoid hypoglycaemia. Insulin requirements may increase during the day due to increased caloric intake, with a fall in nocturnal insulin requirements due to glucose siphoning into the breast milk. Women are therefore advised to reduce their long-acting insulin when breastfeeding. Maternal glucose should be kept as normal as possible to avoid elevations in milk glucose and maternal hypoglycaemia. This is achieved through regular snacking and careful insulin adjustment with full support from the diabetes specialist team.

Breastfeeding

Breastfeeding rates are often disappointingly low despite encouragement [218, 219]. Relevant factors include admission to neonatal care with separation of mothers from their babies, which makes it difficult to establish breastfeeding. Higher educational attainment and previous positive experiences of breastfeeding are strong predictors of success [219, 220]. In women who need insulin, the postpartum insulin requirements during breastfeeding are typically approximately 10% lower than before pregnancy. For women with type 2 diabetes, metformin is approved during breastfeeding, as the levels appearing in breast milk are low [15].

Neonatal care

Neonates born to women with type 1 diabetes should have their blood glucose measured using a method validated for neonatal use. Women should feed their babies within 30 minutes of birth and then at frequent intervals (every 2–3 hours) until feeding maintains pre-feeding capillary plasma glucose levels at a minimum of 2.0 mmol/l. If capillary plasma glucose values are below 2.0 mmol/l on two consecutive readings, despite maximal support for feeding, if there are abnormal clinical signs, or if the baby will not feed orally effectively, additional measures, such as tube feeding or intravenous dextrose, should be used. Up to 50% of babies may need admission for neonatal intensive care [41] for the indications in Table 71.8. Neonates should not be transferred to community care until they are at least 24 hours old, are maintaining their blood glucose at a normal level, and are feeding well.

Table 71.8 Neonatal complications after diabetes in pregnancy.

Directly related to diabetes in pregnancy
Congenital anomalies
Intrauterine growth restriction
Intrapartum hypoxia-ischaemia
Macrosomia, obstructed labour, birth injury
Neonatal death
Polycythaemia/jaundice
Hypoketonaemia, hypoglycaemia
Hypocalcaemia, hypomagnesaemia
Hypertrophic cardiomyopathy
Complications of necessary, or unnecessary, obstetric interventions
Complications of preterm delivery
Complications of caesarean section – respiratory distress, impact on breastfeeding
Iatrogenic
Inappropriate separation of mother and baby
Inappropriate formula supplementation – impact on breastfeeding

Contraception

The discussion about family planning should begin before delivery, particularly if caesarean section is likely, as many women elect to have tubal ligation at the time of their caesarean section; it should also be an essential component of early postpregnancy counselling.

There is a growing opinion that contraception should be initiated before the woman is discharged from hospital. This is due to the recognition that ovulation and sexual activity occur much earlier than previously estimated. In addition, many women miss their postpartum appointments. The WHO has stated that virtually all methods of contraception can be offered to women with type 1 diabetes [221]. However, oestrogen-containing methods should be avoided by women with diabetes-related complications such as retinopathy, nephropathy, or cardiovascular disease. Intrauterine contraceptive methods (IUDs) are particularly suited to women who do not wish to become pregnant within the next year. In women without vascular disease who wish to conceive sooner, combined (oestrogen and progesterone) hormonal contraception is safe. The lowest dose (oestrogen <35 mg) and potency formulation should be used, as the absolute increase in arterial thromboembolism is very low (1/12 000) and comparable to that among users without diabetes and non-users. Barrier and natural family planning methods are less ideal because of high failure rates. Long-acting reversible contraception may be ideal for many women. The risk of unplanned pregnancy outweighs the risk of any given contraception option. Following completion of childbearing, vasectomy and female sterilization are available.

Women with type 1 diabetes should revert to their routine diabetes care under the supervision of their diabetes care team. Women planning further pregnancies should be reminded of the need for preconception planning for optimal pregnancy outcome.

Gestational diabetes mellitus

In contrast to the clearly established association between overt diabetes during pregnancy and adverse pregnancy outcomes, few areas have aroused such controversy as the concept of GDM [222, 223].

For decades its validity has been questioned and confusion generated over disparate approaches to diagnosis and screening [223]. Following the publication of landmark observational clinical trials and RCTs and consensus IADPSG/WHO criteria in 2013 [41, 42], significant progress towards a universal approach to diagnosis was made, but the subject remains one of active debate. The prevalence of GDM is increasing, and globally is now estimated to affect more than 20 million live births (about 1 in 6), mainly in low- and middle-income countries, where most of the morbidity and mortality occur [5]. Obesity is fuelling a rise in GDM and is itself a risk factor for adverse pregnancy outcomes. Increasing recognition that accelerated fetal growth and fat accretion and maternal biochemical abnormalities are already detectable by 20 weeks has generated ongoing research into the virtue of earlier diagnosis than the traditional 28 weeks' gestation, which in turn might allow a greater window for meaningful therapeutic intervention. GDM is associated with significant long-term metabolic and cardiovascular risks for both mother and offspring, with urgent implications for public health prevention.

The first documented case was possibly that of a pregnant women in 1823 with new onset of thirst and glycosuria, which resulted in the delivery of a dead macrosomic baby [224]. The exact origin of the term *gestational diabetes* is difficult to ascertain, but almost certainly grew from a realization of the relationship between fetal survival, birth weight, and hyperglycaemia during pregnancy [225, 226]. The term was used by Pedersen and others towards the end of the 1960s [33].

The first major prospective studies of carbohydrate metabolism in pregnancy were carried out in North America in the 1950s [227, 228]. In a notable study by O'Sullivan and Mahan in 1964 [229], glucose was measured fasting, and at one hour, two hours, and three hours after a 100 g OGTT in an unselected group of 752 pregnant women (45% in second trimester and 52% in third trimester) recruited on registration in a Boston hospital. Those with values two standard deviations above the mean at each threshold (with two threshold values needing to be equalled or exceeded for diagnosis) had the best predictive value for the subsequent diagnosis of diabetes

(using US Public Health Service Criteria). In a second older cohort of 1013 non-pregnant women, 2% of these women developed GDM over an eight-year period (again using US Public Health Service Criteria). Additional studies showed that women meeting this definition of GDM had a fourfold increase in perinatal mortality [230] and an increase in maternal diabetes up to 16 years later [231].

These threshold values were later modified by Carpenter and Coustan [232] to allow for varying assay techniques (use of enzyme vs reducing substances and plasma vs whole blood), subsequently endorsed by the US National Diabetes Data Group [233], and used to diagnose GDM in the USA for the next four to five decades and even to the present day (Table 71.9).

The original concept of GDM required it to be a temporary state with return to normal after delivery and that was the definition used by Pedersen in his pioneering book *The Pregnancy Diabetic and Her Newborn* [33]. More formal efforts to standardize terminology and diagnostic thresholds did not take place until the end of the 1970s, coincidental with an increasing focus on the diagnostic criteria for diabetes outside pregnancy both within the USA [235] and internationally [236, 237].

Currently, the ADA defines GDM as 'carbohydrate intolerance of varying severity with onset or first recognition during pregnancy' [60]. This definition, which emanated from international workshops spanning several decades, applies irrespective of whether or not insulin is used for treatment, or the condition persists after pregnancy. Universal screening employing a 100 g OGTT after 24 weeks' gestation (preceded by a 50 g glucose challenge test) is recommended, using the Carpenter and Coustan modification of the O'Sullivan and Mahan criteria [60, 235] (Table 71.9). During the 1980s and 1990s there was increasing recognition that GDM was likely to include women who had unrecognized diabetes before the index pregnancy.

The WHO originally defined diabetes mellitus as 'a state of chronic hyperglycaemia' on the basis of guidelines used for non-pregnant adults [236], and included an additional category of gestational impaired glucose tolerance (fasting plasma glucose [FPG] $\geq 7.8 \text{ mmol/l}$ and two hours post OGTT $\geq 7.8 \text{ mmol/l}$). This

Table 71.9 Criteria for diagnosis of gestational diabetes with oral glucose tolerance test (OGTT).

Organization	Recommended approach	Fasting threshold (mmol/l)	1 h threshold (mmol/l)	2 h threshold (mmol/l)	3 h threshold (mmol/l)
IADPSG [41]; ADIPS [181]; WHO [214]; FIGO [40]	One-step 2 h, 75 g OGTT	≥ 5.1	≥ 10.0	≥ 8.5	NA
ADA [60]	Two-step 100 g, 3 h, OGTT ^a or One-step 2 h, 75 g OGTT	≥ 5.3 ≥ 5.1	≥ 10.0	≥ 8.6	≥ 7.8
ACOG/C-C [234]	Two-step 3 h, 100 g OGTT ^a	≥ 5.3	≥ 10.0	≥ 8.6	≥ 7.8
NICE [15]	One-step 2 h, 75 g OGTT	≥ 5.6	NA	≥ 7.8	NA
Diabetes Canada [180]	Two-step 2 h, 75 g OGTT (preferred) or One-step 2 h, 75 g OGTT	≥ 5.3 ≥ 5.1	≥ 10.6	≥ 9.0	NA
NDG [13]	Two-step 3 h, 100 g OGTT ^a	≥ 5.8	≥ 10.6	≥ 9.2	≥ 8.0

latter definition was applicable only to women in whom these criteria are first detected during pregnancy. In 1998, the definition was refined to that currently in use [237] when it was recommended that only women with risk factors should undergo OGTT testing. However, national guideline groups from different countries frequently adopted their own modifications of the US and WHO approaches (Table 71.9), resulting in much confusion and perpetuating a lack of international consensus and meaningful epidemiological comparison.

It was against this background that the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study [238] was designed specifically to examine the relevance of minor degrees of hyperglycaemia during pregnancy, short of diabetes, to adverse maternal and fetal outcome. This multicentre, multicultural observational study involved 23 000 pregnant women undergoing a 75 g OGTT at 24–32 weeks' gestation. Clinicians were blinded to the results unless prespecified thresholds were exceeded (fasting glucose >5.8 mmol/l; two-hour glucose >11.1 mmol/l or a random glucose later in

gestation >8.9 mmol/l), and these women were excluded. The study showed continuous independent relationships [238–240] between untreated maternal glucose levels (fasting, one hour, and two hours post glucose load) and each of the primary outcomes: birth weight >90th centile, clinical neonatal hypoglycaemia, primary caesarean section, and cord C-peptide levels (reflecting fetal hyperinsulinaemia) (Figure 71.2). Birth weight and cord C-peptide had the strongest association with maternal glucose. Mean birth weight differences between the highest and lowest glucose categories for the three time points ranged from 242 g to 305 g. Among the secondary outcomes, shoulder dystocia and pre-eclampsia were positively associated with maternal fasting and post-challenge plasma glucose, while preterm delivery, hyperbilirubinaemia, and admission to NICU were related to post-challenge but not fasting glucose [238]. There was no association between perinatal mortality and maternal glucose levels, possibly reflecting the exclusion of 2.9% of women with raised glucose (1.7% with raised baseline two-hour glucose and 1.2% with raised random glucose later in pregnancy); nor was the

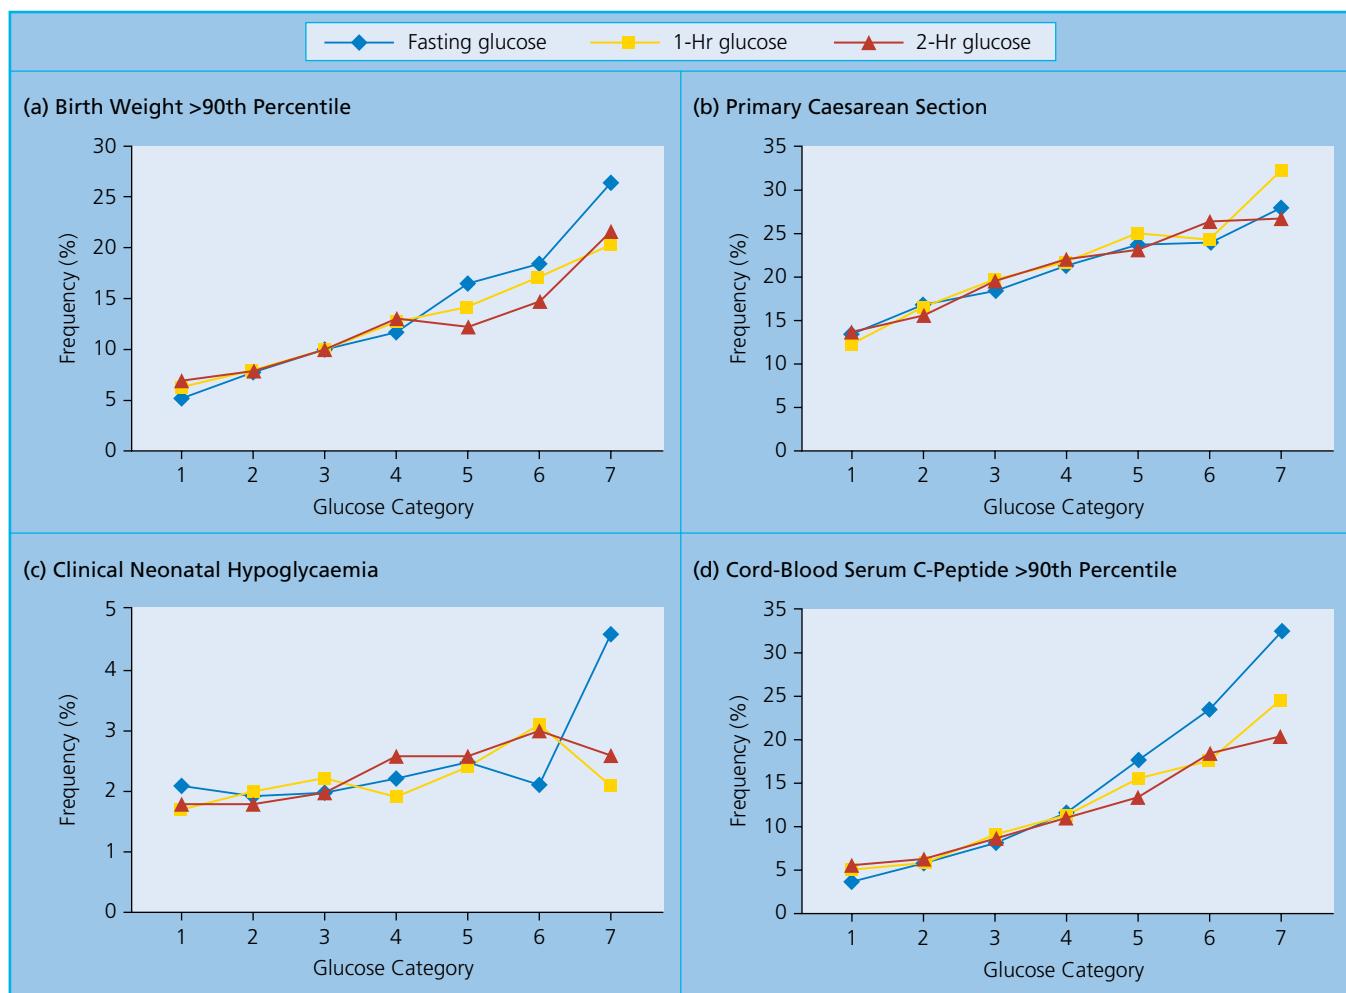

Figure 71.2 (a–d) Frequency of primary outcomes across the glucose categories. Glucose categories are defined as follows. Fasting plasma glucose level: category 1 <75 mg/dl (4.2 mmol/l); category 2 75–79 mg/dl (4.2–4.4 mmol/l); category 3 80–84 mg/dl (4.5–4.7 mmol/l); category 4 85–89 mg/dl (4.8–4.9 mmol/l); category 5 90–94 mg/dl (5.0–5.2 mmol/l); category 6 95–99 mg/dl (5.3–5.5 mmol/l); category 7 ≥100 mg/dl (5.6 mmol/l). One-hour plasma glucose level: category 1 <105 mg/dl (5.8 mmol/l); category 2 106–132 mg/dl (5.9–7.3 mmol/l); category 3 133–155 mg/dl

(7.4–8.6 mmol/l); category 4 156–171 mg/dl (8.7–9.5 mmol/l); category 5 172–193 mg/dl (9.6–10.7 mmol/l); category 6 194–211 mg/dl (10.8–11.7 mmol/l); category 7 ≥212 mg/dl (11.8 mmol/l). Two-hour plasma glucose level: category 1 <90 mg/dl (5.0 mmol/l); category 2 91–108 mg/dl (5.1–6.0 mmol/l); category 3 109–125 mg/dl (6.1–6.9 mmol/l); category 4 126–139 mg/dl (7.0–7.7 mmol/l); category 5 140–157 mg/dl (7.8–8.7 mmol/l); category 6 158–177 mg/dl (8.8–9.8 mmol/l); category 7 ≥178 mg/dl (9.9 mmol/l). Part 11 Diabetes in Special Groups

HAPO study powered to detect such a relationship. More generally, it should be noted that there are no published studies that convincingly demonstrate a relationship between GDM and stillbirth or perinatal mortality [241].

A systematic review and meta-analysis of the association of hyperglycaemia and adverse perinatal outcomes [241], which included 25 reports of up to 207 172 women, reported a graded linear association between fasting and post-load concentrations across the whole glucose distribution. Most adverse perinatal outcomes occurred in women without pre-existing or gestational diabetes.

While demonstration of an association of hyperglycaemia with adverse outcomes is important, the key question is whether intervention confers clinical benefit. This was examined in two randomized controlled intervention trials involving around 1000 women with mild GDM: the Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) [242] and the Maternal and Fetal Medicine Unit Network (MFMU) study [243]. In both trials women not meeting the diagnosis of diabetes outside of pregnancy were identified by a two-step diagnostic test, but with differing criteria for the two hours post-load glucose threshold, and randomized to treatment or no treatment (Table 71.10). Women in the MFMU trial had lesser degrees of hyperglycaemia, as reflected by the need for insulin, between the two studies (8% vs 20%). Both trials used composite endpoints because of the limited number of some clinical outcomes. Neither study reported the between-group differences in the blood glucose measurements achieved.

The composite primary outcome was reduced with treatment versus no treatment in ACHOIS (4% vs 1%); however, the biological plausibility of this result has been questioned, as the reduction was critically dependent on perinatal deaths: five deaths (1%)

versus 0% in the routine care group, including a malformation and a case of severe growth retardation. In both trials, average birth weight, frequency of LGA, and pre-eclampsia were reduced by treatment (Table 71.10). The MFMU trial showed a reduction in caesarean section rate even though women were identified as having GDM. The frequencies of adverse outcomes in the untreated arms of these studies were similar to those found with maternal glycaemia above a putative threshold in the HAPO study.

A 2013 systematic review and meta-analysis of randomized trials for the US Preventive Services Task Force [244], dominated by these two trials, found that appropriate treatment of GDM (nutritional therapy supplemented by insulin if needed and self-blood glucose monitoring) versus routine care resulted in reductions in the following:

- Pre-eclampsia (RR 0.62; 95% CI 0.43 to 0.89; 7.2% vs 11.7%; three trials).
- Birthweight >4000 g (RR 0.50; 95% CI 0.35 to 0.71; five trials).
- Shoulder dystocia (RR 0.42; 95% CI 0.23 to 0.77; three trials).

More recent systematic reviews and meta-analyses have generally confirmed the benefit of treatment of GDM, including pharmacological therapy (primarily insulin and metformin), although most studies are small and variable in quality [245]. It is not always clear if observations are due to lower maternal glucose values or less maternal weight gain.

Based on these studies, consensus recommendations for the screening and diagnosis of hyperglycaemia in pregnancy were published by the IADPSG in 2010 [41] and subsequently endorsed by the WHO in 2013 [42] (Table 71.11). The diagnostic thresholds were met when the risk of adverse pregnancy outcomes (based on a composite of birth weight >90th centile, fetal fat, and cord blood

Table 71.11 Recommendations for the diagnosis of hyperglycaemia in pregnancy and overt diabetes in pregnancy (International Association of Diabetes and Pregnancy Study Groups/World Health Organization criteria).

	Hyperglycaemia in pregnancy	Overt diabetes
Fasting plasma glucose	One or more of 75 g oral glucose tolerance test thresholds must be equalled or exceeded ≥5.1 mmol/l (≥92 mg/dl) or ≥10.0 mmol/l (≥180 mg/dl)	≥7.0 mmol/l (≥126 mg/dl)
1 h plasma glucose		
2 h plasma glucose	≥8.5 mmol/l (≥153 mg/dl)	
HbA _{1c}		≥6.5%
Random plasma glucose ^a		≥11.1 mmol/l (≥200 mg/dl)

^aA random plasma glucose to diagnose diabetes during early pregnancy should be confirmed by a fasting plasma glucose or glycated haemoglobin (HbA_{1c}).

Table 71.12 Early detection of hyperglycaemia in pregnancy (International Association of Diabetes and Pregnancy Study Groups/World Health Organization criteria).

First prenatal visit	
Fasting plasma glucose, HbA _{1c} , or ^a random plasma glucose on all (or only on high-risk women)	If results are not diagnostic of overt diabetes, and a. Fasting plasma glucose ≥5.1 and <7 mmol/l (≥92 and <126 mg/dl), diagnose as hyperglycaemia in pregnancy b. Fasting plasma glucose <5.1 mmol/l (92 mg/dl), test for GDM at 24–28 weeks with 75 g oral glucose tolerance test ^b
24–28 weeks' gestation 75 g oral glucose tolerance test after overnight fast	On all women not already diagnosed as hyperglycaemia in pregnancy or overt diabetes at first visit

GDM, gestational diabetes; HbA_{1c}, glycated haemoglobin.

^aA random plasma glucose to diagnose diabetes during early pregnancy should be confirmed by a fasting plasma glucose or HbA_{1c}.

^bThe 75 g oral glucose tolerance test thresholds represent the average value at which the odds for birth weight, percent body fat, and cord blood C-peptide (representing fetal insulin) exceeded 1.75 times the estimated odds of these outcomes compared with mean glucose values for the whole Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) population.

C-peptide) exceeded 1.75 of the estimated odds of these outcomes, compared with mean glucose values for the whole HAPO population. The recommendations distinguished overt diabetes from more minor degrees of glucose intolerance during pregnancy, and recommended screening for *overt diabetes* at the first prenatal visit, with diagnosis being based on non-pregnant criteria: fasting glucose ≥7 mmol/l or HbA_{1c} ≥48 mmol/l (6.5%) (Table 71.12).

Globally, the consensus recommendations have resulted in a much greater uniformity of approach to diagnosis than existed previously, but the thresholds remain the subject of active debate,

particularly on issues relating to the increase in prevalence, methodology, logistics, medicalization of pregnancy, and cost-economic benefits [40, 246, 247] (Table 71.13).

For all HAPO participants, the prevalence of GDM (including women whose results were unblinded) was 17.8%, but varied from 9.3% (Israeli centre) to 25.5% (US centre) [255]. In most countries the thresholds have translated into a 2–3-fold increase in prevalence of GDM, up to 20–25%, and in some centres to 40% [249]. The appropriateness and validity of these increased rates have been questioned [245–247]. Most observational studies suggest that treatment of GDM defined by IADPSG criteria with high prevalence rates does not substantially reduce outcomes compared with older criteria giving a much lower population prevalence [253].

Methodological concerns relate largely to employment of a single OGTT glucose value, an arbitrary 1.75 risk threshold, and less robust clinical outcomes (birth weight, cord C-peptide, and neonatal skin folds being greater than the population 90% percentile), with RCTs showing only marginal benefit at these thresholds [253, 256–261]. Some would argue that a risk ratio of 2, as used in observational studies, rather than 1.75 would be more reliable [258], or indeed could be approximated if a high fasting glucose and one other raised threshold was used for diagnosis [262].

The thresholds have also been criticized for their potential *medicalization* of pregnancy and particularly in populations where IADPSG-defined thresholds are not associated with increased adverse outcomes [259–261]. Universal criteria defining GDM may both be wasteful and contribute to unnecessary anxiety [263].

The high IADPSG/WHO prevalence rates have been defended on the basis of their similarity to those in non-pregnant adults aged 20–44 years from the most recent US National Health and Nutrition Examination Survey (NHANES; 4.5% overt diabetes; 29.3% impaired glucose tolerance) [249, 250]. As the prevalence of undiagnosed diabetes is highest in this age group, even higher rates might be identified if systematic prepregnancy testing was instituted effectively. In addition, comprehensive gluco-metabolic antenatal screening would help identify both lipid and glucose abnormalities present many years before pregnancy testing [251]. The recent decision to reduce screening of young adults to 35 years is unprecedented and provides further support for the GDM prevalence rates [252].

Although the majority of women in HAPO with adverse outcomes had glucose levels below the thresholds, some of these women may have had one or two values equaling or exceeding the IADPSG thresholds. In addition, other data have shown the importance of even a single abnormal threshold value for prediction of future GDM. While the original HAPO study focused on short-term outcomes, the significant impact of these thresholds for adverse metabolic and cardiovascular outcomes in both mother and offspring has been shown in the long-term follow-up and needs to be incorporated into cost-economic models of care. The majority of women with GDM are managed by diet alone, thus minimizing medical intervention [242, 243]. It has been acknowledged that the IADPSG diagnostic thresholds are not applicable to early pregnancy, and indeed the value of earlier diagnosis of GDM during pregnancy, and by what criteria, is the subject of active research.

Screening strategies and glucose thresholds vary across different countries [5, 15, 40, 60, 179–181, 234] in the use of a preliminary screening test, glucose load, number of glucose values that must be equalled or exceeded, and glycaemic thresholds (Table 71.14). The IADPSG [60] and New Zealand criteria [181] advise early detection by random plasma glucose and HbA_{1c},

Table 71.13 Concerns and comments about the International Association of Diabetes and Pregnancy Study Groups (IADPSG) criteria for gestational diabetes mellitus (GDM) [41].

Basic issue	Specific concern	Comment
Diagnosis of GDM in early pregnancy	IADPSG recommends screening by blood test in first trimester using same diagnostic thresholds as derived from testing in late second trimester [238]	Most international bodies (although not NICE [15]) endorse screening in first trimester with blood test for undiagnosed type 2 diabetes General agreement that IADPSG thresholds should not apply to early pregnancy [248]
Prevalence	2–3-fold increase in prevalence rates	Potential for overdiagnosis and affordability issues, but supported by high prevalence of women with prediabetes in this age group outside pregnancy [249–252]
Methodology	Single OGTT Arbitrary 1.75 glucose threshold Less robust clinical outcomes	Variability and poor reproducibility of OGTT glucose IADPSG 1.75 risk ratio regarded as too low [246] and lack of RCT data for reliability [253] Preference for more robust and clinically meaningful outcomes Supported by high prevalence rates outside pregnancy and adverse long-term data in mother and offspring [254]
Logistics	Increasing number of individuals with diabetes	Management issues with diversion of resources from pregestational diabetes, but can be addressed by strategies such as algorithm-guided management of low-risk individuals
Medicalization	Pregnancies previously considered healthy now given a label with greater medical input and potentially greater intervention, irrespective of glycaemia and fetal growth	Identification of women with GDM who are not at risk of adverse outcomes has psychological and economic consequences [253], but majority of these women can be treated with diet alone
Cost economics	Conflicting cost-economic data Some diagnostic criteria derived largely from cost-economic models with different thresholds [15] Modelling suggests criteria are only cost-effective if caesarean section or maternal diabetes can be prevented	Cost-economic datasets based on non-selected populations, some of which are not blinded, and do not take account of adverse long-term maternal/fetal outcome data

NICE, National Institute for Health and Care Excellence; OGTT, oral glucose tolerance test; RCT, randomized controlled trial.

respectively, while in the UK [15], Canada [180], and USA [60], testing is recommended only if risk factors are present. Screening strategies include selective screening (UK NICE [15]) with testing at 24–28 weeks based on risk factors, universal screening using a two-step approach in the USA (ADA and American College of Obstetrics and Gynecology [AOCG] [60, 234]) and Canada [180], and universal screening using a one-step strategy in countries with high-risk and low-medium-risk populations [264]. In many low-resource settings (e.g. sub-Saharan Africa) testing is not routinely available, partly because the OGTT is cumbersome and labour intensive. Consequently, the International Federation of Gynecology and Obstetrics (FIGO), while supporting WHO/IADPSG criteria with universal biochemical testing, acknowledged that adaptation might be needed across countries to reflect variation in the balance of undiagnosed GDM [40, 249] with access to and quality of laboratory glucose and HbA_{1c} measurement. ACOG opted to retain the two-stage process involving a 50 g glucose challenge test followed by a 100 g OGTT [234], while ADA [60] allows for either the single-stage IADPSG or two-stage method with differing criteria.

By contrast, NICE [15], utilizing a cohort of 40 000 pregnant women, recommended substantially different thresholds based on a cost-economic analysis (fasting ≥ 5.6 mmol/l [101 mg/dl] and two hours ≥ 7.8 mmol/l [140 mg/dl]) among a subset of 18 974 women for whom fasting, one-hour, and two-hour glucose values were available. Uncertainties surrounding the validity of these analyses have been highlighted, however, given that 12 000 of these women had undergone universal screening and that the cost-effectiveness of selective versus universal screening depends on the prevalence of GDM within an individual community [265]. The

NICE two-hour threshold is much lower than the other guidelines and the concordance of the fasting and two-hour UK diagnostic thresholds was estimated to be as low as 55%. Other groups have suggested that lower thresholds would be more appropriate for different ethnic groups [259].

Overt diabetes during pregnancy

The IADPSG [41], WHO [42], and later FIGO [40, 249] distinguished GDM from *overt diabetes in pregnancy* (defined by non-pregnant thresholds of fasting glucose ≥ 7.0 mmol/l [126 mg/dl] or two hours ≥ 11.1 mmol/l [200 mg/dl]) (Table 71.11). The presumption is that women with more severe degrees of hyperglycaemia (including prepregnancy) would be at greater diabetic and obstetric risk (including malformations), and in turn merit more careful vigilance and intensive management. It is noteworthy that such women, for ethical reasons, were excluded from the HAPO study, thus potentially reducing some of the adverse outcomes. Similar exclusions were also applied to the ACHOIS and MFMU studies [242, 243].

GDM: disease entity or risk factor?

The continuous relationship between glucose and adverse outcomes has been viewed by some to be more analogous with the relationship between blood pressure or cholesterol and ischaemic heart disease [181, 246]. Maternal glucose is considered to be one of

Table 71.14 Screening and testing approaches recommended by international diabetes organizations.

Organization	Screening and testing approach	Risk factors used (if any)	Diagnostic method
NICE [15]	Offer women with risk factors OGTT at 24–28 weeks Offer women with previous GDM early capillary glucose monitoring or early pregnancy OGTT	BMI $\geq 30 \text{ kg/m}^2$ High-risk ethnicity First-degree relative with diabetes Previous macrosomia ($\geq 4.5 \text{ kg}$) Previous GDM	2 h 75 g OGTT
Endocrine Society [179]	Test all women using fasting plasma glucose, HbA _{1c} , or an untimed random plasma glucose at the first prenatal visit Those testing negative should undergo repeat testing for GDM at 24–28 weeks	None	2 h 75 g OGTT
ADA [60]	Test women with risk factors at initial visit (to screen for overt diabetes) by HbA _{1c} , fasting glucose, random glucose, or 75 g OGTT Retest those testing negative along with all other women at 24–28 weeks	BMI $\geq 25 \text{ kg/m}^2$ plus one or more of: First-degree relative with diabetes High-risk ethnicity History of CVD or hypertension HDL cholesterol $<0.9 \text{ mmol/l}$ Triglyceride $>2.82 \text{ mmol/l}$ PCOS Physical inactivity Previous GDM Previous hyperglycaemia Age $\geq 40 \text{ yr}$ High-risk ethnicity First-degree relative with diabetes BMI $\geq 30 \text{ kg/m}^2$ Previous macrosomia (4.5 kg or $>90\text{th}$ centile) PCOS Steroid or antipsychotic use Age $\geq 35 \text{ yr}$ High-risk ethnicity Corticosteroid use BMI $\geq 30 \text{ kg/m}^2$ Previous GDM Pre-diabetes Previous infant $>4 \text{ kg}$ PCOS Parent or sibling with type 2 diabetes	50 g GCT followed by 3 h 100 g OGTT in those GCT positive <i>or</i> 2 h 75 g OGTT
ADIPS [181]	Test women with risk factors at first antenatal visit, ideally by OGTT or HbA _{1c} Retest those with normal results, along with all other women, at 24–28 weeks		2 h 75 g OGTT
Diabetes Canada [180]	Test women with risk factors at first antenatal visit for overt diabetes using HbA _{1c} , FPG, or OGTT Retest those testing negative, along with all other women, at 24–28 weeks		50 g GCT followed by 2 h 75 g OGTT in those GCT positive (preferred) <i>or</i> 2 h 75 g OGTT alone

several risk factors, the detection and treatment of which may vary depending on the presence of other risk factors or only if a particular diagnostic or treatment threshold is exceeded. This approach also focuses attention on the outcome of interest, quantification of the risk, relevant risk factors, and a targeted approach to intervention and the tangible benefits of treatment.

At one end of the spectrum are women with previously undiagnosed diabetes at risk of malformations and perinatal mortality, who clearly merit treatment, while at the other end of the spectrum the risk is primarily that of excess fetal growth [238], which may be viewed as a risk factor for adverse outcomes rather than a disease *per se* [258]. Not all women with GDM are at significant risk and only a minority will benefit from treatment [253].

With the possible exception of South Asian women [234], this approach has not been adopted for GDM, although various risk engines have been examined [266]. Equally, some have expressed a preference for the term *hyperglycaemia in pregnancy* [267], which

may help in the conceptualization of risk or in glucose being viewed as one of a number of risk factors, with the potential to reduce the medicalization of pregnancy.

Diagnosis in the first trimester (timing of screening)

Traditionally, with the exception of women known to have previous GDM, screening for GDM has been targeted at 24–28 weeks' gestation due to the development of insulin resistance in the later part of pregnancy [15, 40, 60, 232]. It has also been acknowledged that the IADPSG thresholds are applicable only to diagnosis at 24–32 weeks' gestation (average 28 weeks), and cannot simply be extrapolated to early pregnancy [41, 248] given the changes in glucose metabolism with gestation. NICE guidelines advise against plasma glucose or

HbA_{1c} testing early in pregnancy, even to rule out pre-existing type 2 diabetes, because of the scarcity of cost-effectiveness studies [15].

The case for early identification of GDM [268] is supported by a study showing that diagnosis after 28 weeks' gestation is already accompanied by a twofold higher risk of fetal abdominal circumference >90th centile (OR 2.05), which increases further (OR 4.52) when combined with maternal obesity [269], and ultimately is associated with a fourfold increase in the risk of being born LGA. Moreover, in a large multiracial prospective cohort study, initial acceleration of fetal growth and accrual of fast mass were detectable at 20 weeks' gestation [270]. In India, elevated fetal adiposity was noted before the diagnosis of GDM in women who did not have pre-diabetes or type 2 diabetes in early pregnancy [271]. Offspring of these women had higher adiposity, but did not have an elevated birth weight (*the thin-fat phenotype*).

The onset of gestational diabetes might occur as early as 16–20 weeks' gestation, and earlier maternal hyperglycaemia [272] and fetal hyperinsulinaemia (14–20 weeks) [273] are associated with later development of GDM and LGA babies. Observational studies have shown that fasting glucose (across the normal range up to 5.8 mmol/l [105 mg/dl]) in the first trimester is predictive of later GDM, LGA, and caesarean section [272]. Women with GDM diagnosed in the first trimester (by Carpenter–Coustan criteria) have increased rates of hypertension and pre-eclampsia compared with a later diagnosis [274], with a suggestion (albeit limited by small numbers) of increased rates of neonatal hypoglycaemia and perinatal mortality [275]. Women with GDM and higher HbA_{1c} at diagnosis (41–49 mmol/l [5.9–6.6%]) had increased rates of adverse outcomes (pre-eclampsia and preterm birth), and rates of pre-eclampsia were reduced in a subgroup who were diagnosed and treated before 24 weeks compared with those who began treatment later [276].

A meta-analysis that examined screening for early-onset GDM found that 15–70% of cases could be detected before 24 weeks' gestation [277], while the overall prevalence of early GDM ranged from 0.8% to 22.9% across studies. Although the wide range reflects differing screening methodologies and diagnostic criteria, a considerable proportion of GDM may develop in early gestation and remain undiagnosed under current guidelines. In the meta-analysis, women diagnosed with GDM <24 weeks compared with those diagnosed later had a higher risk of perinatal mortality (RR 3.58), neonatal hypoglycaemia (RR 1.61), and insulin use (RR 1.71). A recent retrospective analysis compared women diagnosed with GDM <24 weeks with those diagnosed >24 weeks in 1471 pregnancies [278] and reported that despite treatment, women diagnosed earlier in pregnancy had significantly higher rates of pregnancy-induced hypertension, postpartum haemorrhage, and need for caesarean section. The offspring meanwhile had higher rates of macrosomia, prematurity, stillbirth, and need for neonatal intensive care.

Women who develop GDM in early pregnancy are more likely to be older, multiparous, with a higher BMI and a family history of type 2 diabetes [277]. In addition, uptake of OGTT in early pregnancy is apparently poor, and in one large prospective study only 23.2% took advantage of the offer of testing [279]. Fasting plasma glucose alone may be more practical in early pregnancy, although a large Chinese cohort of 17 186 pregnancies found that only 37% of women with FPG ≥ 5.1 mmol/l in the first trimester had a positive OGTT at 24–28 weeks [280]. Furthermore, given the changes in glucose metabolism through pregnancy, expert consensus on the diagnostic thresholds for early pregnancy is lacking [248].

While early identification of GDM might allow more timely intervention, more substantive cohorts comparing various risk factors together with dedicated RCTs in early pregnancy are needed, with the important exclusion of women at high likelihood of diabetes before pregnancy, whether defined by impaired fasting glucose (6.0–6.9 mmol/l) or by HbA_{1c} (6–6.5%). An ongoing RCT involving the identification of women with GDM using an OGTT in early pregnancy (<20 weeks) will provide important information regarding whether or not early intervention can improve pregnancy outcomes [281].

Screening tests

Two-step test

The 50 g glucose screening test (GST) involves a blood glucose test before and one hour after a non-fasting 50 g glucose load, followed, if positive, by a diagnostic OGTT. Traditionally in the USA this was endorsed either as the method of choice or, following the IADPSG recommendations, as one of two valid methods of testing for GDM [60]. The non-fasting nature of the test offers convenience, but its greater complexity (scheduling issues, inconvenience, and cost) was associated with poorer uptake of the second visit, even in well-resourced countries such as Canada [282]. This is likely to be greatly magnified in lower- and middle-income countries, resulting in the majority of at-risk pregnancies effectively being untested and leading to missed follow-up opportunities. Other concerns are the poor sensitivity, specificity [283], and reproducibility [284] of post-glucose screening tests.

The two-step strategy misses ~25% of women who would be diagnosed by a full OGTT [282]. Those with a positive screen may modify their lifestyle and other factors prior to their diagnostic OGTT, which may also account for some of the difference in prevalence. The two-step approach fails to identify women primarily manifesting fasting hyperglycaemia, as they do not qualify for the OGTT. In the HAPO study, the frequency of GDM diagnosed by fasting glucose ranged from 24% to 26% in Thailand and Hong Kong to 73–74% in the USA and the Caribbean [253]. The two-step test may therefore miss many women with hyperglycaemia in pregnancy.

One-step universal approach

The one-step universal test offers a single diagnostic OGTT. Given the variability in results due to clinical, pre-analytical, and analytical factors [285, 286], this may result in a differing diagnostic classification on repeat testing; however, the initial dietary nature of any intervention would favour this drawback over failing to detect significant maternal metabolic risk. The poor reproducibility of the GST has also been highlighted [286]. A recent USA-based systematic review found that women with one abnormal value on their diagnostic three-hour OGTT are at substantially higher risk of LGA babies, caesarean delivery, hypertension, Apgar score less than 7, NICU admission, and respiratory distress syndrome [287]. The one-step approach is associated with better perinatal outcomes [288]. For these reasons, it would seem unwise to revert to a two-step approach for such large populations.

A recent US pragmatic RCT by Hillier et al. [289] involving 23 792 predominantly white and Asian women from two Kaiser Permanente health systems identified 16.5% of women using a one-step diagnostic process (75 g OGTT interpreted by IADPSG

criteria) and 8.5% using a two-step process as described earlier. The results showed no maternal or perinatal benefit overall between the two screening strategies [290]. In a responsive commentary, McIntyre et al. [291] highlighted that the lack of effect at a population level was to be anticipated, as 92% of women in each arm were treated in a similar manner and the small reduction in LGA frequency with a one-step versus two-step approach (8.9% vs 9.2%) is consistent with predictions from previous studies [292]. In addition, the Hiller study was integrated into standard care and allowed providers the option of using a diagnostic strategy of their own choice rather than the random allocation (only 66% of women in the one-step group received their allocated testing strategy, compared with 92% in the two-step group), which, although controlled for, raised the possibility of residual bias. Although the one-step approach almost doubled the GDM frequency, it identified women with an almost equal risk of having hyperglycaemia severe enough to merit pharmacotherapy (43% with the one-step and 46% with the two-step method). While outcomes did not differ at a population level, the study was unable to address whether the additional 8% of women diagnosed with GDM using the one-step approach would have derived benefit from treatment [291].

Fasting plasma glucose screening test

Fasting glucose concentrations reach a nadir around the 12th week of pregnancy and then stay relatively constant for the remainder of pregnancy [293]. FPG as a screening test is attractive because it is relatively easy to obtain, well tolerated, reproducible, and inexpensive [293]. Interpretation of studies using FPG, however, is made difficult by the employment of FPG as a screening test (which may enhance sensitivity and assumes 100% reproducibility, which is unlikely to be the case), different glucose loads, and variation in thresholds to be equalled or exceeded for diagnosis [294]. In two studies, using the Carpenter–Coustan and WHO criteria, respectively [295, 296], similar sensitivities (81% and 88%) and specificities (76% and 72%) were found at a FPG threshold of 4.8 mmol/l (86 mg/dl). By contrast, two studies that utilized IADPSG diagnostic criteria reported sensitivities of 92.5% and 74%, respectively [297, 298], at an FPG threshold of 4.7 mmol/l (85 mg/dl). Two studies using FPG as a first screening test for GDM diagnosed in early third trimester by IADPG criteria at an FPG threshold of 5.1 mmol/l (92 mg/dl) reported sensitivities of 27% [299] and 26% [300], with respective specificities of 95% and 90%, suggesting that until further data are available, FPG should not be used for screening purposes in the first trimester.

Glycated haemoglobin as a screening test

When used as a screening test, regardless of when the test is done, the higher the HbA_{1c}, the more likely the diagnosis of GDM [293]; however, there is a marked overlap in values between women with and without GDM, thus limiting its value [301]. In several studies in which all women received diagnostic testing for GDM using a threshold of 5.4–5.7% (35–48 mmol/mol), sensitivities varied from 26% to 86% and specificities from 21% to 92% [293]. A large ($n = 8497$) study examined HbA_{1c} as a screening test at the first prenatal visit (median 47 d) for the diagnosis of GDM in later pregnancy defined by IADPSG criteria. In the study 82% of the 692 women diagnosed with GDM had an HbA_{1c} result <5.9% (41 mmol/mol) and 23% of GDM was diagnosed prior to 20 weeks; the remaining 77% was discovered either on initial or repeat OGTT testing after 20 weeks. Only 5% of 8497 women who underwent HbA_{1c} screening proceeded to undertake the OGTT [279].

Selective versus universal screening

Approaches to GDM detection vary widely (Table 71.14). Those international bodies that advocate universal screening do so based on the high prevalence rates of GDM [302], the generally asymptomatic nature of GDM, and the association of hyperglycaemia with adverse pregnancy outcomes independent of other risk factors.

Risk factor-based screening is the selection of women with such risk factors to undergo formal testing for GDM. Women with one or more clinical or obstetric risk factors are generally at high risk of GDM [293, 303]. NICE has defined five such factors: family history in a first-degree relative, BMI >30 kg/m², previous big baby (>4.5 kg), previous GDM, and belonging to certain ethnic groups (e.g. from Latin America, Africa, Pacific Islands, Southeast Asia, or the Asian subcontinent) [15]. Other risk factors include maternal age (e.g. ≥30 yr) and increased parity [15, 285]. Certain risk factors (e.g. previous GDM) have greater positive predictive value, while others (previous GDM, previous macrosomia) create a bias for parity to be a risk factor. The greater the number of risk factors, the greater the positive predictive value for GDM [293]. Risk factors are only around 50% sensitive and specific for GDM, meaning that some women with GDM will only be identified through universal testing, regardless of how risk is defined. In a recent systematic review and meta-analysis assessing the performance of risk factor screening, there was no superior combination [303]. Approximately 70% of women would need to undergo testing to identify 80% of cases of GDM, and all women would need to undergo testing to achieve a sensitivity above 90%. Across studies, the NICE criteria had a sensitivity of 78.2% and specificity of 31.7%; overall, 67.2% of women would require OGTT employing NICE screening criteria [15]. The NICE recommendation is based largely on cost-economic considerations, although in another UK report GDM screening was cost-effective if the population GDM frequency was greater than 4.2% [265].

Poor compliance rates with risk factor-based protocols, together with the inconvenience and non-compliance with return for non-diagnostic testing [40], would also favour a universal approach [253]. Alternatively, FIGO has suggested pragmatic approaches [249] to accommodate differing country and healthcare systems. In individual populations and in countries where IADPSG-defined OGTT thresholds are not associated with adverse outcomes, treatment at different glycaemic thresholds may be needed to achieve comparable outcomes [261]. A global consensus for GDM diagnosis may remain the ideal [291].

Risk engine

The fact that pregnancy outcomes relate to multiple risk factors has generated interest in whether a *risk engine* approach might give a more comprehensive appreciation of the relationship between maternal demographic and biological risk factors and adverse pregnancy outcomes [266], especially where the prevalence of maternal obesity is high and its effects on pregnancy complications may predominate [304]. The development of personalized composite risk scores may optimize the benefits of antenatal intervention, but there is a need to recognize differential risk among ethnic groups [234], or relative risk contributions by differential predictors for outcomes of GDM or its complications [305]. In addition, the current strategy does not reflect the pathogenesis of GDM, which is likely to be heterogeneous [306–308] and might further help identify those women who would benefit the most from

continuing monitoring and intervention. Prediction of GDM is likely to be facilitated by integrating healthcare databases containing relevant clinical and biochemical variables, while targeting resources to those most in need in low- and middle-income countries [305].

Cost-effectiveness of screening

Relevant issues include the costs and benefits of treatment of GDM and the cost and risk of those who have the disease but with a negative screening result. Cost models will differ depending on whether the outcomes are confined to more physiological endpoints, such as LGA, or more adverse maternal and fetal outcomes. Most models have not factored in long-term health outcomes.

Two previous large RCTs showed benefit from treatment of GDM [257, 258]. Each of these studies employed different glucose loads, different numbers of elevated OGTT results, and different glycaemic thresholds from IADPSG to define GDM, as well as different thresholds to initiate insulin treatment. More recent studies comparing IADPSG with traditional thresholds have not shown improvements in treatment, and some have compared one-step versus two-step diagnostic approaches rather than the cost-effectiveness of IADPSG thresholds [249].

Studies on the cost-effectiveness of GDM screening strategies and diagnostic criteria are limited [309–311]. Using a quality-adjusted life year, one study determined that no cost-effective screening was indicated for populations where the risk was <1%, while for those with a risk of >4.2% a universal OGTT was the most cost-effective [265]. Two studies concluded that testing with the new IADPSG criteria was expensive but cost-effective [312, 313], while other studies [260] did not find it cost-effective.

While the focus has been largely on immediate pregnancy outcomes, much of the personal and public health *value* of GDM detection lies in the opportunity to identify women who carry long-term risk of developing overt diabetes, cardiovascular disease, and premature mortality [254, 314–319]. Future cost-economic modelling of various diagnostic thresholds and screening and preventive strategies must include both short- and long-term outcomes [320, 321] together with consideration of more specific analysis pertaining to particular populations and low-income settings [322].

Management of gestational diabetes

Management and glycaemic targets advised by international bodies are shown in Table 71.5. NICE glucose targets (fasting <5.3 mmol/l, one-hour post-prandial <7.8 mmol/l, and two-hour post-prandial glucose <6.7 mmol/l) are similar to those of diabetes preceding pregnancy. FPG levels of ≥5.8 mmol/l are associated with an increased risk of preventable perinatal complications [99] and are thus an indicator that pharmacological treatment is likely to be of benefit. NICE recommends that women with a fasting blood glucose level of ≥7.0 mmol/l at diagnosis of GDM should be treated with insulin in preference to oral diabetes drugs [15].

Treatment of mild hyperglycaemia reduces fetal growth and the proportion of infants born LGA, but it is unclear whether infants who are small or appropriate for gestational age benefit from treatment. In an elegant study, Hispanic women with mild hyperglycaemia (fasting glucose <5.8 mmol/l) and fetal abdominal

circumference greater than the 75th centile were randomized to diet therapy alone (29 women) or diet with twice-daily insulin (30 women), with target fasting glucose of 4.4 mmol/l and two-hour post-prandial <6.1 mmol/l. The LGA rate in the diet-treated group was 45%, significantly greater than the insulin-treated group (13%), and the diet-treated group had an initial abdominal circumference <75th centile (14%) [99]. There remains the possibility of overtreatment producing growth-retarded babies.

Diet and lifestyle modification

Women with GDM require education and individualized nutritional advice [323, 324]. The food plan should provide adequate calorie intake to promote fetal growth and maternal health, achieve glycaemic goals, and promote weight gain according to 2009 Institute of Medicine recommendations [213]. There is no definitive research to specify an optimal calorie intake for women with GDM or determine whether calorie needs differ from those of pregnant women without GDM. The key principles are to reduce overall energy intake and limit the proportion derived from carbohydrates. Simple carbohydrates result in higher post-meal glucose excursions than more complex carbohydrates. Recognized dietary modifications to lower blood glucose levels include reducing caloric intake for women with overweight and obesity (e.g. to ~25 kcal/kg body weight), limiting carbohydrate to 35–40% of total calories, and utilizing carbohydrate foods with a low glycaemic index. The Dietary Reference Intakes for all pregnant women recommend a minimum of 175 g carbohydrate, 71 g protein, and 28 g fibre. The diet should emphasize monounsaturated and polyunsaturated fats while limiting saturated fats and avoiding trans fats. Regular exercise is often recommended and there is limited evidence that it reduces fetal birth weight [325].

Self-monitoring of blood glucose (fasting and one-hour post meals) provides early warning of progressive hyperglycaemia and the need for additional therapy, especially if associated with accelerated fetal growth. Lifestyle change is sufficient to control hyperglycaemia in 80–90% of women [242, 243]. Women treated with diet alone are usually at lower risk and logically might be managed in a less intense setting using a treatment algorithm.

Pharmacological treatment

Insulin

If diet and exercise are insufficient to manage maternal hyperglycaemia, insulin is an effective treatment to prevent fetal complications, especially those related to fetal overgrowth. It is tailored to glycaemic targets and preferred by some international bodies as the mainstay of treatment because it does not cross the placenta [60]. The goals of treatment (including reduction of post-prandial hyperglycaemia) are similar to those for type 1 diabetes and multiple-daily insulin regimens are frequently used. The starting dose of insulin is 0.1 unit/kg/d and with expert advice can easily be commenced as an outpatient with active titration. Both twice-daily and multiple-daily insulin injections are reasonable delivery strategies and neither has been shown to be superior to the other during pregnancy [326].

There are some women with GDM requiring medical therapy who, due to cost, language barriers, comprehension, or cultural influences, may be unable to use insulin safely. Oral agents may be an alternative in these women after a discussion of the known risks and the need for more long-term safety data in the offspring.

Metformin

In the largest trial [327], 751 Australian women with GDM at 20–33 weeks' gestation were randomized to metformin (1000–2000 mg daily), with insulin supplementation if needed, or insulin. Perinatal morbidity (composite outcome) was similar in the two groups (32.0% vs 32.2%, respectively). Severe neonatal hypoglycaemia (<1.6 mmol/l) was lower with metformin (3.3% vs 8.1%; $p = 0.008$), but preterm birth was more common (12.1% vs 7.6%; $p = 0.04$). Maternal weight gain was lower in the metformin group (0.4 vs 2.0 kg; $p = 0.001$). Glycaemic levels were similar between the groups, although 46.3% of women in the metformin group required insulin.

Seven subsequent smaller trials largely confirmed the safety and efficacy of metformin in GDM compared with insulin [328], while three trials comparing metformin with glibenclamide suggested less maternal weight gain, lower birth weights, and higher neonatal blood glucose levels. In most of these trials, approximately half of metformin-treated women required insulin. These women were generally older with higher baseline BMI, more marked and earlier hyperglycaemia, and earlier diagnosis and treatment of GDM. In systematic reviews, metformin was associated with a lower risk of neonatal hypoglycaemia and less maternal weight gain than insulin [260, 329–333].

Metformin readily crosses the placenta, resulting in umbilical cord blood levels of metformin as high as or higher than simultaneous maternal levels [60]. In a follow up of 7–9-year-old offspring in the Metformin in Gestational diabetes study (MiG-TOFU), offspring exposed to metformin compared with insulin in one cohort were heavier and had a higher waist-to-hip ratio and waist circumference [334]. In two RCTs of metformin use in pregnancy for polycystic ovary syndrome (PCOS), follow-up of 4-year-old offspring exposed to metformin had higher BMI and increased obesity, while at 5–10 years exposed offspring had higher BMI, waist-to-hip ratio, and waist circumference, and a borderline increase in fat mass [335]. A recent meta-analysis concluded that metformin exposure resulted in smaller neonates with acceleration of postnatal growth resulting in higher BMI in childhood [336]. Other follow-up trials are currently in progress. Due to the potential for growth restriction or acidosis in the setting of placental insufficiency, metformin should not be used in women with hypertension or pre-eclampsia or those at risk for IUGR [60].

UK NICE guidelines approve the use of metformin to treat GDM after appropriate discussion of the benefits and risks [15]. Rapid dose escalation and early commencement of insulin (possibly even concurrently with metformin) are advised to minimize the duration of hyperglycaemia in women with high BMI, previous GDM, and high baseline glucose, suggesting likely failure with metformin as a single agent. ADA guidance recommends the substitution of insulin [60] because it crosses the placenta and has limited efficacy.

Sulfonylureas

The only large randomized trial of glibenclamide (glyburide) [337] involved randomization of 404 women with fasting hyperglycaemia despite diet at 11–33 weeks' gestation to insulin or glibenclamide therapy (2.5–20 mg daily). Glycaemic levels and neonatal outcomes were similar between the two groups. In the glibenclamide group, 4% needed insulin. Subsequently four small RCTs comparing glibenclamide with insulin reported an increased rate of neonatal hypoglycaemia, macrosomia, and IUGR [332, 333, 338]. Other retrospective observational studies have generally confirmed the effectiveness of glibenclamide, but variously reported increased

rates of pre-eclampsia, macrosomia, lower ponderal index, lower Apgar scores, the need for phototherapy, neonatal hypoglycaemia, stillbirth (in those treated early in gestation), and NICU admission. Approximately 20% of women treated with glibenclamide needed to be switched to insulin [328].

Sulfonylureas cross the placenta and concentrations of glibenclamide in umbilical cord plasma are approximately 50–70% of maternal levels [60, 339]. In a meta-analysis and systematic review in 2015 [329], glibenclamide was associated with a higher rate of neonatal hypoglycaemia and macrosomia than insulin or metformin. More recently, glibenclamide failed a non-inferiority test compared with insulin based on a composite outcome of neonatal hypoglycaemia, macrosomia, and hyperbilirubinaemia [340]. Long-term safety data for offspring exposed to glibenclamide are not available. Furthermore, glibenclamide failed to provide adequate glycaemic levels in 23% of women with GDM [341]. No international body approves the use of glibenclamide during pregnancy.

Delivery

The UK NICE guidelines recommend that women with GDM treated with tablets or insulin should be delivered before 40 weeks' gestation [15], but in practice obstetricians make a decision based on individual risk. Delivery guidelines are similar to those for diabetes preceding pregnancy, particularly for women on insulin. In general, glycaemic management during delivery does not require such intense monitoring or a glucose infusion.

Postpartum management

Post-delivery, any pharmacological treatment started during pregnancy is discontinued in anticipation that the woman will revert to normal glucose tolerance. This can be established provisionally using capillary glucose monitoring before leaving hospital, but should be confirmed by formal postnatal testing. Traditionally, the latter involved an OGTT test around six weeks post-delivery, although uptake rates of only around 23–58% are reported [15].

GDM is a risk factor for subsequent GDM [342], type 2 diabetes [343, 344], the metabolic syndrome [345, 346], and increased cardiovascular risk [315–319] compared to women without GDM. Women with GDM diagnosed during pregnancy need to have repeat testing postnatally for the early detection of previously unrecognized type 2 diabetes or pre-diabetes, and, if suspected, formal exclusion of type 1 diabetes and genetic types of diabetes. The postnatal visit also provides a unique opportunity to offer lifestyle advice, screen for cardiovascular risk factors, and remind women of the need for regular contraception and early referral in the eventuality of future pregnancy. A simple gestational recall register or an appointment with a dedicated cardiovascular coordinator might improve the follow-up of women with gestational diabetes [347]. Despite this evidence, only half (58%) of women in the UK in the first year after a GDM pregnancy underwent any glucose testing and even fewer had a lipid test [316]. Although the risk of incident type 2 diabetes is recognized, and previous history of gestational diabetes is incorporated into the QDiabetes-2018 risk prediction algorithm [348], this information has not been incorporated into cardiovascular disease risk calculators.

Various social and medical risk factors for non-attendance for postnatal screening have been identified. Women who missed testing were at a high risk of cardiovascular disease [349]. FPG is conceivably a simpler and cheaper alternative, but the need for an overnight fast may present difficulties to mothers with young children. Limitations of HbA_{1c} relate to increased red blood cell

turnover in pregnancy and blood loss at delivery, although in its favour are the convenience of a single non-fasting blood test, higher pre-analytical stability, ease of repetition, and availability of point-of-care testing, especially in resource-limited settings. The OGTT is more sensitive at detecting glucose intolerance (including both diabetes and pre-diabetes), although these comparisons are in relation to the OGTT as the gold standard rather than independent outcomes [349].

Most international bodies continue to recommend postnatal OGTT testing [60, 180, 181]. By contrast, the NICE 2015 guidelines recommend either a fasting plasma glucose (FPG) or HbA_{1c} at least 13 weeks after delivery rather than OGTT testing for postpartum screening [15]. All women with GDM, irrespective of postnatal glycaemic status, should be counselled that their lifetime risk of diabetes is higher than the rest of the population and offered lifestyle interventions, similar to people with impaired glucose tolerance. High-risk groups (e.g. certain ethnic minorities, those with overweight or obesity, women diagnosed early in pregnancy) should be specifically targeted for intervention strategies. Those with normal or impaired glucose tolerance postnatally should have ongoing surveillance by annual fasting glucose or HbA_{1c} every 1–3 years [15, 60], along with continuing lifestyle education and monitoring of cardiovascular risk factors. Follow-up plans are often poor, as these women fall between primary and secondary care teams and no international guidelines recommend screening for other cardiovascular risk factors.

Maternal obesity

The increasing prevalence of obesity in women of reproductive age is being translated into pregnancy [350, 351] and is projected to increase further [352]. In 2011–2014, 34% of US women aged 20–39 years had obesity (57% among Hispanic Black women [353]), while among live births in 2015, 26% of women had obesity prepregnancy and another 26% were overweight [354]. Maternal obesity and gestational weight gain can be viewed as important factors in fetal overnutrition and, together with a reduction in cigarette smoking, largely explain the trend to increasing birth weight [355].

Pregnant women with obesity are at increased risk for various maternal and perinatal complications, which increase with the severity of obesity [356–358]. One-quarter of pregnancy complications are attributable to overweight or obesity [358]. Women with obesity and high gestational weight gain have the highest risks of pregnancy complications, and the latter is a potentially modifiable risk factor [359, 360].

Maternal overweight and obesity are associated with increased risks of adverse pregnancy outcomes both during and outside of pregnancy. Maternal complications include hypertensive disorders of pregnancy [361], gestational diabetes [247, 255, 362], and maternal mortality [9, 49]. Fetal or neonatal complications, including stillbirth [363], birth defects [49, 82], macrosomia [247, 364], and shoulder dystocia [365, 366], also occur more frequently in babies born to women with obesity, but reports are more variable for other possible adverse outcomes such as preterm delivery and early neonatal death [255].

The relative importance of obesity *per se* and hyperglycaemia to adverse pregnancy outcomes is difficult to ascertain from many previous studies due to methodological weaknesses. For example, in some reports routine screening for hyperglycaemia was not undertaken or not described [255]. In some studies that involved universal glucose screening, detailed analyses of the prevalence of

GDM in women with overweight or obesity were not reported [367]. Moreover, in none of the previous studies were glucose results blinded from women or their caregivers, which may have influenced both clinical decision-making and ascertainment of pregnancy outcomes.

Excessive maternal weight gain is also associated with these same pregnancy and neonatal morbidities [359, 368] and, although GDM is associated with greater weight gain particularly in early pregnancy [369, 370], it is the weight gain that has the dominant effect on fetal growth [364]. Although GDM is associated with maternal obesity, the latter has a greater impact on these adverse outcomes [359, 364, 368]. Interpregnancy weight gain is also associated with poorer outcomes in subsequent pregnancies [371, 372].

Obesity in pregnancy increases the risk of GDM by a factor of 3.0 for women with moderate obesity and by 5.6 for women with morbid obesity [356]. The prevalence of GDM increases by 0.92% for each 1 kg/m² increase in BMI [356]. Insulin resistance is a hallmark of both obesity and GDM. All pregnant women have a reduced amount and phosphorylation of skeletal muscle insulin receptor (IRS1), the most important and abundant insulin receptor substrate in skeletal muscle, indicating a lower capacity for insulin signalling in pregnancy [373]. In women with pre-existing insulin resistance, the physiological rise in insulin resistance of pregnancy cannot always be compensated for by increased insulin secretion predisposing some women with obesity to develop GDM.

Interpretation of the relative clinical and population health importance of GDM and obesity, which frequently coexist, is difficult, as with few exceptions many studies fail to control for population heterogeneity, screening, and treatment [238, 239]. These problems were addressed by the large observational multicultural, multicentre HAPO study involving 23 000 untreated women during pregnancy with detailed characterization of GDM and weight status. In this study, obesity was present in 13.7% and GDM by IADPSG criteria in 16.1%; only 25% of the women with GDM had obesity [239, 240]. The HAPO study showed that maternal BMI and glycaemia have similar independent and essentially additive associations with adverse pregnancy outcomes [239, 240] (Figures 71.3 and 71.4). Maternal BMI was also strongly related to fetal adiposity and hyperinsulinaemia, even after adjustment for maternal glycaemia [239]. This highlights the potential importance of other nutrients including triglycerides, free fatty acids, and amino acids [374], and potentially total caloric intake. In addition, adipocytokines, inflammatory markers, and changes in physical activity may play a role in determining fetal size and adiposity [375]. Both maternal BMI and glucose were associated with increased frequency of caesarean section [255, 376]. The relative *importance* of these factors is heavily influenced by the potential costs and benefits of preventive or treatment strategies, which have practical and health-economic implications [377]. The same effects of gestational weight gain, independent of HbA_{1c}, are also observed in pregnancies of women with type 1 diabetes and type 2 diabetes [378, 379].

The US Institute of Medicine guidelines [213] (Table 71.6) suggest a total weight gain target of 5–9 kg for women with obesity during pregnancy, but even lower targets (including weight loss) might be associated with better outcomes [380, 381]. Compared with women with obesity who gain >5 kg during pregnancy, those who lose or gain <5 kg in weight in pregnancy have babies that are on average 190 g lighter (with a rate of SGA babies similar to women with normal weight) [382].

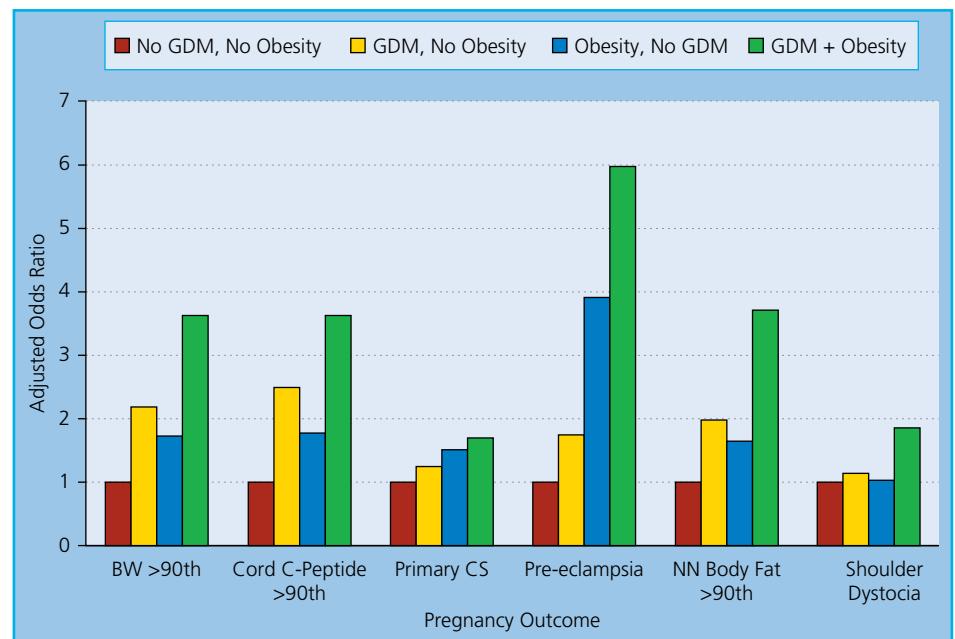

Figure 71.3 Odds ratios for pregnancy complications by obesity and gestational diabetes mellitus (GDM) status. Fully adjusted odds ratios for selected pregnancy complications in the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study. The 'No GDM, No Obesity' category served as the referent group for all complications. The other categories, as labelled, refer to GDM alone, Obesity alone, and the combination of both factors. Odds ratios refer to Model II as detailed in the original publication with full adjustment for potential confounders. BW, body weight; CS, caesarean section; NN, neonatal. Source: Data from Catalano et al. 2012 [240].

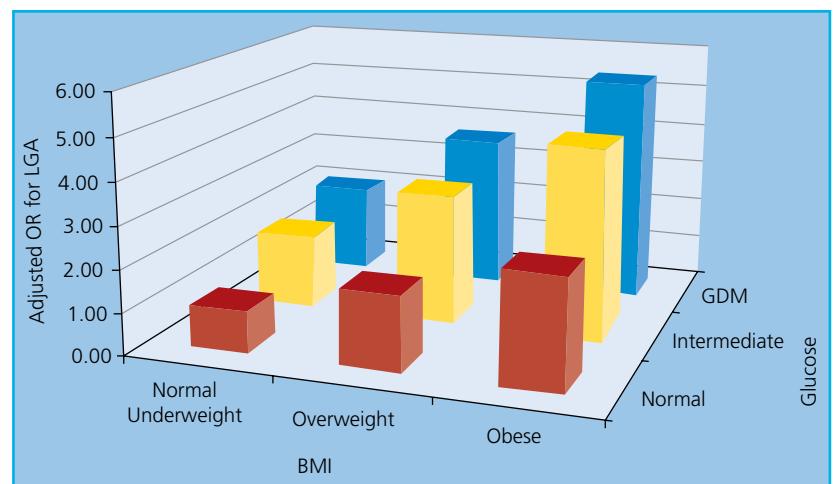

Figure 71.4 Odds ratios (OR) for a low-for-gestational age (LGA) infant divided by three category classifications of glycaemia and body mass index (BMI). Fully adjusted OR for delivery of an LGA infant characterized as birth weight >90th centile in Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study participants [240]. The group with normal glucose levels and normal- or underweight-range BMI served as the referent group. The intermediate glucose group was defined according to their mean standard deviation (Z) scores for the fasting, one-hour, and two-hour glucose levels during the diagnostic oral glucose tolerance test (OGTT). The values used to define this category were chosen to achieve a frequency of intermediate glucose equivalent to the frequency of overweight in the HAPO study cohort [238]. BMI was measured at the time of the diagnostic OGTT and converted to equivalent World Health Organization categories by regression analysis. GDM, gestational diabetes mellitus. Source: Data from Catalano et al. 2012 [240].

Malformations

Obesity is associated with an increased risk of congenital anomalies, including neural tube defects, cardiac malformations, orofacial defects, and limb-reduction abnormalities [82, 83]. The risk of most congenital abnormalities, including neural tube defects and congenital heart defects, increases with the severity of maternal obesity [82, 83], with the exception of gastroschisis. An analysis of the Florida Birth Defects Registry showed an increase in prevalence of birth defects in live-born infants, increasing from 3.9% in underweight women to 5.3% in those with obesity with $\text{BMI} >40 \text{ kg/m}^2$ [383]. Maternal obesity reduces the chances of detecting congenital anomalies antenatally by 23% [384]. The mechanism for these associations is not well defined, but is likely related to an altered nutritional milieu during fetal development.

Effects on neonatal complications

Offspring of women with obesity have greater Homeostatic Model Assessment for Insulin Resistance (HOMA-IR), leptin, and interleukin-6 measurements in cord blood [385], a marginal increase in

birth weight, no change in lean body mass, but a significant increase in percentage body fat from 9.7% to 11.6% [386]. The risk of LGA infants increases with greater maternal weight gain in obesity [368]. Compared with normal-weight euglycaemic women, the odds for LGA, adjusted for weight gain during pregnancy, were 1.96 for normal-weight women with GDM, 2.63 for women with obesity but not GDM, and 5.47 for women with both obesity and GDM [387]. Infants born to women with obesity and morbid obesity are at increased risk of neonatal hypoglycaemia, premature delivery, admission to intensive care, and jaundice. The effects of maternal diabetes and maternal obesity on the offspring are both additive and independent.

Long-term outcomes for the mother

In women with a history of GDM, the risk of recurrent GDM is 30–84% [342]. GDM is a risk factor for type 2 diabetes and indeed the original diagnostic thresholds were defined on this basis [239]. Even a slight elevation in blood glucose during a screening oral glucose challenge test or a diagnostic OGTT, or isolated

hyperglycaemia at one hour during an OGTT, is associated with an increased risk of postpartum hyperglycaemia [388].

A meta-analysis of 20 studies in 2009 demonstrated that women with previous GDM had a 4.7-fold risk of developing diabetes within five years of having GDM, 9.3-fold after five years or more, compared with a normoglycaemic pregnancy [389]. An estimated 17–50% of women with prior GDM will develop type 2 diabetes within 1–5 years of pregnancy; this increases to 35–70% at 10–20 years after the index pregnancy [388–392]. The lifetime risk of type 2 diabetes is up to 10 times higher [343, 344]. The absolute risk increases linearly through a woman's lifetime, being approximately 20% at 10 years, 30% at 20 years, 40% at 30 years, 50% at 40 years, and 60% at 50 years [344].

Postpartum diabetes is a multifactorial condition involving the interaction of modifiable and non-modifiable risk factors. Previous studies have identified various risk factors, including maternal age, family history of diabetes, glycaemic indices during pregnancy, weight, healthy diet, exercise, and breastfeeding [393, 394]. Those women with the highest blood glucose levels at diagnosis of GDM, those who needed insulin treatment in pregnancy, those with impaired β -cell function, and those who are overweight and gain most weight after their GDM pregnancy tend to develop type 2 diabetes the earliest [395, 396].

A problem with follow-up studies has been the variable definitions of GDM and lack of control for confounding variables. Of particular importance in this regard is the Hyperglycaemia and Adverse Pregnancy Outcomes Follow-Up Study (HAPOFUS) [254, 397–401], involving 4679 mothers (mean age 41.7 years). At a median of 11.4 years of follow-up, 52.2% of mothers with untreated GDM during pregnancy developed a disorder of glucose metabolism versus 20.1% of mothers without GDM (OR 3.44; 95% CI 2.85 to 4.14). More than twice as many mothers with IADPSG-defined GDM compared with mothers with Carpenter–Coustan criteria-defined GDM (240 vs 106) developed a disorder of glucose metabolism [254].

The similarities in risk factors for the development of GDM and type 2 diabetes have long been recognized. Women studied at the time of normal glucose tolerance present with the hallmarks of insulin resistance and hyperinsulinaemia [402]. Indeed, GDM is best regarded as a form of type 2 diabetes, with the same risk factors [401]. Other studies [403, 404] highlight the greater prevalence of a cluster of cardiovascular factors such as obesity ($BMI \geq 30\text{ kg/m}^2$), hypertension, and dyslipidaemia in women with previous GDM, with the prevalence of the metabolic syndrome being 40% (three times that of the control group) [405].

In several large-cohort observational studies [319, 405], higher rates of incident ischaemic heart disease were observed independent of the onset of type 2 diabetes. Women with prior GDM have 1.95-fold higher odds of developing cardiovascular disease compared to women without GDM [406]. The lifetime risk of cardiovascular disease following GDM was most marked in those women who progressed to overt type 2 diabetes (hazard ratio [HR] 2.82; 95% CI 2.24 to 3.30), but an increased risk (HR 1.41; 95% CI 1.11 to 1.80) was present even for women without progression. In addition, a recent Canadian population-based study [317] showed that women with hyperglycaemia who did not meet the diagnostic thresholds for GDM still had a higher risk of cardiovascular disease, although some of these women might have met the more stringent IDAPSG/WHO criteria.

These data highlight that GDM and hyperglycaemia in pregnancy are associated with a high risk of both diabetes and future

cardiovascular disease. The management strategy should involve the comprehensive identification and systematic treatment of risk factors for both conditions.

Long-term outcomes for the offspring

Infants of mothers with hyperglycaemia in pregnancy (both pre-existing and gestational) are more likely than infants of normoglycaemic mothers to be born LGA as a consequence of excess fetal growth and adiposity. The HAPO study showed a linear independent association between maternal glycaemia and odds of LGA birth weight, with an odds of 1.38 for each standard deviation increase in maternal fasting glucose [238]. Hyperglycaemia is independent of maternal obesity and excessive gestational weight gain, which also contribute to this risk [239]. Excess adiposity in the offspring can be independent of birth weight [407].

Infants of women with diabetes are at increased risk of certain chronic diseases, including obesity, diabetes, and the metabolic syndrome in later life, with implications for public health [254, 397–401, 406, 407]. In addition, the Pedersen hypothesis has been expanded to envisage a role for other fuels besides glucose *fuel-mediated teratogenesis*, later encapsulated in the developmental origins hypothesis, in which hyperglycaemia *in utero* is envisaged to drive the development of obesity and diabetes through fetal metabolic programming [408]. Under this hypothesis, such conditioning in female offspring could increase the propensity to GDM and hence lead to a transgenerational cycle with major public health implications [409].

Similar concerns pertain to the global increase in childhood obesity [410–413], where current prevalence rates indicate that by the age of 2 years, one in ten children in the USA have obesity and more than half will have obesity by the age of 35 years [413]. This persistence of obesity into early adulthood is likely to increase the risk of type 2 diabetes and cardiovascular disease.

A problem in the interpretation of long-term outcome studies is that some of the earlier studies were conducted in populations with a high prevalence of diabetes, many fail to control for confounding variables, and alternative explanations for the associations, such as shared genetic or familial associations, are possible. The original seminal long-term studies in the Pima, a population with a very high prevalence of type 2 diabetes, showed that offspring of women with type 2 diabetes during pregnancy had an increased risk of early-onset type 2 diabetes compared with offspring of mothers without diabetes [414]. Similar findings were reported from an ethnically diverse population from Chicago (with a lower background prevalence of type 2 diabetes), in which the prevalence of impaired glucose tolerance among offspring exposed to maternal pregestational GDM *in utero* was 20% by the age of 16 years (10 times higher than in the general population of similar age) [415]. The prevalence of type 2 diabetes or pre-diabetes among adult offspring of Danish women with GDM was 21% compared to 12% among offspring of women screened for GDM but found to be negative [416]. Elevated rates in the prevalence of type 2 diabetes or pre-diabetes were also reported in the offspring of women with type 1 diabetes [416, 417]; the prevalence of type 2 diabetes or pre-diabetes was 11% in Danish adult offspring of women with type 1 diabetes compared with 4% in offspring of women without diabetes. In support of the intrauterine environment over shared genetic and environmental factors, studies in the Pima showed that siblings born before the mother's diagnosis of type 2 diabetes had a lower prevalence of diabetes and a lower mean BMI compared to their sibling born after the diagnosis [418]. Other studies have observed an excess frequency

of maternal versus paternal transmission of diabetes [419], although this finding has not been consistent across all studies [420].

In the Pima, offspring of mothers with type 2 diabetes during pregnancy were at greater risk of obesity and higher body weight for age than offspring of women with pre-diabetes or without diabetes [421], but obesity in the offspring was significantly related to both maternal and paternal BMI [422]. These findings have been confirmed in other population groups [423]. Similarly, offspring of mothers with GDM have an increased risk of developing the metabolic syndrome [345] and have other cardiovascular risk [346] independent of birth weight [345]. These risk factors have also been found in offspring of women with type 1 diabetes [424].

The higher prevalence of obesity among women with GDM confounds the association of GDM with childhood obesity. Higher maternal BMI is associated with higher childhood adiposity through shared genetics, familial lifestyle and environmental factors, and the intrauterine environment [425]. Both maternal and paternal BMI are positively associated with obesity and high waist circumference in the offspring [426, 427], which could be interpreted on the basis of shared genetic factors and a shared postnatal environment [428]. Adjustment for parental obesity and for postnatal environmental factors may be important to avoid confounding bias in studies of the long-term risk of obesity associated with intrauterine exposure to diabetes [428–430]. Adjustment for maternal BMI has resulted in inconsistent results and in some studies attenuated the associations between GDM and childhood obesity, leading to the question of whether the association was independent [431, 432].

Mechanistically, it is possible that adjustment for maternal prepregnancy BMI may partially obscure the full effect of fetal overnutrition due to its contribution to a fuel-rich environment and elevated intrauterine glucose [433]. In addition, maternal screening for GDM is often not universal and is more likely to be offered to women with overweight or obesity, resulting in underdiagnosis of GDM among normal-weight women and consequently underestimation of the true association between maternal and offspring obesity/diabetes after adjustment for maternal BMI. On the other hand, animal models have demonstrated altered epigenetic regulation leading to altered cellular signalling [434], or disturbances in the development of central fetal pathways controlling appetite and energy balance [435].

Against this background, the HAPO follow-up study of 4832 children at a median duration of follow-up of 11.4 years reported that 39.5% of the offspring of women with GDM had overweight or obesity and 19.1% had obesity, compared with 28.6% and 9.9%, respectively, in offspring of normoglycaemic mothers [254, 397]. The study showed that IADPSG-defined GDM, independently of maternal BMI, was associated with childhood obesity as well as direct measures of child adiposity, such as sum of skin folds or body fat percentage. These associations were stronger than the associations with BMI, likely reflecting contributions of both fat and lean body mass to BMI. This was consistent with the independent and additive effects of maternal and GDM on newborn adiposity outcomes in the HAPO study [238, 239].

Whether an association of GDM with newborn and childhood outcomes is mediated solely through mixed nutrients (e.g. sugars, lipids, and amino acids), as proposed by Freinkel [436], remains to be determined. However, recent metabolomic studies performed within the HAPO study and within other cohorts support the concept that mixed nutrients contribute to associations of maternal hyperglycaemia with newborn outcomes [437].

Lifestyle intervention trials during pregnancy

Recent lifestyle interventions during pregnancy are detailed in Table 71.15 [438–447, 450–452]. Lifestyle interventions in pregnant women with obesity may have the potential to limit gestational weight gain, which is important for reducing postpartum weight retention and limiting pregestational weight in a subsequent pregnancy. Lifestyle interventions are generally difficult to undertake and often labour intensive [453]. They frequently differ in the combination of behavioural, dietary, and physical activities, and the intensity and monitoring of fidelity, thus making comparisons difficult. Other limitations include the likelihood of attracting the healthiest women, lack of blinding, and commencement of interventions too late in pregnancy. The Finnish Gestational Diabetes Prevention Study (RADIEL) [446], involving women at high risk of GDM and ~30% with previous GDM, showed a reduction in GDM, but other studies have not shown any reduction in clinical, maternal, and neonatal outcomes such as GDM, pre-eclampsia, macrosomia, and preterm birth. Pregestational BMI is a stronger predictor of maternal and neonatal pregnancy outcomes than gestational weight gain [364] and these women have more insulin resistance and higher circulating plasma triglycerides from the beginning of pregnancy [454]. Several studies have shown the importance of interpregnancy weight change for the risk of complications in the next pregnancy [371, 372]. A mild to moderate interpregnancy weight loss in women with obesity significantly reduces the risk of subsequent LGA infants in observational studies without increasing the risk of SGA infants.

A 2015 Cochrane review of 13 RCTs and 4983 women and their babies assessed the effects of combined diet and exercise interventions and reported that diet and exercise interventions did not change the risk of developing GDM [455]. This was also found in other systematic reviews and meta-analyses [456–459]. Several reviews indicated that some antenatal interventions are associated with reduced gestational weight gain, and it seems that dietary interventions are most effective; however, studies need to be interpreted cautiously given that they are generally of low/moderate quality.

Telehealth interventions are growing in popularity for use in pregnancy for conditions such as GDM [460], although trials to date have been undertaken in highly select groups of individuals. Other concerns include usability of technology, reliability of data, and ability to inform clinical decision making, but with continuing development and refinement of technologies they seem to offer promise.

No intervention studies have been shown to reduce the long-term impact of GDM during pregnancy on both mother and baby. Taken together, the findings highlight the importance of optimizing maternal pregestational body weight and the metabolic conditions before conception. The interpregnancy interval may be a crucial period for targeting weight loss in future studies. In the meantime, gestational weight gain should be avoided, healthy eating and an active lifestyle promoted, and breastfeeding and weight loss supported after pregnancy.

Postnatal intervention trials

Given the increased risk of type 2 diabetes after pregnancy in women with GDM, and the importance of prepregnancy BMI and interpregnancy weight gain, intervention trials have also investigated modifiable risk factors [393, 394] after pregnancy, with the aim of improving the postpartum metabolic phenotype and reducing the incidence of type 2 diabetes.

Table 71.15 Lifestyle intervention trials during pregnancy.

Author (year) Study [reference]	Design	Population	Intervention	Results
Phelan (2011) Fit for Delivery [438]	RCT, intervention vs control	BMI 19.8–40 kg/m ² ; USA; n = 401	Low-intensity behavioural intervention; one F2F contact with interventionist at study entry and 3 short supportive phone calls	Reduction in exceeding 1990 IOM criteria for GWG: 40.2% vs 52.1%; p = 0.003 (normal weight only); no significant effect on GWG in overweight/obese
Luoto (2011) NELLI [439]	Cluster RCT, intervention vs control	All BMI groups; euglycaemic but at least one GDM risk factor; Finland; n = 399	5 F2F antenatal visits with nurses, with individual dietary and exercise counselling	No effect on GWG (13.8 vs 14.2 kg; p = 0.52); significantly lower birth weight in intervention group vs control: 3532 vs 3659 g (p = 0.008); and significant reduction in birth weight/week and LGA; no effect on GDM or macrosomia
Vinter (2011) LIP [440]	RCT, intervention vs control	BMI ≥30 kg/m ² ; Denmark; n = 360	4 individual F2F visits with dietitians, weekly training sessions in groups with physiotherapists, pedometer and free fitness club membership	Significant reduction in GWG: 7.0 vs 8.6 kg; p = 0.01; no effect on birth weight, LGA, or GDM
Walsh (2012) ROLO [441]	RCT, intervention vs control	2nd pregnancy; prior infant >4000 g; Ireland; n = 800	Low glycaemic index diet from early pregnancy (1 group session with dietitians); follow-up with written material and 2 sessions with reinforcement	No significant difference in birth weight or macrosomia; significant reduction in GWG: -1.3 kg (95% CI -2.4 to -0.2); p = 0.01
Bogaerts (2013) [442]	RCT, 3 groups: lifestyle, brochure, and control	BMI ≥29 kg/m ² ; Belgium; n = 205	Brochure group received written information on healthy lifestyle; lifestyle group had 4 antenatal intervention sessions with midwives trained in motivational interviewing	Significant reduction in GWG in both intervention groups vs control: 9.5 vs 10.6 vs 13.5 kg; p = 0.007; significantly less anxiety in active lifestyle group only; no effect on birthweight or GDM
Renault (2014) TOP [443]	RCT, 3 groups: physical activity (PA) + Diet, PA, and control	BMI ≥30 kg/m ² ; Denmark; n = 425	Dietary advice by dietitians every 2 weeks (F2F and phone calls); PA included pedometer with encouragement to aim for 11 000 steps daily	Significant reduction in GWG in both intervention groups vs controls: 8.6 vs 9.4 vs 10.9 kg; p = 0.01; no effect on birth weight, LGA, or GDM
Dodd (2014) LIMIT [444]	RCT, intervention vs control	BMI ≥25 kg/m ² ; Australia; n = 2212	Dietary, exercise, and behavioural strategies delivered by dietitians and assistants at 2 F2F visits followed up by 3 personal phone calls	No reduction in LGA in intervention vs control: 19% vs 21%; p = 0.24; significantly lower rate of macrosomic infants (>4000 g): 15% vs 19%; p = 0.04; no difference in GWG: 9.39 vs 9.44 kg; p = 0.89
Poston (2015) UPBEAT [445]	RCT, intervention vs control	BMI ≥30 kg/m ² ; UK; n = 1555	Behavioural intervention; 8 weekly health trainer-led sessions in groups or individualized	No difference in GDM between intervention vs controls: 25% vs 26%; p = 0.68; no difference in LGA: 9% vs 8%; p = 0.40; significant reduction in GWG: 7.19 kg vs 7.76 kg; p = 0.041
Koivusalo (2015) RADIEL [446]	RCT, intervention vs control	BMI ≥30 kg/m ² ; Finland; n = 293	Individual counselling on diet, physical activity, and weight control from study nurses and one group meeting with dietitian	GDM incidence 13.9% (intervention) vs 21.6% control (95% CI 0.40 to 0.98%; p = 0.044) after adjustment for baseline variables; significant reduction in GWG: -0.58 kg (95% CI -1.12 to -0.04); adjusted p = 0.037
Simmons (2017) DALI [447]	RCT, 3 groups: healthy eating (HE), physical activity (PA), and HE + PA	BMI ≥29 kg/m ² ; 9 European countries; n = 436	5 F2F and 4 optional telephone coaching sessions; based on principles of motivational interviewing	Significantly lower GWG in HE women: -2.02 kg; 95% CI -3.58 to -0.46. No difference in fasting glucose/insulin resistance; no significant difference between HE + PA and other groups; GDM prevalence similar in all intervention groups
Dodd (2019) GROW [450]	RCT, (dietary + lifestyle) + metformin vs placebo	BMI ≥25 kg/m ² ; 10–20 weeks' gestation; Australia; n = 514	Dietary and lifestyle intervention with additional metformin or placebo	No significant difference in birth weight >4000 g (16% metformin vs 14% placebo); metformin group had significantly lower average weekly GWG (-0.08 kg; 95% CI -0.14 to -0.02; p = 0.007). No difference in total GWG or pregnancy and birth outcomes
Ferrara (2020) GLOW [451]	RCT, telehealth lifestyle intervention vs usual antenatal care	BMI 25–40 kg/m ² ; 8–20 weeks' gestation; USA; n = 398	2 F2F and 11 telephone sessions on behavioural interventions	48% women in lifestyle vs 69% in control exceeded IOM recommendations for GWG/week (relative risk 0.70, 95% CI 0.59 to 0.83); mean between-group difference lifestyle vs control: (-0.07 kg/wk, 95% CI -0.09 to -0.04). No between-group differences in perinatal complications
Yew (2021) SMART-GDM [452]	RCT, smartphone-based lifestyle-based coaching programme vs usual care	GDM; 12–30 weeks' gestation; mean BMI 25.6 kg/m ² ; Singapore; n = 340	Smartphone-based lifestyle-based coaching program vs usual care	With intervention, no significant reduction in excessive GWG (primary outcome), absolute GWG, or maternal or delivery outcomes; significant reduction in average glucose readings and composite outcome (not prespecified) of neonatal complications (38.1% vs 53.7%)

BMI, body mass index; CI, confidence interval; F2F, face-to-face; GDM, gestational diabetes mellitus; GWG, gestational weight gain; IOM, Institute of Medicine; LGA, large for gestational age; RCT, randomized controlled trial.

Pharmacological interventions

A significant dose-dependent increase in insulin sensitivity and a reduced insulin response were observed in women with previous GDM who had been randomized to either 200 or 400 mg/d troglitazone [461], with participants in the TRoglitazone In the Prevention Of Diabetes (TRIPOD) trial randomized to the troglitazone (400 mg/d) group demonstrating a 55% reduction in the risk of diabetes progression [462]. The US Diabetes Prevention Program (DPP) demonstrated that metformin reduced the cumulative incidence of diabetes in women with impaired glucose tolerance and previous GDM by 50.4% compared with placebo [463, 464]. The results of this study suggest that interventions such as metformin treatment are effective for preventing the progression to diabetes, even many years after delivery.

Breastfeeding

Lactation improves glucose tolerance in the early postpartum period, but it remains uncertain whether future risk of type 2 diabetes is reduced, with only a few studies having examined breastfeeding and postpartum glucose tolerance in women with previous GDM. Ziegler et al. followed women with GDM for up to 19 years and found that breastfeeding for >3 months reduced postpartum diabetes by 46% [465]. A 12-year follow-up in the Nurses' Health Study reported that increasing duration of lactation was associated with reduced risk of type 2 diabetes, with each additional year decreasing the risk by 15% [466]. However, when stratified by GDM status, no association between lactation and risk of type 2 diabetes was evident.

Physical activity

Physical activity reduces the incidence of type 2 diabetes in both the general population and in those with a history of GDM. A large 16-year prospective cohort study showed that increasing physical activity may help lower the risk of progression from GDM to type 2 diabetes [467]. A small feasibility study assessing a structured behavioural intervention to increase physical activity in women failed to achieve its goal of increasing step count to 10 000 steps/d [468]. Interventions involving the promotion of physical activity alone are limited, with the majority of trials utilizing a multicomponent lifestyle approach of which physical activity is one behaviour.

Diet

Following a healthy dietary pattern reduces the risk of developing diabetes [469]. In women with obesity and previous GDM, a weight loss regimen consisting of 40% versus 55% carbohydrate resulted in similar weight loss, although the former had lower triglyceride levels [470]. Asian women who followed a low glycaemic index eating plan reported significant reductions in body weight, BMI, and waist-to-hip ratio at six months postpartum [471]. Among participants in the Nurses' Health Study II cohort with a history of GDM, those consuming diets within the highest quartile for the Mediterranean diet, Dietary Approaches to Stop Hypertension (DASH) diet, and alternate Healthy Eating Index diet had a 40–57% lower risk of developing postpartum diabetes compared with women in the lowest quartile over a 14-year follow-up period [472]. Studies implementing dietary change during pregnancy in women with GDM have reported positive results for the duration of the index pregnancy; however, changes were not sustained postpartum [473, 474], highlighting the need to identify strategies to encourage continued engagement during the postpartum period. Loss of 10–15% of body weight through dietary modification can result in remission of type 2 diabetes [475, 476].

Diet and physical activity

Combined diet and physical activity promotion programmes aim to prevent type 2 diabetes [477], with weight loss being the risk factor explaining the greatest variance in risk and the one most amenable to change [478]. While outcomes such as weight loss and reduction in BMI have been successfully achieved in combined interventions [479, 480], this has not consistently translated into a reduced incidence of the development of type 2 diabetes [481, 482]. Ratner et al. found lifestyle modification to be as effective as treatment with metformin in reducing the incidence of diabetes by 50% compared with controls [464]. A more recent Spanish study reported that after three years' follow-up fewer women assigned to a diet and physical activity intervention group developed glucose disorders than the control group [483]. Further studies are needed to elucidate which are the key features to optimize the effectiveness of these programmes by translating them into long-term health outcomes.

Lifestyle interventions with a telephone component

Numerous studies have examined the effect of lifestyle interventions delivered either in full or partially via telephone in women with a history of GDM. A US phone intervention based on DPP guidelines (diet, exercise, breastfeeding) versus controls observed no difference in the proportion of women achieving their prepregnancy weight at 12 months postpartum [484]. Two Australian studies comprising phone-based behavioural interventions reported no effect on weight, BMI, or physical activity [485, 486]. A large US study of 2280 women with GDM observed that women receiving 13 DPP-based phone sessions over a 12-month period had higher odds of meeting weight goals at 6 weeks, 6 months, and 12 months postpartum and of achieving greater increases in vigorous-intensity physical activity [487]. Two years following delivery of a lifestyle intervention underpinned by motivational interviewing techniques, Hedderson et al. observed a decrease in total energy intake and percentage of calories from fats, and increase in physical activity in women who received the intervention compared with controls [488]. Many of these trials use multiple methods of delivery, making it difficult to ascertain which precise elements are exerting the greatest effect. The delivery of an intervention remotely by telephone is attractive, as it often reduces the need for the woman to leave the home or arrange childcare when attending appointments. The effectiveness of remote/partially remote programmes needs to be further investigated.

Lifestyle interventions with a digital component

The proliferation of mobile devices has facilitated the design, development, and delivery of remote digital interventions, which have the potential to introduce lifestyle change by supplementing or replacing face-to-face contact. Web-based education, pedometers, text message reminders, internet forums, emails, and apps have all been utilized in RCTs for women with previous GDM in recent years. Some studies have demonstrated significant improvement in post-intervention weight loss [489, 490], but others have shown no effect [485, 491]. Glycaemic indices remained similar between intervention and control groups [492, 493]. The possibility of utilizing digital technology to assist with the delivery of health promotion interventions is attractive for both the service provider and the service user [494]. However, the pace of development of technology necessitates regular monitoring and updating of devices and systems to remain relevant. The identification of key intervention components needs to be prioritized in future studies. Lack of standardized reporting and timepoint of assessment presents a barrier to

direct comparison between trials. Research is needed into the development of a core outcome set with which to facilitate direct comparison or combination of results from different studies.

Probiotics

Given the role of gut microbiota in regulating metabolism, there has been interest in the possible role of probiotics in prevention of GDM. A Finish study involving 256 pregnant at-risk women, who were randomized in the first trimester to probiotic dietary intervention or control, showed a reduction in maternal glycaemia and rate of GDM in the intervention group (36 vs 13%) [495], but these results were not replicated in two more recent studies in women with obesity at high risk of GDM [496, 497].

Future work

Current evidence would suggest a benefit of diet and exercise in women at risk of GDM [498, 499], but the results of interventions during pregnancy have generally been disappointing and studies are of variable quality. Future trials may need to be started much earlier in pregnancy and particularly focused on women between pregnancies and those women planning pregnancy.

Most cases of type 2 diabetes can be prevented or significantly delayed by lifestyle intervention and the use of metformin. Only

five to six women with a history of GDM and pre-diabetes need to be treated with either intervention to prevent one case of diabetes over three years [464]. Recent data have highlighted the importance of weight loss both to reduce risk and to effect remission of type 2 diabetes. These lines of evidence would suggest that women with GDM and their families form a key high-risk group for whom there is a compelling case for targeted intervention. Intervention trials in women with previous GDM, investigating modifiable risk factors to improve the postpartum metabolic phenotype and reduce future incidences of type 2 diabetes, have demonstrated considerable promise; however, these women face various obstacles to implementing lifestyle changes, and as a result attrition of women with GDM to follow-up evaluations after delivery is problematic. The main factors include time pressure, emotional stress in adjusting to a baby, and poor social support [448, 449]. Successful translation of pragmatic lifestyle interventions into effective evidence-based practice needs to address and overcome these challenges. Further long-term offspring studies are needed, but to date the efficacy of GDM treatment during pregnancy in preventing long-term offspring complications remains unproven, with negative results reported both by the ACHOIS study [320] and the MFMU trials [321].

Key points

- The prevalence of diabetes is increasing in older people because of increased life expectancy.
- The phenotype of diabetes in old age is characterized by an increased prevalence of multiple comorbidities, geriatric syndromes, and frailty.
- A comprehensive geriatric assessment should be performed at the initial diagnosis of diabetes and annually thereafter.
- A multidisciplinary team approach with a multidimensional assessment, including screening for physical and cognitive function, is important to meet the complex needs of older people with diabetes.
- Hypoglycaemia is common in older people with diabetes owing to multiple comorbidities, and can be less easily recognized or misdiagnosed because of reduced autonomic symptoms.
- Increasing glucose levels, unexplained hypoglycaemia, or reduced self-care should alert the clinician to the presence of dementia or depression.
- Tight glycaemic targets are reasonable in fit older people, but a relaxed approach is more appropriate in frail older people at risk of hypoglycaemia.
- An individualized and holistic care plan is key to diabetes care in older people.
- Older people with diabetes living in care homes are particularly vulnerable and require greater specialist input.
- Quality of life should always be the focus for individualized care.

With the increasing ageing of the population, changing lifestyle and urbanization, the prevalence of diabetes has or is likely to reach epidemic levels in most countries, especially in older people ≥ 75 years [1]. Ageing is associated with body composition changes that lead to increased insulin resistance, glucose intolerance, and increased risk of diabetes [2]. As a result, more older people are developing diabetes. The lifetime risk of developing diabetes is high, reaching 22.4% for women and 18.9% for men from the age of 60 years [3]. Older people with diabetes are exposed to the interplay between metabolic dysfunction, vascular disease, and the ageing process in combination with other age-related disorders. Geriatric syndromes and frailty are emerging as a third category of complications in addition to the traditional micro- and macrovascular disease [4]. Therefore, diabetes in old age may lead to considerable disability. Unlike other chronic conditions, diabetes care is dependent on self-management, which may be compromised by the presence of comorbidities and geriatric syndromes. Owing to the heterogeneous nature and variations in comorbidity, life expectancy, and functional status, ranging from a fit individual living independently in the community to a fully dependent person living in a care home, therapeutic interventions and metabolic targets should be individualized, taking into consideration individual preference while putting quality of life at the heart of the care plan. This chapter reviews the phenotype of diabetes in old age and addresses the key areas and special considerations for the care of older people with diabetes to meet their complex needs.

Epidemiology

In 2017, about 8.4% of the world population had diabetes and this is expected to reach 10% in 2045 [1]. The prevalence of diabetes rises with increasing age. Worldwide, the greatest proportional increase in the number of people with diabetes by age group is expected to occur in those aged 60–79 years [3]. For example, in France, the prevalence has increased to 14.2% in people aged 65–74 years, peaking at 19.7% in men and 14.2% in women aged 75–79 years. More than half of those with diabetes were ≥ 65 years [5]. In the USA, 14% of the population is estimated to have diabetes and the prevalence is highest in those aged ≥ 65 years; by 2050 diabetes prevalence could be as high as 33% of the whole population [6]. Furthermore, a similar number may remain undiagnosed. In the US National Health and Nutrition Examination Survey, the prevalence of diagnosed diabetes in those ≥ 75 years was 14.9% and undiagnosed diabetes based on fasting plasma glucose and two-hour oral glucose tolerance test was 13.4%, making a total prevalence of diabetes of 28.3%, with undiagnosed diabetes constituting ~47%. The prevalence of *pre-diabetes*, defined as either impaired fasting glycaemia or impaired glucose tolerance, was 46.7% in those aged ≥ 75 years. Therefore, the total prevalence of diabetes and pre-diabetes was ~75% in older people ≥ 75 years [1].

Low- and middle-income countries will have the greatest burden of diabetes, where the prevalence will increase in adults

(aged 20–79 years) by 69% by 2030 compared to only 20% in higher-income countries [7]. This is likely driven by the growth and ageing of the population, changing lifestyle and urbanization in these countries. The prevalence of diabetes among older Chinese in rural Taiwan aged 72.6 years was 16.9% in 2000 and increased to 23.7% in 2005 [8]. In minority ethnic groups living in high-income countries, the incidence and prevalence of diabetes are higher than in white European populations. For example, the prevalence of diabetes in older Mexican Americans (≥ 75 years) almost doubled between 1993–1994 and 2004–2005, from 20.3% to 37.2%, in comparison to an increase from 10.4% to 16.4% in the general population of the same age [9].

Diabetes prevalence in care homes is also high. In 2004, 24.6% of US nursing home residents had diabetes; among residents aged 65–74, 75–84, and ≥ 85 years, the prevalence of diabetes was 36.1%, 29.5%, and 18.3%, respectively [10]. The prevalence of diabetes steadily increased in US nursing homes (16.9% to 26.4% in men and 16.1% to 22.2% in women) between 1995 and 2004. A more recent survey showed a further increase in the prevalence of diabetes, with 32.8% of residents living with diabetes [11]. Ethnic disparities in diabetes prevalence are also well documented in care home settings. In US nursing homes, the adjusted odds of diabetes are approximately twofold higher in African American and Hispanic residents relative to white American residents, present in 22.5% of white Americans and 35.6% of those from other ethnic groups [10].

Pathogenesis

Glucose homeostasis requires both normal insulin secretion by the pancreatic β cells and normal glucose utilization by the peripheral tissues that are sensitive to insulin. Diabetes in old age is linked to increased insulin resistance and decreased insulin secretion, with a principal defect of insulin resistance in individuals with obesity and insulin secretion in those who are lean. It is likely that both genetic and environmental factors are involved in the pathogenesis of the insulin secretory dysfunction and insulin resistance. As older people are heterogeneous, the extent and rate of deterioration in glucose homeostasis are variable, leading to insignificant changes in some individuals and diabetes in others (Box 72.1).

Increased insulin resistance

Ageing is associated with body composition changes that result in increased insulin resistance [12]. Increased visceral fat is associated with increased rates of lipolysis causing high levels of free fatty acids, which may have a role in reducing peripheral insulin sensitivity [13]. Reduction of muscle mass or sarcopenia occurs with ageing through physical inactivity and, as the muscle is the main site of glucose consumption, the loss of muscle mass increases insulin resistance [12]. Accumulation of lipids within the muscles is another factor reducing insulin sensitivity. A reduction in mitochondrial function [14] may also contribute to age-related glucose intolerance by reducing oxidative metabolism, physical fitness, and oxidative capacity. Low concentrations of adiponectin, leptin, and insulin-like growth factor I (IGF-I), and high concentrations of tumour necrosis factor α (TNF- α), are associated with ageing and linked to increased insulin resistance and incident diabetes [14–16].

Decreased insulin secretion

Insulin secretion diminishes by 0.7% per year with increasing age because of reduced function and increased apoptosis of pancreatic β cells [17]. β -cell autoimmunity may lead to activation of an

acute-phase response in older people with diabetes, with hypersecretion of interleukins, C-reactive protein, and TNF- α , which may reduce insulin secretion [18]. Disturbances in the physiology of the gut-derived incretins, gastric inhibitory polypeptide (GIP) and glucagon-like peptide 1 (GLP-1), may be another factor involved in β -cell dysfunction [19]. Both peptides enhance insulin secretion after meals and may have a role in maintaining β -cell growth, proliferation, and inhibition of apoptosis. Ageing is associated with reduced levels and function of these peptides [20].

Diabetes phenotype in old age

Diabetes in older people is associated with coexistent multiple comorbidity burden, geriatric syndromes, and frailty (Box 72.2).

Comorbidity burden

Diabetes in older people is associated with increased atherosclerosis, premature ageing, and increased disability. Older people with

Box 72.2 Diabetes phenotype in older people with diabetes

- Multiple comorbidities.
- Cognitive dysfunction.
- Depression.
- Physical dysfunction.
- Falls and fractures.
- Urinary incontinence.
- Polypharmacy.
- Less muscle mass and poor muscle quality.
- Malnutrition.
- Frailty.
- Nutritional need and hydration.
- Irregular eating pattern, especially in people with dementia.
- Vulnerability to hypoglycaemia.

diabetes frequently have at least one comorbid chronic disease in addition to diabetes, and as many as 40% have at least three conditions [21]. The comorbidity burden is even higher in care home residents with diabetes. For example, those with diabetes have more cardiovascular disease, visual problems, pressure sores, limb amputations, and kidney failure than residents without diabetes [22]. In a retrospective case note review of 75 nursing home residents with diabetes in the UK, significant levels of disability were shown in areas of continence, feeding, mobility, and communication. The average number of comorbidities per individual was 4 (range 1 to 8) [23]. The mortality rate was 34% after one year of follow-up, indicating severe comorbidity [24]. In another study, residents with diabetes had a greater comorbidity burden (Hierarchical Condition Category 1.90 vs 1.58), were prescribed more medications, and experienced more hospitalizations (37% vs 18%) than residents without diabetes [11].

Geriatic syndromes

Geriatic syndromes, such as cognitive and physical dysfunction, depression, falls, and urinary incontinence, are common in older people with diabetes and may have subtle presentations [25]. Diabetes is associated with a twofold increased risk of being unable to perform daily physical tasks, such as walking, doing housework, or climbing stairs, and 1.6-fold greater risk of difficulties performing basic personal care, such as bathing, using the toilet, dressing, and eating. Diabetes complications, such as neuropathy, arthritis, and vascular disease, are contributors to physical disability in older people with diabetes [26, 27]. The Study of Osteoporotic Fractures has shown that diabetes also increases the risk of falls (odds ratio [OR] 2.78; 95% confidence interval [CI] 1.82 to 4.25). History of arthritis, musculoskeletal pain, depression, poor vision, and peripheral neuropathy are the main predictors of falling among older people with diabetes [28]. The risk of developing Alzheimer's disease or vascular dementia is twofold higher in older people with diabetes compared to age-matched people without diabetes [29]. In the Health, Aging, and Body Composition Study, older people (70–79 years old) with diabetes had an increased incidence of depression compared with those without diabetes (23.5% vs 19.0%, hazard ratio [HR] 1.31; 95% CI 1.07 to 1.61) [30].

Frailty

Frailty is a condition characterized by a reduction in physiological reserve and in the ability to resist physical or psychological stressors [31]. Its definition is largely based on the presence of three or more phenotypes (weight loss, weakness, decreased physical activity, exhaustion, and slow gait speed) [32]. Frailty is viewed as a wasting disease, with weight loss being one of its criteria. Undernutrition, which is common in older people, seems to be a risk factor for frailty. In the USA, ~16% of older persons living in the community are undernourished; these figures rise to 59% in long-term care institutions and 65% in acute care hospitals [33]. Sarcopenia or muscle mass loss is a component of frailty, which seems to be accelerated when diabetes is present. In a community study of 3153 people ≥65 years, appendicular lean mass loss in men with diabetes was twice that of men without diabetes (3.0% vs 1.5%) and in women with diabetes was 1.8 times that of those without diabetes (3.4% vs 1.9%) over four years of follow-up.

The mechanisms explaining these results may be related to reduced muscle protein synthesis as a result of lower testosterone and IGF-I and increased muscle protein breakdown caused by a higher rate of inflammation [34]. Diabetes also causes sarcopenia through the catabolic effect of insulin deficiency and by increasing intramyocellular lipid accumulation [35]. In another study, older people with type 2 diabetes had accelerated decline in leg lean mass, muscle strength, and longer sit to stand time compared to those with normoglycaemia [36]. Another factor related to malnutrition and frailty may be oral health. For example, optimal nutrition may not be maintained because of poor dentition, dry mouth, reduced taste sensation, palatability, and appetite change with increasing age [37].

Clinical presentation

Diabetes can be asymptomatic in up to 50% of older people [38]. However, when symptoms are present they are mostly non-specific and may be attributed to ageing. Non-specific symptoms, such as general malaise, fatigue, or lethargy, are common manifestation of diabetes in old age. Geriatric syndromes, such as falls and urinary incontinence, may be the first manifestation of diabetes. Symptoms may be atypical, for example anorexia rather than the typical polyphagia. The classic osmotic symptoms are usually less prominent because of the increased renal threshold for glucose (reducing the intensity of polyuria) and impairment of thirst sensation (reducing the intensity of polydipsia). Hyperosmolar hyperglycaemic state may be the presenting symptom, or diabetes may be first diagnosed during an acute illness or following a routine blood test (Box 72.3).

Box 72.3 Special considerations for the diagnosis and assessment of diabetes in old age: clinical presentation and diagnosis

- Fasting blood glucose may be normal in up to one-third of cases.
- Post-prandial or two-hour oral glucose tolerance test are more reliable.
- Glycated haemoglobin ($\text{HbA}_{1\text{c}}$) is specific but less sensitive as a diagnostic test.
- Symptoms may be absent in up to 50% of individuals with diabetes.
- Osmotic symptoms are less prominent.
- Other symptoms may be non-specific such as fatigue or lethargy.

Comprehensive geriatric assessment

Comprehensive geriatric assessment should be performed on initial diagnosis and annually, including assessment of:

- Cognitive function.
- Screening for depression.
- Assessment for frailty.
- Falls risk.
- Activities of daily living ability.
- Presence of urinary incontinence and chronic pain.
- Nutritional status.
- Medication taking and polypharmacy.
- Social circumstances.

Diagnosis

The diagnostic criteria for diabetes are the same irrespective of age (Chapter 2). Clinicians should be aware that fasting glucose concentration may be normal in the early stages of diabetes and is therefore less sensitive in diagnosing diabetes in old age; however, the two-hour oral glucose tolerance test (OGTT) appears to capture undiagnosed cases [39].

Since February 2011, glycated haemoglobin (HbA_{1c}) has been used as a diagnostic test for diabetes. However, although HbA_{1c} has high specificity (98.7%), its low sensitivity (46.8%) means that it can miss more than half of people with diabetes [40]. There are several pitfalls to using HbA_{1c} in older people. HbA_{1c} increases with age after adjustment for glucose, suggesting that non-glycaemic factors contribute to this increase. Furthermore, iron-deficiency anaemia, which is common in older people, is associated with an increase in HbA_{1c} independent of changes in blood glucose. Both of these factors will lead to overdiagnosis of diabetes in older people if HbA_{1c} is used in preference to glucose. The diagnosis should be confirmed by a second laboratory test in the absence of diabetes symptoms as for younger people.

Management

The phenotype of diabetes in old age is highly variable and affected by comorbidity, geriatric syndromes, and frailty. Therefore, the diabetes management should consider the heterogeneous nature of the diabetes and the complex needs of the individual. A comprehensive geriatric assessment should be performed after the initial diagnosis and annually, as age-related comorbidities may impair diabetes management (Figure 72.1). Hyperglycaemia should not be treated in isolation, but as part of a multifactorial intervention to reduce cardiovascular risk. Cardiovascular complications remain the main cause of mortality, accounting for 50–75% of all deaths in people with diabetes [41]. Management includes health behaviour modification and pharmacological interventions for hyperglycaemia and cardiovascular risk factors (Box 72.4).

Health behaviour modifications

Health behaviour modification includes changes in diet, weight reduction, smoking cessation (the single most effective means of

Box 72.4 Management of cardiovascular risk factors in older people with diabetes

Health behaviour modifications

- Smoking cessation.
- Balanced diet with adequate nutrition, especially in frail individuals.
- Regular exercise.
- Weight loss in those who are overweight or obese.

Hyperglycaemia

- Tight glycaemic targets in fit or newly diagnosed people.
- Conservative approach in frail persons.
- Avoid hypoglycaemia.

Hypertension

- A target systolic blood pressure of 140 mmHg is reasonable in fit individuals, but higher targets around 150–160 mmHg are appropriate in frail or very old (≥ 85 years) persons.
- Achieving target blood pressure is more important than the antihypertensive drug class used, and most people will need more than one drug to achieve the target.

Dyslipidaemia

- Statin therapy in older people with diabetes is beneficial and should be offered unless specifically contraindicated or life expectancy is limited by frailty and comorbidities.
- The routine use of fibrates or niacin in addition to statin is not recommended.

Aspirin

- Aspirin therapy should be considered selectively in older people with diabetes and high cardiovascular risk, but after assessment of their bleeding risk.

Multiple interventions

- Hypoglycaemia should not be treated in isolation, but as part of a multiple cardiovascular risk factor reduction.
- Statins and antihypertensive drugs have the largest effect in reducing cardiovascular events, followed by anti-diabetes agents and aspirin.

Reverse metabolism

- In frail individuals targets should be relaxed, because of the inverse relationship between cardiovascular risk factors and mortality.

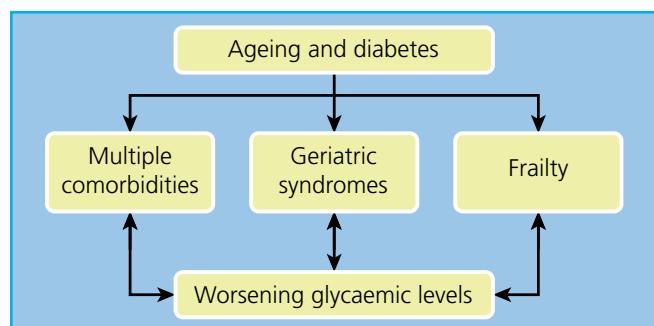

Figure 72.1 Interaction between the diabetes phenotype in old age and glycaemic levels. The interplay between ageing and diabetes leads to the development of the characteristic phenotype of diabetes in old age of multiple comorbidities, geriatric syndromes, and frailty, which in turn may lead to worsening of glycaemic levels setting a vicious circle.

reducing mortality [42]), and regular exercise to reduce visceral obesity and improve insulin sensitivity.

Ageing is associated with increased insulin resistance through the loss of skeletal muscle mass [12]. Muscle mass is dependent on a balance between muscle protein synthesis and breakdown; protein intake with exercise training synergistically increases skeletal muscle mass in older people. In one trial, protein supplementation for frail older people who were engaged in resistance training resulted in muscle hypertrophy, and increases in muscle strength, muscle mass, and performance [43]. A diet that is high in fibre and potassium and low in saturated fats and refined carbohydrates and salt may help achieve an ideal body weight as well as improving the lipid profile, significantly lowering blood pressure and reducing the overall cardiovascular risk [44]. A Mediterranean

diet, especially high intake of vegetables and fruits, was associated with reduced risk of frailty syndrome in older women with type 2 diabetes [45]. In the Diabetes Prevention Program, lifestyle intervention including modest weight reduction, a healthy low-fat diet, and regular exercise reduced the development of diabetes, and this beneficial effect persisted for up to 10 years after the end of the study, especially in older people (≥ 60 years) [46]. Additional benefits of exercise for older people may include increased muscle strength and improved walking balance. In the Look AHEAD (Action for Health in Diabetes) study, intensive lifestyle intervention significantly increased the probability of diabetes remission and improved other clinical outcomes [47]. The Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) also demonstrated a beneficial effect of exercise and nutrition on cognitive function in older people with diabetes [48].

Hyperglycaemia

Although the evidence in reducing microvascular disease by tight glycaemic management is established, there is ongoing debate about whether reducing blood glucose to near-normal levels results in lower cardiovascular events (Table 72.1) [49–52]. In frail older people, the benefit of blood glucose management diminishes in the presence of other comorbidities. In a decision analysis to assess the effects of baseline health status on prioritization of therapy, blood pressure management conferred a larger benefit than glucose at advanced ages (75–79 years) and the expected benefits of both therapies steadily declined as the level of comorbidity and functional impairment increased [53]. Therefore, in older people who are frail with multiple comorbidities and functional impairment, tight glycaemic targets may be more harmful by inducing hypoglycaemia. It is important to address individual goals of therapy, guided by the individual preferences, life expectancy, comorbidities, and the influences of therapy on quality of life. The advantages and disadvantages of anti-diabetes medications in older people are detailed in Table 72.2.

Hypertension

A target systolic blood pressure of ~ 140 mmHg is reasonable in older people with diabetes, as maintenance of a systolic pressure between 130 and 140 mmHg is associated with a reduction of adverse cardiovascular outcomes in older people with hypertension and diabetes. Tighter control is not warranted, however, as this may be associated with an increase in adverse events. In the International Verapamil SR-Trandolapril (INVEST) study, controlling systolic blood pressure to < 130 mmHg was not associated with better cardiovascular outcomes than usual control of 130–140 mmHg in individuals aged ≥ 55 years, and it was associated with a non-significant increased risk of mortality (11.0% vs 10.2%; adjusted HR 1.20; 95% CI 0.99 to 1.45, $p = 0.06$) [54]. Tight blood pressure management (target < 120 mmHg systolic) was also not beneficial and was associated with adverse outcomes in older people (40–79 years) with diabetes [55]. The Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET) also had similar conclusions for older individuals, mean age 66 ± 7 years, of whom 57% were aged ≥ 65 years [56]. The more recent Systolic Blood Pressure Intervention Trial (SPRINT) showed that treating to a systolic blood pressure target of < 120 mmHg compared with a target < 140 mmHg resulted in significantly lower rates of fatal and non-fatal major cardiovascular events (HR 0.66; 95% CI 0.51 to 0.85) and death from any cause (HR 0.67; 95% CI 0.49 to 0.91) in older people ≥ 75 years of age. However, this study did not enrol older people with diabetes, stroke, heart failure, dementia, limited life expectancy of < 3 years, unintentional weight loss ($> 10\%$ of body weight during the preceding six months), or those residing in nursing homes. Individuals with these conditions may not benefit from such intensive treatment and may be at increased risk of adverse events [57].

Two meta-analyses of older people with diabetes did not show reduced myocardial infarction or mortality rates with systolic blood pressures < 140 mmHg [58, 59]. In very old people (> 80 years) the targets may be even more relaxed. The Hypertension in the Very Elderly Trial (HYVET), which included older people aged

Table 72.1 Summary of published trials evaluating the effect of lowering glucose concentration on cardiovascular outcomes.

	UKPDS follow-up [49]	ACCORD [50]	ADVANCE [51]	VADT [52]
Number of participants	3277	10 251	11 140	1791
Mean (SD) age (years)	62 (8.0)	62.2 (6.8)	66 (6.0)	60.5 (9.0)
Inclusion criteria	Newly diagnosed type 2 diabetes	Age 40–79 years with history of CVD or age 55–79 years with evidence of atherosclerosis, albuminuria, LVH, or two additional risk factors for CVD	Diagnosis of type 2 diabetes at ≥ 30 years of age or age ≥ 55 years or history of macro- or microvascular disease	Type 2 diabetes with inadequate response to maximum dose of oral agent or insulin therapy
History of cardiovascular disease	People with significant CVD excluded	35%	32%	40%
Duration of diabetes on entry (years)	Newly diagnosed	10.0	8.0	11.5
Cardiovascular outcome	Benefit	Harm	No benefit	No benefit
Hypoglycaemia intensive vs standard therapy (%)	2.4% for sulfonylurea, 1.8% for insulin, and 0.7% for standard therapy ^a	16.2 vs 5.1	53 vs 38	24.1 vs 17.6

ACCORD, Action to Control Cardiovascular Risk in Diabetes; ADVANCE, Action in Diabetes and Vascular Disease: Pretezax and Diamicron MR Controlled Evaluation; CVD, cardiovascular disease; LVH, left ventricular hypertrophy; SD, standard deviation; UKPDS, UK Prospective Diabetes Study; VADT, Veterans Affairs Diabetes Trial.

^a Only rates of severe hypoglycaemia were reported in the intervention phase of the study.

Table 72.2 Advantages and disadvantages of anti-diabetes medications in older people.

Medication	Advantages	Disadvantages
Sulfonylureas	Suitable for those with renal impairment or low risk of hypoglycaemia	Increased risk of hypoglycaemia and weight gain Long-acting sulfonylureas should be avoided
Metformin	Low risk of hypoglycaemia Cardiovascular benefit Weight neutral	Increased risk of lactic acidosis in those with renal impairment Heart failure, sepsis, and dehydration
Meglitinides	Short-acting Suitable for those with erratic eating pattern	Risk of hypoglycaemia and weight gain, but less than sulfonylureas
α -Glucosidase inhibitors	Low risk of weight gain and hypoglycaemia	Weak hypoglycaemic action Gastrointestinal side effects
Pioglitazone	Suitable for those with renal impairment Less risk of hypoglycaemia	Fluid retention Worsens heart failure Increases fracture risk and possibly bladder cancer
Dipeptidyl peptidase 4 (DPP-4) inhibitors	Low risk of hypoglycaemia Weight loss	Gastrointestinal side effects Dose mostly needs to be adjusted with renal impairment
Glucagon-like peptide 1 (GLP-1) receptor agonists	Low risk of hypoglycaemia Weight loss	Injectable Weight loss in frail individuals Not suitable in renal failure Nausea common Possible risk of pancreatitis
Sodium–glucose cotransporter 2 (SGLT-2) inhibitors	Low risk of hypoglycaemia Weight loss	Not suitable for frail older people with weight loss Heavy glucosuria increases risk of urinary tract infections, candidiasis, dehydration, and hypotension
Insulin	Effective Tailored rapidly to changes in need Improves quality of life.	High risk of hypoglycaemia and weight gain

≥ 80 years with sustained systolic blood pressure > 180 mmHg, 7% of whom had diabetes, showed a significant 33.7% (HR 0.66; 95% CI 0.53 to 0.82, $p < 0.001$) reduction in cardiovascular events with a target blood pressure of 150/80 mmHg. However, the individuals included in HYVET were healthier than those in the general population, with a low baseline rate of known cardiovascular disease (11.5%), myocardial infarction (3.1%), or heart failure (2.9%). Therefore, the results may not apply to all older persons, especially those with multiple comorbidities or living in care homes [60]. In another community study of people aged ≥ 85 years there was a U-shaped relationship, with a systolic blood pressure of 164.2 mmHg (95% CI 154.1 to 183.8 mmHg) being associated with the lowest mortality, suggesting that the optimal systolic blood pressure for this age group could be > 140 mmHg [61]. Thiazide diuretics, angiotensin receptor blockers, angiotensin-converting enzyme inhibitors, and calcium channel blockers are reasonable first-choice agents, although higher doses of diuretics may worsen

blood glucose and lipid profile. Most people will require more than one antihypertensive agent.

Dyslipidaemia

There are no large clinical trials of lipid-lowering interventions specifically in older people with diabetes. Post hoc analysis of the Heart Protection Study, which included participants with diabetes aged between 40 and 80 years, showed a significant 25% risk reduction of cardiovascular events [62]. The Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) was designed for older people aged 70–82 years (10.5% had diabetes) with either pre-existing vascular disease (secondary prevention) or elevated risk of such disease due to smoking, hypertension, or diabetes (primary prevention), and showed 15% lower cardiovascular endpoints in the statin group [63]. A meta-analysis of 18 686 people with diabetes in 14 trials of statin therapy for primary prevention showed a similar 20% relative risk reduction in major adverse vascular outcomes in older (≥ 65 years) compared to younger (< 65 years) people [64]. Therefore, the evidence for statin therapy is established for older people with diabetes up to the age of 80 years, whether they have no underlying heart disease (primary prevention) or already have established heart disease (secondary prevention).

In very old people (> 80 years), cholesterol targets are unclear. A review of observational studies including 13 622 participants showed that low total cholesterol (< 5.5 mmol/l) was associated with the highest mortality rate in those > 80 years old [65]. The routine use of a fibrate or niacin in addition to statin therapy did not reduce cardiovascular events beyond the effects of statins and is not recommended [66, 67]. Cardiovascular prevention with statins emerges fairly quickly (within 1–2 years), suggesting that statins may be offered to nearly all older people with diabetes except those with very limited life expectancy. Chronological age *per se* should not exclude people from receiving therapy, but functional or biological age as well as the impact of long-term drug therapy on safety and quality of life should be considered.

Aspirin therapy

Aspirin reduces cardiovascular morbidity and mortality in people with a history of cardiovascular disease [68]. However, evidence for aspirin use in primary cardiovascular risk prevention is still unclear. A meta-analysis of aspirin treatment as primary prevention in people with diabetes demonstrated a trend towards a 10% reduction in cardiovascular events, but this needs to be balanced against an increased risk of haemorrhage [69]. A more recent meta-analysis has shown a statistically significant protective effect of aspirin and a moderate level of confidence for the administration for the primary prevention in diabetes, particularly in older individuals (age ≥ 60 years) [70]. Presence of diabetes *per se* does not justify aspirin use. However, most older people with diabetes have a high burden of cardiovascular risk factors and are likely to benefit from aspirin therapy. Therefore, aspirin use should be considered selectively in older individuals with diabetes and high cardiovascular risk after assessment of the risk of bleeding.

Multiple risk intervention

Cardiovascular risk factors tend to cluster in what is known as the *metabolic syndrome*. Both age and diabetes increase the prevalence of the metabolic syndrome. In a Norwegian study, the prevalence increased from 11.0% in men aged 20–29 years to 47.2% in men aged 80–89 years, and from 9.2% to 64.4% for women in the corresponding age groups [71]. In a population-based study of 5632 white

European people (65–84 years old), the prevalence was 64.9% and 87.1% in men and women with diabetes, respectively, compared to 25.9% and 55.2% in men and women without diabetes [72]. Although metabolic syndrome is postulated as a risk factor for cardiovascular disease, in a prospective study of 1025 older people aged 65–74 years [73] and an analysis of the outcomes of two prospective studies in people aged over 60 years [74], the metabolic syndrome was shown to be a marker of cardiovascular disease, but did not enhance risk prediction above and beyond the risk associated with its individual components.

Multifactorial interventions are appropriate and show that the use of statins and antihypertensive drugs has the largest effect in reducing cardiovascular events, with anti-diabetes agents and aspirin the next most important interventions [75]. More effort is needed to optimize this comprehensive approach, as many older people do not receive this level of care [76].

Reverse metabolism

In frail older people, the power of traditional cardiovascular risk factors including hypertension, dyslipidaemia, and hyperglycaemia to predict risk of cardiovascular disease seems to diminish with age, leading to a paradoxical relationship [77]. The more commonly proposed explanations include the association of low body weight and low cholesterol with increased protein energy malnutrition and increased inflammation associated with frailty [78]. In a study of 331 very old people (mean age 85 ± 7 years), low body mass index, low blood pressure, low total and high density lipoprotein (HDL) cholesterol, and high insulin sensitivity in individuals without diabetes predicted total mortality, indicating a *reverse metabolism* that is probably attributable to malnutrition and chronic disorders, which have a negative impact on survival [79]. Low albumin (a marker of malnutrition) and high C-reactive protein (a marker of inflammation) were associated with these cardiometabolic factors, limiting their prognostic value for cardiovascular risk in older people [79]. It is important to recognize that many older people with diabetes are frail and the expected benefit of tight metabolic management declines as morbidity and functional impairment increase, thus functional status and level of comorbidity are important factors in assessing risk [53].

Special considerations in old age

Hypoglycaemia

Hypoglycaemia is commoner in older people with diabetes because of the associated comorbidities, geriatric syndromes, polypharmacy, long duration of diabetes, and the increased prevalence of hepatic and renal dysfunction (Box 72.5). Although there is a paucity of data about the incidence of hypoglycaemia in older people, the reported incidence of hypoglycaemia varies in the literature, owing to differences in the definition used and the age of the populations studied. In a US retrospective population-based study of 19932 Medicaid individuals aged ≥ 65 years, the incidence of severe hypoglycaemia was 1.23 episodes per 100 person-years for people treated with sulfonylureas and 2.76 episodes per 100 person-years in those treated with insulin [80]. However, the strict definition of severe hypoglycaemia (an episode leading to fatal outcome or hospital admission) may have underestimated the true frequency of events. Also, the data collection was conducted before the publication of the evidence for the benefit of tight glycaemic management in type 2 diabetes in 1998 [81].

Box 72.5 Hypoglycaemia in older people with diabetes

Incidence

- Increased in old age due to multiple comorbidities, under-nutrition, polypharmacy, long duration of diabetes, and renal or hepatic impairment.

Difficult recognition

- Non-specific symptoms.
- Misdiagnosed for stroke, vertigo, or visual disturbance.
- Misinterpreted as dementia-related symptoms, such as agitation or behaviour change.
- Atypical presentation, e.g. confusion or passive delirium.
- Little warning or unawareness of autonomic symptoms.
- People with dementia are unable to communicate their feelings or symptoms.

Consequences

- Acute events such as cardiac arrhythmias or stroke.
- Chronic consequences such as mental and physical dysfunction.

The subsequent trends towards tighter glycaemic targets have resulted in more frequent hypoglycaemic episodes, with insulin becoming the second commonest medication associated with adverse events reported to the US Food and Drug Administration, with a threefold increase in reported events from 1998 to 2005 [82]. Insulin was the second most frequent medication associated with emergency department visits in older people ≥ 65 years; 95.4% of episodes were related to hypoglycaemia, 24.1% involved loss of consciousness or seizure, and 25.1% required hospitalization [83]. More recently, in a prospective study involving 3347 people, median age 66.1 years, from DiaRegis, a multicentre registry of people with diabetes in Germany, the annual incidence of hypoglycaemia of any severity was 14.1% [84].

Although hypoglycaemia incidence is difficult to estimate accurately, it is likely to be higher in older than younger people. In a prospective observational study of 3810 people in primary care, 11% of participants reported at least one episode of hypoglycaemia of any severity in a 12-month period. Older people (≥ 70 years) reported more episodes than younger (< 60 years) people (12.8% vs 9.0%, $p < 0.01$). Significant differences were also seen for symptomatic episodes without a need for help (9.2% vs 5.6%) and symptomatic episodes with a need for medical assistance (0.7% vs 0.1%) [85]. In care homes the incidence of hypoglycaemia is likely to be much higher than in a community setting, reaching up to 41.9% in one study over a one-year period (median 2, range 1–10 episodes/person/yr) because of the higher levels of comorbidities [86].

Recognition

Although hypoglycaemia in older people with diabetes is common, its recognition and diagnosis can be difficult. For example, owing to the predominance of neurological rather than autonomic symptoms, hypoglycaemia may present with symptoms such as dizziness or visual disturbance, resulting in misdiagnosis [87]. Another diagnostic challenge is the similarity in the clinical presentation of hypoglycaemia with that of dementia, where people may present with agitation, increased confusion, or behavioural

changes. Furthermore, symptoms of hypoglycaemia tend to be less specific with increasing age. In a survey of hypoglycaemia symptoms perception by older people with diabetes (age 82.3 ± 3.9 years) attending an outpatient clinic, the majority of respondents reported no diabetes-specific symptoms of being generally unwell when their blood glucose level dropped, making the recognition of hypoglycaemic episodes more difficult for healthcare professionals [88]. This was also demonstrated in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, with non-specific fatigue or weakness being the commonest symptoms of hypoglycaemia experienced by the participants (mean age 62.2 ± 6.8 years) [89]. In older people the threshold of autonomic symptoms of hypoglycaemia occurs at a lower blood glucose concentration while cognitive dysfunction occurs at a higher level compared with younger adults. Therefore, autonomic and neurological symptoms occur almost simultaneously with little warning [90]. This is referred to as *impaired awareness of hypoglycaemia* [91]. Subclinical hypoglycaemia or episodes with fewer symptoms may further reduce awareness, leading to a vicious cycle whereby one episode of hypoglycaemia can induce further hypoglycaemia [92]. Therefore, many episodes of hypoglycaemia may be unrecognized and under-reported by both people with diabetes and healthcare professionals, and subsequently the frequency is likely to be underestimated.

Consequences

Older people with diabetes are likely to be at a higher risk of the adverse consequences of hypoglycaemia because of the increased prevalence of comorbidities, undernutrition, and polypharmacy compared with younger people [93]. Severe hypoglycaemia may lead to serious acute vascular events, such as stroke, myocardial infarction, acute cardiac failure, and ventricular arrhythmias [94, 95]. The morbidity attributed to recurrent episodes of hypoglycaemia is associated with silent and chronic complications, which could lead to significant physical and cognitive dysfunction and eventually to frailty, disability, and increased mortality. In a Taiwanese study of 234 residents aged 77.5 years living in long-term care facilities, of whom 35.5% had diabetes, hypoglycaemia was associated with disability and reduced function. Functional status was worse in those who experienced hypoglycaemia in comparison with those with no history of hypoglycaemia (mean Barthel Index score 22.5 vs 38.2). Complete dependence, defined as Barthel Index score <30, was also commoner in people with hypoglycaemia (69.2% vs 50%) [86].

The burden of hypoglycaemia leading to hospitalization is higher in old age and may contribute to increased frailty and reduced quality of life. In a US study of 33 492 people with diabetes aged ~60 years, accidents resulting in hospital visits occurred in 5.5% of those with hypoglycaemia compared to 2.8% of those without. Hypoglycaemia was associated with significantly increased hazards for any accident (HR 1.39; 95% CI 1.21 to 1.59, $p < 0.001$), accidental falls (HR 1.36; 95% CI 1.13 to 1.65, $p < 0.001$), and motor vehicle accidents (HR 1.82; 95% CI 1.18 to 2.80, $p = 0.007$) after adjustment for baseline characteristics. In an age-stratified analysis, the risk of falls was twice as high among older people, ≥ 65 years, compared with younger individuals, and hypoglycaemia was significantly associated with a greater than 50% increase in the hazard of falls (adjusted HR 1.52; 95% CI 1.18 to 1.95) [96]. Hypoglycaemia also increases the risk of fractures, which may lead to disability and frailty. In a retrospective observational study of 361 210 Medicare-covered people with diabetes ≥ 65 years old, those with hypoglycaemic

events had a significantly higher proportion of fall-related fractures compared to those without hypoglycaemia (5.24% vs 2.67%, $p < 0.001$). Hypoglycaemic events increased the risk of falls and fractures by 70% (OR 1.7; 95% CI 1.58 to 1.83) [97].

Dementia

Progressive decline in cognitive function leading to dementia is common in older people with diabetes. Persistent hyperglycaemia increases the risk of cerebrovascular disease by inducing inflammation, endothelial dysfunction, oxidative stress, and insulin resistance, leading to an increased incidence of vascular dementia [98]. Moreover, accelerated brain ageing from altered amyloid metabolism, increased protein glycation, and direct cerebral glucotoxicity may explain the increased incidence of Alzheimer's dementia [99]. Structural changes in the brain have been noted with diabetes and dementia. For example, cerebral atrophy and hippocampal atrophy are reported more frequently in older people with diabetes and contribute to cognitive dysfunction, especially impairment in immediate memory [100]. It seems that brain insulin resistance increases in Alzheimer's disease, suggesting that Alzheimer's may be caused by a cerebral manifestation of diabetes.

Risk

Among people with diabetes, the relative risk of Alzheimer's disease is 1.56 (95% CI 1.41 to 1.73), while vascular dementia is increased 2.27-fold (95% CI 1.94 to 2.66) and all types of dementia by 1.73-fold (95% CI 1.65 to 1.82) compared to those without diabetes [101]. In a prospective study of older people (>60 years) with diabetes, age, microvascular disease, diabetic foot, cerebrovascular disease, cardiovascular disease, acute metabolic events, depression, and education were used to develop a risk score for dementia. Over 10 years, the risk of developing dementia was 5.3% (95% CI 4.2 to 6.3) for the lowest score (-1) and 73.3% (95% CI 64.8 to 81.8) for the highest (12–19) sum scores [102]. The presence of diabetes also accelerates mortality rate in people with dementia. In a retrospective Australian study, the mortality rate for people with diabetes and dementia was almost twice that of those with dementia but without diabetes (HR 1.9; 95% CI 1.3 to 2.9) [103].

Implications

Older people with diabetes and dementia experience difficulties in performing self-care tasks. In a community-based study of 1398 people with diabetes aged 70 years, diabetes self-care tasks decreased as cognitive impairment increased, with exercise and diet adherence being the most strongly associated with cognitive impairment [104]. The combination of diabetes and dementia is likely to be associated with an increased incidence of treatment adverse events, such as severe hypoglycaemia [105]. Due to erratic eating patterns associated with dementia, older people with diabetes are also at risk of malnutrition, dehydration, and worsening diabetes control. Carers of people with diabetes and dementia face extraordinary challenges to care for both conditions, especially in people who develop behaviour changes. Their needs should be identified early to allow for greater support from the healthcare system.

Management

Although there is an association between hyperglycaemia and cognitive dysfunction, intensive glycaemic management does not prevent a decline in mental function [106]. Once dementia develops diabetes self-care deteriorates, and so clinicians need to check for cognitive dysfunction if declining self-care occurs. Clinicians

Box 72.6 Dementia in older people with diabetes

Screening

Should be performed annually or earlier if one of the following is observed:

- Less medication taking.
- Forgetfulness in how to handle insulin injections.
- Forgetting how to recognize or treat hypoglycaemia.
- Difficulties in how to interpret blood glucose results or make decisions regarding adjusting insulin doses.
- Declining general self-care.
- Erratic eating pattern and missing meals.
- Not following dietary requirements.
- Recurrent unexplained hypoglycaemia.

Screening tool (Mini-Cog)

Ask the person to repeat three items such as lemon, key, and balloon, then provide a clock face:

- Ask the person to draw the numbers of the clock face.
- Ask the person to draw the hands of the clock to show the time as ten to three.
- Ask the person to recall the three items.

Give one mark for each task performed and for each item remembered. A score of 0–3 out of a maximum of 5 defines cognitive impairment.

1.10–1.49), 80% (HR 1.80; 95% CI 1.37 to 2.36) and 94% (HR 1.94; 95% CI 1.42 to 2.64) in those with a history of one, two, and three or more severe hypoglycaemic episodes (defined as hypoglycaemia needing hospital admission or emergency department visit), respectively independent of glycaemic levels, medications, and comorbidities. The attributable risk of dementia was 2.39% (95% CI 1.72 to 3.01) per year in people with compared with those with no history of hypoglycaemia [110].

In an observational cohort study of 302 participants with diabetes, mean age 75.7 ± 4.6 years, a cross-sectional association between severe hypoglycaemia and cognitive function was observed. People with dementia (16% of participants) or cognitive impairment (14%) were significantly more likely to have been hospitalized with hypoglycaemia than people with normal cognitive function (3.8%), $p = 0.004$ [112]. A prospective association between historical hypoglycaemia and cognitive decline in a subsample of the participants without dementia was not found. However, the prospective phase of this study was limited by the small number of participants ($n = 205$) and short duration of follow-up (18 months), which may have limited the power to detect any association between incident hypoglycaemia and cognitive dysfunction [105]. More recently, in the Edinburgh population-based cross-sectional study of 1066 people with type 2 diabetes, mean age 67.9 ± 4.2 years, self-reported history of severe hypoglycaemia was associated with poorer late life cognitive ability. Those who reported at least one episode of severe hypoglycaemia demonstrated poorer performance on tests of verbal fluency (34.5 vs 37.3, $p = 0.02$), digit symbol testing (45.9 vs 49.9, $p = 0.002$), letter-number sequencing (9.1 vs 9.8, $p = 0.005$), and trail making ($p < 0.001$) independent of diabetes duration, vascular risk factors, or vascular complications. These associations persisted after adjustment for estimated prior cognitive ability, suggesting that the association may be attributable to an effect of hypoglycaemia on age-related cognitive decline [113]. A linear relationship was observed between poorer general cognitive ability and increasing frequency of severe hypoglycaemia over the year preceding cognitive testing, supporting results of earlier studies.

Management of diabetes

Glycaemic targets

Glycaemic targets should be individualized taking into consideration overall health and life expectancy.

Fit older people

For healthier older people with low prevalence of cardiovascular risk factors, especially those with a new diagnosis of diabetes, tight glycaemic targets with an HbA_{1c} around 53 mmol/mol (7%) are reasonable, as these are likely to reduce diabetes complications [49], while persistent hyperglycaemia is associated with increased risk of falls [114] and mortality [115] regardless of the associated comorbidities.

Frail older people

For frail older people or those with established cardiovascular disease, a safer target around 58–64 mmol/mol (7.5–8.0%) is appropriate. The presence of multiple comorbidities is a potential competitor for the benefit of tight glycaemic levels in this population. In a decision analysis to assess the effects of comorbid conditions and functional impairment, the expected benefits of tight glycaemic levels

should also be aware that dementia may be associated with language impairment, disorientation, and personality changes that may mimic the symptoms of hypoglycaemia [107]. The Mini Cog test is a simple screening tool for dementia that has a sensitivity of 86.4% (95% CI 64.0 to 96.4%) and a specificity of 91.1% (95% CI 85.6 to 94.6%) and takes only three minutes to perform [108].

Older people with diabetes and dementia have complex needs because of increased dependency and unpredictable behavioural changes as the decline in cognitive function continues. For example, hydration should be maintained because of impaired thirst sensation to avoid risk of volume depletion and hyperglycaemic crises. In people treated with insulin, the new class of long-acting insulin analogues may be a good option as they reduce the risk of hypoglycaemia and can be conveniently injected once daily [109]. People who have erratic eating patterns and unpredictable caloric intake could be managed with a regimen where short-acting insulin analogues are administered only after meal consumption, thus reducing the risk of hypoglycaemia if a meal is missed or only partly consumed (Box 72.6).

Hypoglycaemia–dementia interaction

The brain is highly dependent on glucose for its metabolism and is particularly vulnerable to hypoglycaemia, especially in older people. After each hypoglycaemic episode major cognitive changes occur, leading to post-hypoglycaemic encephalopathy. Repeated episodes of hypoglycaemia may contribute to cognitive dysfunction and the relationship appears to be bidirectional. History of severe hypoglycaemia increases risk of cognitive dysfunction [110] and cognitive dysfunction increases risk of hypoglycaemia [111]. Therefore, recurrent hypoglycaemia may be associated with impaired cognitive function and development of dementia. In a retrospective study of 16 667 older people with diabetes, mean age 65 years, the risk of dementia increased by 26% (HR 1.26; 95% CI

(HbA_{1c} 53 versus 63 mmol/mol; 7.0% vs 7.9%) declined steadily as the level of comorbidities and functional impairment increased. One to two points were allocated for each comorbidity, according to severity, to create a mortality index score. In people aged 60–64 years with new-onset diabetes, the quality-adjusted days declined from 106 (95% CI 97 to 117) days to 44 days (range 38–50) with three additional points in mortality index score, and to eight days (range 5–10) with seven additional index points [53].

Very frail older people

For very frail older people, residents in nursing homes, and those with limited life expectancy, a target HbA_{1c} of 64–75 mmol/mol (8.0–9.0%) is suitable. Tight glycaemic targets in this population may be harmful by inducing hypoglycaemia and reducing quality of life. However, higher HbA_{1c} (>75 mmol/mol; >9.0%) is associated with increased mortality [116]. Targets in this population should focus on short-term day-to-day blood glucose management rather than long-term HbA_{1c}, to avoid both hyperglycaemia, which may lead to lethargy, dehydration, visual impairment, and infections, and hypoglycaemia, which may lead to falls and confusion (Figure 72.2).

Polypharmacy

Clinical guidelines are largely disease specific, age neutral, and driven by numerical surrogates, such as HbA_{1c} or blood pressure, but do not necessarily consider hard endpoints and outcomes

relevant to older people, such as physical function, disability, or quality of life [117]. Indiscriminate application of guidelines may lead to overtreatment and polypharmacy (taking >4 drugs), with potential harm and increased hospitalization in older people. For example, older people are more liable to experience adverse effects of antihypertensive medications, such as renin angiotensin system blockers leading to acute kidney injury, hyperkalaemia, or hypotension with further deterioration of renal function, especially in those with existing chronic kidney disease. Withdrawal of these drugs in older people (mean age 73.3 years) with stage 4 and 5 chronic kidney disease improved kidney function [118]. A gradual decrease of blood pressure is an essential strategy in treating older people with hypertension to avoid an accelerated blood pressure drop with subsequent falls. Blood pressure should be measured both lying and standing and the individuals asked about orthostatic symptoms to avoid orthostatic hypotension. It is important to realize that the presence of orthostatic symptoms, such as dizziness, light-headedness, or faintness, is associated with an increased risk of falls (OR 8.21; 95% CI 4.17 to 16.19) rather than orthostatic hypotension *per se* [119].

Avoidance of hypoglycaemia is essential, especially in those with impaired kidney or liver function that delays the clearance of anti-diabetes medications [120]. Glycaemic goals should be regularly reviewed and anti-diabetes medications adjusted with increasing age, especially in those with the onset of cognitive impairment or frailty. Declining weight, malnutrition, and frailty may lead to a reduced need for anti-diabetes medications while increasing the risk of hypoglycaemia. Anti-diabetes medications have been safely withdrawn in a cohort of frail nursing home older people with type 2 diabetes, mean age 84.4 ± 6.8 years [121], and in another group in the community, mean age 86.5 ± 3.2 years, attending outpatient clinics without a deterioration of their glycaemic levels [122]. The main characteristics of these individuals were significant weight loss, increased comorbidities including dementia and polypharmacy, with recurrent hypoglycaemia [122]. Therefore, people with these criteria appear to be suitable candidates for a trial of anti-diabetes medication withdrawal. Higher doses of statins should be avoided in frail older people, who may be more susceptible to drug-related myopathy. Non-steroidal anti-inflammatory drugs should be used carefully in older people with diabetes, especially those with chronic kidney disease, because of the increased risk of acute kidney injury. Polypharmacy is common: in a British care home study, 84% of residents with diabetes were taking >4 drugs, with a high proportion (59%) of residents prescribed drugs for cardiovascular disease prevention. This may be inappropriate in this disabled population with limited life expectancy, as polypharmacy leads to increased risk of drug errors, hypoglycaemia, and hospitalization. Therefore, regular medication review of care home residents with diabetes should be undertaken, as it has the potential to reduce costs and minimize adverse drug reactions [123].

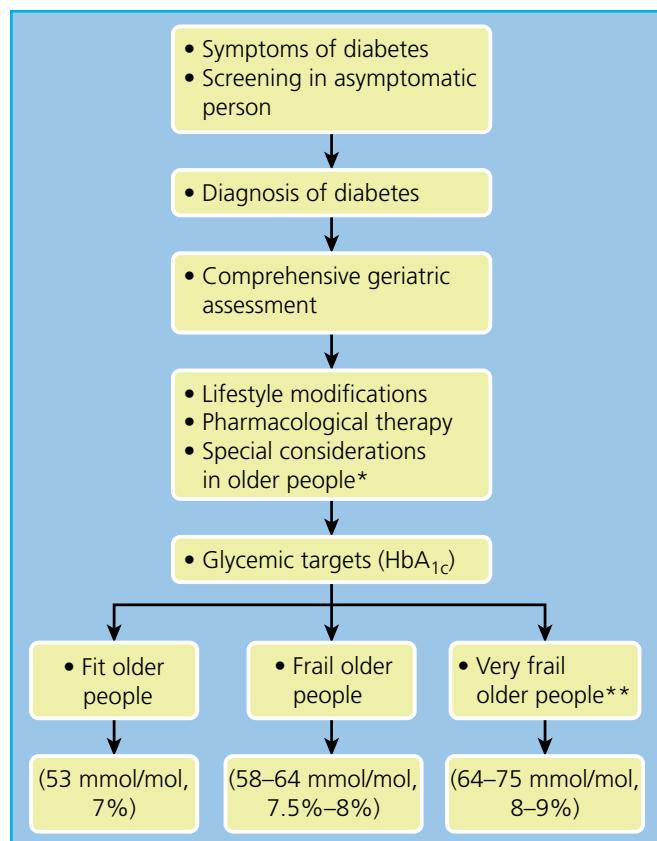

Figure 72.2 Diabetes diagnosis, management, and glycaemic targets.

*Considerations such as risk of hypoglycaemia, dementia, polypharmacy, and residents in care homes. **In very frail older people with limited life expectancy, short-term targets of blood glucose >4 but <15 mmol/l are more important than the long-term glycated haemoglobin (HbA_{1c}) target.

Care homes

Care home residents with diabetes are likely to be frail, with multiple comorbidities and limited life expectancy. Therefore short-term glycaemic targets with minimal diabetes-related interventions are important to maintain quality of life. Maintaining a random blood glucose between 4 and 15 mmol/l (70–270 mg/dl) is reasonable, as blood glucose outside this range is likely to be symptomatic and result in cognitive changes [124]. Maintaining blood glucose in this *comfort zone* may ensure *comfort care*, avoiding both hyperglycaemia

Box 72.7 Recommendation for care of older people with diabetes in care homes

On admission to care home

- Each resident should be screened for the presence of diabetes.
- Each resident with diabetes should have assessment for functional loss and interventions in place to delay disability.

During their stay at a care home

- Residents should be regularly reviewed for the presence of hypoglycaemic symptoms, especially for those on insulin or sulfonylureas.
- Resident with diabetes should have optimal blood pressure and blood glucose regulation to help maintain cognitive and physical performance.

Good clinical practice in care homes

- All residents should have an annual screen for diabetes.
- Each resident with diabetes should have an individualized diabetes care plan.
- Care homes with diabetes residents should have an agreed diabetes care policy or protocol that is regularly audited.
- Diabetes education and training courses should be available to care home staff.
- A risk–benefit approach should be adopted in the management of residents with diabetes in terms of medications, metabolic targets, and extent of performing investigations, with a focus on enhancing quality of life, maintaining functional status, and avoiding hospital admission for diabetes-related complications.

and hypoglycaemia, thereby reducing malaise and improving mental function and general well-being [125] (Box 72.7).

Care plans

Care homes should have a policy for diabetes care, including diabetes screening for residents on admission and an individualized care plan for residents. Care plans should be tailored to individual needs and take into consideration the individual's values, preferences, life expectancy, comorbidities, and the impact of diabetes management (polypharmacy, glucose monitoring) on quality of life. Medications should be reviewed to switch those taking longer-acting sulfonylureas to shorter-acting agents and polypharmacy reviewed regularly. Screening for complications relevant to older people, such as cognition, physical function, and depression, should be included in their annual review.

Nutrition

Nutritional guidelines should not be too restrictive but tailored to be healthy and to reflect personal preferences. Individuals are free to exercise personal choices with respect to food selection. Diabetes treatment is then adjusted accordingly. The aims of nutritional intervention include maintenance of healthy body weight and avoidance of malnutrition.

Holistic approach

An individualized, holistic care plan is recommended to address care home residents' complex needs [126]. Residents with diabetes should have an annual comprehensive foot examination to identify

risk factors for ulcers and amputations. Podiatry input should be available regularly. Residents with diabetes should have an initial comprehensive eye examination and annually thereafter. Domiciliary optometric services may be an option for residents who are not able to travel.

Education

As older people are at increased risk of hypoglycaemia [87, 95] and may tolerate low blood glucose with no specific symptoms due to diminished autonomic response, it is important that residents and care home staff are educated to recognize the symptoms and treat hypoglycaemia. In a study that delivered a diabetes educational programme to care home staff, staff knowledge improved and was retained at 12 months, and led to improved quality of care up to a year after the intervention [127].

Conclusion

Ageing is associated with increased insulin resistance, due to decreased muscle mass, increased visceral fat, and decreased insulin secretion, because of diminished β -cell mass and function, leading to glucose intolerance and diabetes in genetically susceptible individuals. Through population ageing and increased life expectancy, diabetes is increasingly becoming a disease of older age. The phenotype of diabetes in old age is characterized by an increased prevalence of multiple comorbidities, geriatric syndromes, and frailty. Therefore, the assessment of older people with diabetes on diagnosis and annually thereafter should be comprehensive and include screening for these syndromes, especially cognitive and physical dysfunction. Older people are a highly heterogeneous population, ranging from a fit person living in the community to a frail individual with multiple comorbidities living in a care home. Management should therefore be individualized, with variable metabolic targets from optimal glycaemic levels in fit individuals to a conservative approach in frail ones. More attention should be focused on optimal management of undernutrition in frail older people by improving nutrition and physical activity to maintain muscle mass and improve overall function. Quality of life should be at the centre of the management plan.

Future perspectives

Although tight glycaemic levels will continue to be the aim for older fit and independent people with diabetes, these are not suitable for those who are frail and at a high risk of side effects due to polypharmacy [128]. A new approach to defining glycaemic targets based on the level of function has recently been introduced by the International Diabetes Federation and represents the first comprehensive guidance in this area [129].

There is a need for clinical trials specifically designed for older people with diabetes to explore the real benefit of glycaemic management in this diverse group. Comprehensive geriatric assessment including physical and mental health assessment will continue to be essential in view of the epidemiological shift of diabetes towards older age. Frailty and geriatric syndromes are emerging as complications in older people with diabetes and will need interventions beyond glycaemic management. There remains a lack of

intervention studies that reduce disability and improve quality of life in older people with diabetes. A focus on improvements in function may be of greater clinical relevance in frail older people with diabetes than metabolic targets alone. The MID-Frail study will evaluate the clinical, functional, social, and economic impact of

a multimodal intervention (resistance training exercise, diet, and education) in frail and pre-frail participants aged ≥ 70 years with type 2 diabetes compared with usual clinical practice [130]. This may have an impact on reducing functional decline, promoting independence, and maintaining quality of life.

Key points

- Death is an expected part of life and therefore end-of-life care is a vital aspect of holistic diabetes care.
- Diabetes often contributes to the cause of death, but diabetes as the main cause of death is under-reported on death certificates, with most deaths attributed to other causes such as cardiovascular disease, heart failure, chronic kidney disease, and cancer.
- It is estimated that 6.7 million people with diabetes aged 20–79 died in 2021. Diabetes was the ninth leading cause of death worldwide in 2019.
- People are approaching their end of life when they are likely to die within the next 12 months.
- Generic end-of-life guidance applies to people dying with diabetes.
- Glycaemic targets may be relaxed in the last year of life; glycated haemoglobin (HbA_{1c}) may not be required during this time. The blood glucose should be kept between 6 and 15 mmol/l (110–270 mg/dl).

- Hypoglycaemia in people taking insulin or oral hypoglycaemic agents is predictive of mortality.
- Insulin treatment must not be stopped in dying people with type 1 diabetes to prevent ketoacidosis, which can be a diabetes-specific cause of death.
- People with diabetes should document their values and end-of-life care preferences in an Advance Care Directive/Plan while they can make autonomous decisions. This aids end-of-life care decision making by healthcare professionals and the family.
- Healthcare professionals should have initial and regular training and competency assessment in end-of-life care.

Dying with diabetes

Diabetes is common, with an overall global prevalence in adults of 537 million people in 2021. The prevalence is expected to increase to 643 million by 2031 and 783 million by 2045 [1]. The prevalence is higher in older people: 10–30% of people in Europe of pensionable age have diabetes and 25% of care home residents in the UK have diabetes [2].

Although survival with diabetes has been improving, people with diabetes still have reduced life expectancy compared with the general population, especially those in low- and middle-income countries and those living in remote areas [1]. The UK National Diabetes Audit shows there are 500 premature deaths per week in the UK [3].

China and India had the most recorded number of deaths attributed to diabetes in 2021, but these countries also have the largest populations. The highest proportion of total deaths associated with diabetes are Singapore (29%) and Pakistan (29%). Russia and Czechia have the lowest proportion of deaths, each with approximately 1% of total deaths. Diabetes is said to have been responsible for 416 000 deaths in Africa in 2021 [1]. In the USA, diabetes and its complications were the seventh leading cause of death in 2019, accounting for 87 647 deaths [4]. In

Australia, diabetes was the most significant underlying cause of death in over 3300 deaths between 1985 and 2017, with higher death rates in Aboriginal and Torres Strait Islander people, especially women [5].

These data may underestimate death rates because only 35–40% of recorded deaths in people known to have diabetes included diabetes on their death certificate and only 10–15% had it listed as the underlying cause of death [6]. There are apparent variations in mortality related to diabetes across the world, but generally as the prevalence increases so do deaths, especially if diabetes is not well managed from diagnosis [7].

Causes of death attributed directly to diabetes include ketoacidosis, severe hypoglycaemia, and hyperosmolar hyperglycaemic state. These deaths account for only a minority of all diabetes-related deaths [8]. In high-income countries, the premature mortality in people with diabetes is predominantly caused by a higher prevalence of cardiovascular disease, particularly heart failure, which accounts for 75% of all deaths and is associated with a 10-year reduction in life expectancy [1]. The next most common causes of death are chronic kidney disease [7] and cancer [9]. Individuals with type 2 diabetes are at increased risk of developing certain cancers because both conditions share many of the same risk factors, including ageing, obesity, physical inactivity, high-fat-high-sugar diets, alcohol, and smoking [9, 10].

[†]Deceased on 14 October 2021.

It follows that healthcare professionals working with adults will encounter people with diabetes who are dying in various care settings. They should know how to discuss end-of-life issues with their patients and help them document advance care directives or plans to address their needs at the end of life. Significantly, initiating palliative care early improves outcomes and this care can be incorporated with usual diabetes care [11].

End of life

Palliative medicine is a surprisingly young specialty even in high-income countries, probably because death has been regarded as a failure of medical care. This attitude began to change following the pioneering work of people such as Dame Cicely Saunders and the International Declarations about the rights of the dying person. In 1976 the Parliamentary Assembly of the Council of Europe resolved that ‘The prolongation of life should not in itself constitute the exclusive aim of medical practice, which must be concerned equally with the relief of suffering’ [12].

The principles of care at the end of life apply to everyone who is terminally ill and have been articulated in numerous publications, which have themselves been revised in line with evidence and experience (Table 73.1) [13]. The sensitive application of such principles tailored to the individual and supplemented by excellent communication with them and their families and among healthcare professionals is likely to result in the best possible outcome under the circumstances, which is a *good death* for the individual.

Early identification of people entering the end-of-life phase

Although self-evident, end-of-life care cannot start until healthcare professionals realize the individual is dying and communicate that they are in the terminal phase of life to all relevant people. Recognizing when the person is at their end of life is not intuitive, particularly when medical and nursing staff have been providing active management intended to achieve a cure. Guidance has been produced to assist healthcare professionals to recognize deterioration and the terminal stage of life.

Table 73.1 Key principles of end-of-life care in people with diabetes.

Provision of a painless and symptom-free death
Tailor glucose-lowering therapy and minimize diabetes-related adverse treatment effects
Avoid metabolic decompensation and diabetes-related emergencies such as:
<ul style="list-style-type: none">• frequent and unnecessary hypoglycaemia• diabetic ketoacidosis• hyperosmolar hyperglycaemic state• persistent symptomatic hyperglycaemia
Avoidance of foot complications in frail, bed-bound people with diabetes
Avoidance of symptomatic clinical dehydration
Provision of an appropriate level of intervention according to stage of illness, symptom profile, and respect for dignity
Supporting and maintaining the empowerment of the individual person (in their diabetes self-management) and carers to the last possible stage.

The General Medical Council UK [14] states that individuals are approaching the end of life when they are likely to die within the next 12 months. This includes those whose death is imminent (expected within a few hours or days) and those with:

- Advanced, progressive, incurable conditions.
- General frailty and coexisting conditions that mean they are expected to die within 12 months.
- Existing conditions if they are at risk of dying from a sudden acute crisis in their condition, e.g. dementia and chronic diseases such as diabetes, where each crisis depletes the individual's overall reserves.
- Life-threatening acute conditions caused by sudden catastrophic events.

Research suggests that people prefer a death free of pain and discomfort to a longer life; however, these thoughts and feelings may differ according to cultural beliefs [15]. People are more likely to have their preferred death if they document a clear advance care plan based on their values. Values are those things that give meaning and purpose to their lives [13, 15].

The Gold Standards Framework for end-of-life care, developed in the UK [16], identified triggers that can help healthcare professionals determine whether the individual is nearing their end of life (Box 73.1).

The Gold Standards Framework also defines four main stages of end of life [16]:

1. Stable from diagnosis (usually lasting years).
2. Unstable, advanced disease (usually lasting months).
3. Deteriorating, exacerbations (usually lasting weeks).
4. Last days of life pathway (usually lasting days).

This model was adapted in Australia and Canada, whose guidance includes five stages with the inclusion of death and bereavement. Providing bereavement care to families is considered to be an integral part of care provision [18, 20]:

1. Disease advancement.
2. Experiencing life-limiting illness.
3. Dependency and symptom increase.
4. Decline and last days.
5. Death and bereavement.

Other organizations provide similar assessment tools to help healthcare professionals in determining if an individual is entering the end-of-life phase. The Supportive & Palliative Care Indicators Tool (SPICIT™, University of Edinburgh, UK), developed in Scotland, provides this information for people from a variety of countries and in particular those from a low-income setting. These tools are available in different languages [21].

Management of diabetes at the end of life

The care of the dying person with diabetes is challenging, encompassing changes to glycaemic target ranges, determining individual and carer expectations, reducing the risk of hyperglycaemia and hypoglycaemia, managing the effects of other medications, such as glucocorticosteroids, and tailoring diabetes medications depending on the stage of end of life. Planning for end-of-life care in people with diabetes is often seen as a direct choice between treating or withdrawal of treatment for diabetes [11, 13, 20]; in practice, caring for the dying person is more complex, especially when they have diabetes.

Planning for the end of life (advance care planning) should start early so that the individual can clearly document their values, the things that give meaning and purpose to their life, and the care they

Box 73.1 Gold standards framework for end-of-life care**The ‘surprise question’: would you be surprised if this person were to die in the next few months, weeks, or days?**

The answer to this question should encompass a range of clinical, comorbidity, social, and other factors that give a whole picture of deterioration. If the healthcare professional would not be surprised, then it is important to consider what measures might be taken to improve the person's quality of life now; and in preparation for possible further decline to check whether their advance care plan for end of life is still current.

General indicators of decline: deterioration, increasing need, or choice for no further active care

These include:

- Decreasing activity: functional performance status, declining limited self-care, in bed or chair 50% of day, and increasing dependence in most activities of daily living.
- Comorbidity, which is regarded as the biggest predictive indicator of mortality and morbidity.
- General physical decline and increasing need for support.
- Advanced disease with an unstable, deteriorating complex symptom burden.
- Decreasing response to treatments.
- Decreasing reversibility of exacerbations of underlying illnesses, which indicate reducing reserves.
- Individual chooses to have no further active treatment.
- Progressive weight loss (>10%) in past six months.
- Repeated unplanned or crisis admissions.
- Sentinel event, e.g. serious fall, bereavement, transfer to nursing home.
- Serum albumin <25 g/l.
- Considered eligible for additional financial support and benefits.

For people with diabetes who are using insulin or β -cell secretagogues, the development of hypoglycaemia should be added to the indicators that a person is at the end of life. It has long been recognized that the development of hypoglycaemia in people who have not previously been prone to this is a poor prognostic sign [17]. This is true for hospitalized individuals, in whom the excess mortality is not caused by hypoglycaemia *per se*, but by associated comorbidities [18]. It seems that this also applies to out-of-hospital hypoglycaemia. An audit of 1835 paramedic call-outs for hypoglycaemia in 2015 in the UK revealed that within one year following the call-out, 4.4% of people with type 1 diabetes and 22% of those with type 2 diabetes had died [19]. Hypoglycaemia in this context is multifactorial, arising from reduced food intake, weight loss, and/or impaired kidney function without adjustment of the dose of hypoglycaemic medication.

Factors related to the risk of hypoglycaemia include taking insulin preparations, sulfonylurea (e.g. gliclazide, glipizide, glimepiride), and prandial regulators (nateglinide, repaglinide). People with diabetes who are at particular high risk include those who also have one or more of the following:

- Poor appetite/erratic eating pattern.
- Weight loss.
- Renal deterioration.
- Liver impairment/carcinoma.
- Autonomic neuropathy (gastroparesis).
- Nausea and vomiting.
- Previous gastrectomy.
- Frailty.
- Memory problems.
- Oropharyngeal and oesophageal tumours [13].

Specific clinical indicators related to certain conditions

These relate to specific conditions, such as cardiovascular disease. Although diabetes is not mentioned, it frequently occurs in association with those conditions that are specifically mentioned, including cancer, chronic obstructive airways disease, heart disease, renal disease, general and specific neurological disease, such as motor neurone disease, Parkinson's disease, and multiple sclerosis, frailty, dementia, and stroke [1].

will accept or not accept in specific situations. Clearly documented values help healthcare professionals and families make decisions about the care the dying person would accept when the person no longer has decisional capacity, even if they have not documented the specific care they do or do not want [11, 13].

There was a dearth of guidance on end-of-life diabetes care until Dunning et al. first published their guidance in 2010 [22]. Most

other generic end-of-life guidelines did not attempt to address the specific issues encountered by people with diabetes, so Diabetes UK commissioned a working party in 2010 to review available data and the existing guidance from around the world. The agreed aim of the working party was to summarize a consistent but high-quality approach towards end-of-life care for people with diabetes by providing guidance and clinical care recommendations. These

were developed in partnership with multiple professional groups and formed a consensus of opinion across care and professional boundaries [23]. The original Diabetes UK guidelines have been revised over the years. The latest update was commissioned by Diabetes UK and undertaken by Trend Diabetes in 2021. This included more specific updates relating to cancer, chronic kidney disease, and Covid-19 [13].

These and other guidelines formed the basis of the inclusion of sections on end-of-life care within clinical guidelines for managing type 2 diabetes, such as the International Diabetes Foundation's (IDF) Global Guideline for Managing Type 2 Diabetes [24] and the RACGP/Diabetes Australia guidelines for Managing Type 2 Diabetes [25].

The key principles underlying high-quality diabetes care at the end of life are summarized in Table 73.1. The consensus recommendations addressed the major clinical problems that people with diabetes encounter at the end of life and how these could best be managed. The recommendations were aligned to the generic Gold Standards Framework for end-of-life care [16]. They included a review of the use of anti-diabetes therapies and set glycaemic targets that aimed to minimize hypoglycaemia and improve safety for the individual. UK algorithms developed in 2013 for specific situations, such as use of daily steroid therapy and treating hypoglycaemia, have since been updated (Figure 73.1) [13]. It was hoped that these guidelines would contribute to the development of a consistent approach to care delivery and act as a platform for future partnerships among all healthcare sectors and the public.

Glycaemic targets

There have been no well-designed studies supporting or providing insight into glucose regulation, diabetes self-management, or the use of particular diabetes therapies at the end of life. Maintaining appropriate metabolic management at all terminal stages of life might seem an achievable goal in most people with diabetes, but the influences of the stress response to severe illness, disturbances in glucose metabolism caused by malignancy, use of steroids, and frequent infections can be challenging for clinicians providing diabetes care. People dying with diabetes may have an increased frequency of symptoms such as pain, constipation, and fatigue, which can be difficult to ameliorate unless healthcare professionals have experience providing tailored diabetes therapy in combination with adequate pain relief including use of opiates, when indicated for symptom control.

There is no evidence to justify the use of glycated haemoglobin (HbA_{1c}) testing in end-of-life diabetes care. The optimal range of blood glucose values will vary according to the stage of the illness, nutritional status, and diabetes treatments given [13, 24]. Others have argued that measuring HbA_{1c} should cease when estimated survival is only a few months, not least because using HbA_{1c} to diagnose diabetes in this situation is not validated [26].

It is likely that the optimal glycaemic range will vary according to the stage of illness, the ability to eat and drink normally, the risk of hypoglycaemia, the nutritional status, and concomitant treatments. Many people prefer not to have frequent blood glucose estimations, particularly if they understand that the result may not have an immediate impact on management; their wishes should be respected.

Some have argued for a blood glucose target range of 180–270 mg/dl (10–15 mmol/l) or even up to 360 mg/dl (20 mmol/l), although the latter may not be appropriate because of the increased risk of ketoacidosis in people with type 1 diabetes and hyperosmolar states in those with type 2 diabetes. Consensus guidance for

glycaemic targets recommended 6–15 mmol/l (108–270 mg/dl) and this range is one of the suggested quality metrics for end-of-life care (Box 73.2) [2, 13, 22]. This range will help to avoid hypoglycaemia and hyperglycaemia in individuals in the last year of life. The number of daily capillary blood glucose tests should be reduced in those with type 2 diabetes in tandem with the reduction or cessation of diabetes medications as the individual enters the final months, weeks, and days of life. Individuals with type 1 diabetes will need to remain on insulin until death to avoid diabetic ketoacidosis. Blood glucose testing should continue in this situation at least on a daily basis to rule out overt hypoglycaemia or hyperglycaemia. The use of continual glucose monitoring systems can be useful tools in some cases, as this will be less invasive [13].

Since people with diabetes are increasingly used to a care planning approach in which they take informed decisions about their care, everyone with capacity should continue to be involved in their care planning for as long as possible, including decisions about setting blood glucose and other target ranges and the frequency of blood glucose monitoring [11, 13]. Ideally, documentation of an end-of-life advanced care plan should be in place as early as possible to help avoid uncertainty for healthcare professionals and families.

Medicines management during the last year of life

Specific recommendations that are aligned to life expectancy are given in the IDF and UK guidelines. In general, non-insulin glucose-lowering therapies can be reduced and eventually stopped depending on other factors, such as poor appetite, weight loss, and anorexia (Table 73.2). It may be necessary to discontinue insulin treatment in people with type 2 diabetes, but insulin should never be stopped in people with type 1 diabetes (Table 73.3). However, managing blood glucose levels to avoid hyperglycaemia and hypoglycaemia is essential to control the unpleasant symptoms associated with these conditions. Thus, insulin can be used with a palliative intent.

Other non-diabetes medications

Once it is recognized that a person has reached the end of their life, a review of all prescribed medication is indicated. It is important to stop or reconsider doses of any medicines that are not beneficial and those that are causing symptoms. Many people with diabetes are prescribed medication intended to reduce the risk of cardiovascular events in the long term, including angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor antagonists, other antihypertensives, aspirin or anti-platelet agents, statins, and other lipid-lowering agents. There are significant potential side effects associated with these medicines and stopping some or all of them may improve quality of life.

Decisions should be made in conjunction with the individual and their family, to avoid giving the impression that their medical advisers are 'giving up on them'. Most decisions to reduce or stop medicines are usually based on clinical common sense rather than robust evidence. A proactive approach to de-intensifying therapies should be based on the risk–benefit impact of continuing them. Any changes need to be made in agreement with the individual and/or their family [13, 14]. Drugs frequently used in palliative care include anti-secretory drugs, analgesics, and sedatives and relaxants. Experts in the field of palliative care should advise on the use of these drugs [13].

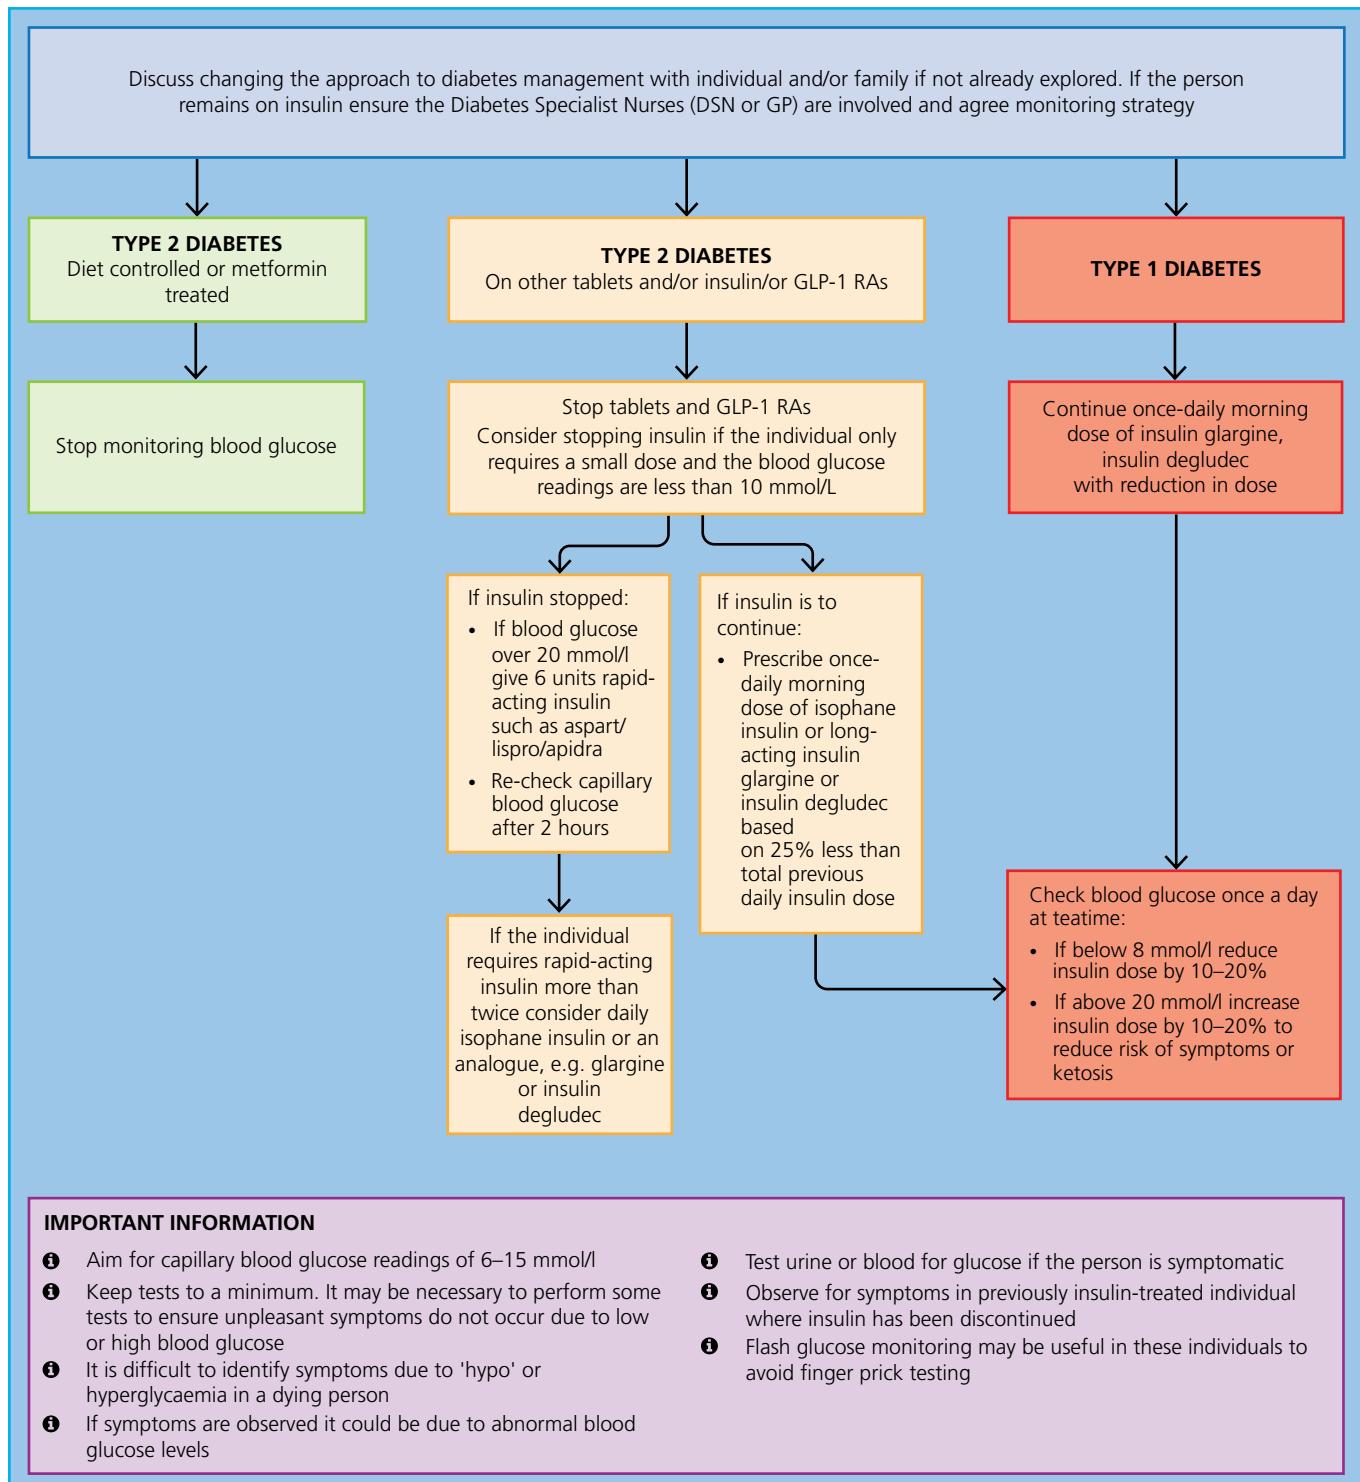

Figure 73.1 Management of diabetes in the dying person. GLP-1 RA, glucagon-like peptide 1 receptor agonist.

Box 73.2 Glucose targets for end-of-life care

Aim 1: No glucose level less than 6 mmol/l (110 mg/dl).

Aim 2: No glucose level higher than 15 mmol/l (270 mg/dl).

The UK algorithm for diabetes at the end of life (Figure 73.1) provides guidance on how to manage diabetes in the dying person. It can be reassuring for relatives and carers to know that these recommendations for end-of-life care are being followed and that diabetes is being *managed differently* rather than being *ignored*. The

Table 73.2 End-of-life medicine management: non-insulin therapies.

Metformin standard or Metformin SR	Sulfonylureas Gliclazide, glipizide, glimepiride, repaglinide	Pioglitazone	Gliptins Alogliptin, linagliptin, saxagliptin, sitagliptin	GLP-1 RAs Exenatide or liraglutide, lixisenatide, semaglutide, exenatide extended release, oral semaglutide, dulaglutide	SGLT-2 inhibitors Dapagliflozin, empagliflozin, ertugliflozin, canagliflozin	
Risk of hypoglycaemia with non-insulin therapies when used as mono-therapy						
	✗ No risk	✓ Moderate risk	✗ No risk	✓ Low risk	✗ No risk	✓ Low risk
General considerations						
Review dose according to changing renal function	Review if dietary intake is reduced and/or there is significant weight loss	The risk–benefit ratio for pioglitazone in individuals with terminal disease requires review and should only be prescribed if benefits can clearly be identified	Review doses in accordance with individual licences if renal function deteriorates	Review if eating patterns change or significant weight loss occurs	Refer to SPC for doses	
Withdraw if creatinine >150 mmol/l or eGFR <30 ml/l/1.73 m ²	Review dose if renal or liver function deteriorates and consider a switch to tolbutamide		Some gliptins can be used for all stages of renal disease	Withdraw if abdominal pain or pancreatitis develops	Refer to individual SPC for renal guidance	
Review if gastrointestinal disease is present or symptoms of nausea, heartburn, diarrhoea, or flatulence are making individuals miserable with discomfort	Review tolbutamide dose if liver function deteriorates as hypoglycaemia may occur	Should not be used in individuals with or at risk of bladder tumour or heart failure	Combination with sulfonylurea increases the risk of hypoglycaemia	Refer to individual product SPC for doses	Stop if evidence of clinical dehydration, peripheral vascular disease, or foot ulceration in acute illness and pre-surgery Test for ketones if there is acute illness

Table 73.3 End-of-life medicine management: insulin therapies.

The simplest regimen should be chosen if switching to insulin only. Both once- or twice-daily injection can be considered
Doses may need to change with changes in renal function
Equipment for insulin delivery may need to be reassessed if physical capabilities alter, manual dexterity or vision is poor, or carers become involved in administering insulin
Carers and healthcare professionals may need education to safely manage insulin
Hypoglycaemia risk will need to be reassessed when eating patterns change
An evening basal insulin in combination with daytime oral anti-diabetes agents may be a good first-line treatment choice
A change of insulin regimen may be needed to match changes in food intake and activity levels

flowchart was designed to minimize symptoms of diabetes and keep invasive testing to a minimum.

Insulin

The general principles of insulin management are summarized in Table 73.3. Insulin therapy should not be completely withdrawn in type 1 diabetes due to the risk of diabetic ketoacidosis. Insulin

requirements in the last months and weeks of life in people with type 2 diabetes, however, often significantly reduce as appetite diminishes, and insulin can be reduced or even discontinued in some individuals.

Continuous subcutaneous infusion of insulin–insulin pumps

Insulin pumps are increasingly being used to manage diabetes in an end-of-life phase; there is limited value in the extensive training of healthcare professionals in their use, however, as insulin pump users are likely to be well informed about adapting their pump settings for illness and have a good awareness of food intake in terms of carbohydrate and protein content. If the person with diabetes feels capable of using the pump, they should be encouraged to do so; nevertheless, carers may need education in pump use and insulin dose adjustment if it is physically difficult for the person with diabetes to make setting and cannula changes. Members of the specialist team who are adept at dealing with lifestyle and appetite changes in managing pumps may need to develop their understanding of the implications of chemotherapy or radiotherapy regimens in order to give appropriate advice.

Should the individual wish to continue to use their insulin pump, the infusion rates can be adapted to cope with even the last days of life. Close cooperation between diabetes specialist teams is crucial, since the caring team may be unfamiliar with the insulin

pump. The diabetes specialist team can advise about alternative insulin regimens in situations where pump treatment is no longer considered to be appropriate or feasible, but planning ahead will minimize the understandable anxiety associated with switching to a different insulin delivery method. This could and should be documented in the individual's advance care plan. On a practical note, insulin pumps may be returned to the issuing department when they are no longer required, as they can be reconditioned and reissued.

Nutrition

It is important that people in end-of-life care are reviewed regularly to determine whether they are becoming malnourished or dehydrated. If there are concerns that an individual is not receiving adequate nutrition or hydration by mouth, even with support, an assessment of their condition and their individual requirements must be undertaken and consideration given to different forms of clinically assisted nutrition consistent with their advance care plan. If the individual refuses to eat or drink or has swallowing difficulties, an assessment of the underlying cause, for example depression, dry mouth, oral candidiasis, or painful mouth ulcers, and possible treatment should be offered [9, 13, 27, 28].

Individuals treated with chemotherapy may experience loss of taste and this treatment can induce nausea and vomiting. Eating helps people to feel better and is a social activity. It is a great concern to individuals and their families when there is loss of appetite and weight, and an inability to participate in the family eating together. Food supplements, although glucose rich, are sometimes the only nutrition that is tolerated. If these are used, a treatment review should be undertaken to avoid symptoms of hyperglycaemia [9, 13, 28, 29].

Poor appetite or reductions in meal size along with swallowing difficulties experienced by some individuals will affect glycaemic levels and may lead to hypoglycaemia. People with type 2 diabetes may be taking several oral anti-diabetes therapies, which may be difficult to swallow because of tablet size or the number of medications prescribed. In these instances, a medication review should be undertaken and treatment regimens simplified. Individuals may also prefer to take smaller meals more frequently. Avoidance of glucose-rich foods may no longer be appropriate; consequently, diabetes therapies may need to be adjusted to reduce hyperglycaemic symptoms. It is entirely appropriate to relax dietary restrictions originally designed to minimize weight gain and stabilize glucose levels. People with diabetes can be offered any of their favourite foods in order to tempt them to eat. Other guidance includes:

- Consider using metformin in powdered form or syrup (if it is available) if people cannot cope with tablets.
- Avoid sulfonylurea preparations to reduce hypoglycaemia risk.
- If small meals are being taken, repaglinide can be useful for managing small regular meals, with dose adjustments according to food intake.
- Low-dose insulin may be the only option for people whose glucose levels are high despite a significantly reduced oral intake.
- People with poor intake will need lower doses of insulin to avoid hypoglycaemia.

In some cases individuals may be on enteral feeding to provide adequate nutrition and to avoid hypoglycaemia and hyperglycae-

mia and unpleasant symptoms. A referral should be considered to the dietetic services, who may assist with a nutritional assessment and meal planning [11, 13].

Managing diabetes in people treated with glucocorticosteroids

The use of steroid therapy in people at the end of life can alleviate symptoms, reduce fatigue, increase appetite, and improve quality of life [30]. Steroids can be given using various regimens and in variable doses. The most common method is a short course of prednisolone given in the morning, which will lead to raised blood glucose readings later in the day that reduce overnight.

Individuals living with cancer are often treated with dexamethasone twice daily, which can lead to hyperglycaemia throughout the 24-hour period. The use of dexamethasone in individuals with Covid-19 has also become a staple part of their treatment plan (Figure 73.2) [30].

The commonest treatment for steroid-induced hyperglycaemia is a sulphonylurea, such as gliclazide, or isophane (neutral protamine Hagedorn, NPH) insulin (Table 73.4) [13]. People taking very short courses of steroids (<3 days) may only require close monitoring. Target ranges should aim to achieve a blood glucose concentration between 6 and 15 mmol/l (108–270 mg/dl) and no osmotic symptoms. Any diabetes treatments should be reduced or stopped in tandem with steroid reduction to avoid hypoglycaemia.

Withdrawing diabetes and other medication

The decision to withdraw treatment including anti-diabetes medication is difficult. Recognizing the concept of a good death for all people entering an end-of-life phase can be an awkward aspect of caring to communicate. Key priorities should be decided with the individual and their family as early as possible and documented in an advance care plan. Generally, people want to be free from pain, to be with family and loved ones, and to be treated with dignity and respect at all times [31].

The use of an advance care plan or a living will is becoming more common. An advance care plan is a legal document in many countries; it needs to be signed and witnessed and enables the person with diabetes to accept or refuse specific types of treatment at an indeterminate time in the future. Healthcare professionals need to know if an advance care directive or plan is in place [13, 31–34]. Most guidance recognizes that any withdrawal of diabetes-related treatments warrants close liaison with the person with diabetes, the family, and the family doctor, and *must* consider the person's wishes, family concerns, and the presence of an advance directive.

Treatment withdrawal can be considered:

- When the person with diabetes is entering the terminal phase of life.
- Where frequent treatment-related hypoglycaemia is causing distress and significant management difficulties.
- Where continued treatment with insulin poses an unacceptable risk of hypoglycaemia or where the benefits of stricter glucose management cannot be justified.
- Where continued use of blood pressure or lipid-lowering therapy cannot be justified on health benefit considerations.

Table 73.4 Suggested treatments for hyperglycaemia when using steroids.

Regimen	Treatment
Once-daily steroid therapy	Morning administration of a sulfonylurea, e.g. gliclazide, or morning isophane NPH insulin
Twice-daily steroid therapy	Consider using a twice-daily sulfonylurea (e.g. gliclazide) or isophane insulin If hypoglycaemia is a concern, consider changing to a long-acting insulin analogue, such as insulin glargin or insulin degludec

Source: Joint British Diabetes Societies for Inpatient Care 2021 [29].

- Where continued food or fluid is not the choice of the individual who is dying.
- Where prescribing anti-infective therapy is unlikely to benefit the individual.

Workforce

Dissatisfaction with and complaints about care provided at the end of life still occur too frequently and are usually attributable to inadequate understanding of the complexities of the situation, failure of

communication, or both. Lack of workforce knowledge and training to deliver end-of-life care is a common feature of professionals delivering diabetes care in both hospital and community settings [14, 35].

Conversely, palliative care clinicians may lack up-to-date skills in diabetes medication and management, which affects their ability to offer holistic packages of care. Healthcare professionals need to know where their area of responsibility lies and recognize when they need to consult with other team members and colleagues, specialist teams, social services, or voluntary organizations in order to ensure a holistic approach to care. All staff caring for individuals at the end of life should receive initial and ongoing training and have been assessed for competency [35, 36].

Competency is defined as 'The state of having the knowledge, judgment, skills, energy, experience, and motivation required to respond adequately to the demands of one's professional responsibilities' [22]. The competency framework from the comprehensive Integrated Career and Competency Framework for Diabetes Nursing illustrates the different competencies expected of healthcare professionals and unregistered practitioners involved in the care of someone with diabetes at the end of their life [35].

12 Delivery and Organization of Diabetes Care

74

The Role of the Multidisciplinary Team across Primary and Secondary Care

Samuel Seidu and Kamlesh Khunti

Diabetes Research Centre, University of Leicester, Leicester General Hospital, Leicester, UK

Key points

- The rising prevalence of diabetes coupled with increasing life expectancy makes it impossible for specialist centres to cope with the demands of diabetes care, thus necessitating a shift to primary care.
- In an integrated diabetes care model, innovative collaboration between primary care and specialists can result in the creation of new healthcare organizations that can provide integrated diabetes care for their local populations.
- Care provision in community settings (i.e. other than within general practices) requires a collaborative unit of diabetes specialist support teams based on the needs of the local population.
- Multidisciplinary teams are essential for the care of people with diabetes from early life to end of life.
- Multidisciplinary teams are essential for the management of various complications of diabetes.
- The composition of multidisciplinary teams should span a wide range of specialties and community care workers in order to address the complexities of diabetes.

Diabetes has been recognized as a global epidemic. In 2019 the prevalence of diabetes was estimated to be 463 million worldwide and this is expected to rise to 700 million by 2045 [1]. It is a complex chronic disease affecting multiple organ systems, often accompanied by other comorbid conditions, with an associated disease management burden for the individual with the condition. The rising prevalence coupled with the increasing life expectancy makes it impossible for specialist centres to cope with the demands of diabetes care, as they did until ~30 years ago, thus necessitating a shift to primary care (Box 74.1) [2]. Community or primary care diabetes management is therefore a logical focal point for implementing strategies that improve the care of individuals with diabetes [3]. Multifactorial intervention in the management of type 2 diabetes leads to reductions in cardiovascular mortality [4, 5]. The management of the multiple cardiovascular risk factors in diabetes care requires multidisciplinary teams. The organization of these teams needs clinicians not just to have expertise in their chosen fields, but to be skilled in an interprofessional approach. The multidisciplinary approach to diabetes management is based on the premise that against the background of a common framework, decisions on the aims of treatment should be dictated by the insight of several professions. This normally requires team building, which focuses on developing a common culture and giving priority to professional and social interactions. The purpose of this multidisciplinary

Box 74.1 Definitions

- *Cardiovascular* refers to risks and complications related to the heart and the vessels.
- *Care* refers to the provision of what is necessary for the health of people with diabetes.
- *Community* refers to the care of individuals with diabetes outside of the hospital setting, usually delivered by specialists.
- *Diabetes* refers to all types of diabetes.
- *Integration* refers to bringing together people of different healthcare professional backgrounds into unrestricted association, with the aim of delivering a seamless care package for people with diabetes.
- *Models* refer to a system of care worthy of emulation.
- *Multidisciplinary* refers to the combination of various healthcare disciplines to care for individuals with diabetes.
- *Primary* refers to care of people with diabetes by general practitioners or family physicians.
- *Specialist* refers to physicians with special interest in diabetes. These are usually based in the hospital setting.
- *Team* refers to the coming together of health professionals to achieve a common goal.

approach is to ensure that activities around the complexities of screening, diagnosis, early and late management, and treatment of complications are coordinated in a seamless, integrated approach, with the aim of ensuring an optimal individualized management plan for each person with diabetes.

Coronary heart disease is a frequent complication and a major cause of mortality in people with diabetes. Therefore, its presence can create added complexity for an already burdensome regimen. People with type 2 diabetes also experience further burden from other, non-cardiovascular comorbidities (e.g. osteoarthritis, chronic obstructive pulmonary disease), with only 17.6% having only diabetes [6]. Those >65 years old will have a median of 6.5 other conditions in addition to diabetes, whereas those <65 will have a median of 2.9 other conditions [6]. The treatment of the complications and comorbidities requires coordination across several specialists. System management is therefore essential, including the flexibility to deliver personalized care and identify and meet the individual requirements of people with complex needs. In dealing with these complexities, integration of care around the individual with diabetes is pivotal to deliver seamless, optimal, and effective care. Integration refers to bringing together people of different healthcare professional backgrounds into unrestricted association, with the aim of delivering a seamless care package for people with diabetes.

The process is enhanced by telemedicine, which promotes self-monitoring of the individual with diabetes and enables the provision of accurate and timely data transmission and sharing between people with diabetes and clinicians. It fosters innovative approaches to streamlining diabetes management and monitoring. There is now an opportunity for virtual clinics, run jointly by generalists and specialists joining in at the same time [7].

Upskilling of primary or community care professionals in multidisciplinary teams

In an integrated diabetes care model, innovative collaboration between primary care and specialists can result in the creation of new healthcare organizations that can provide integrated diabetes care for their local populations. With the person with diabetes at the centre, delivery of care can revolve around them, with the aspiration of having an organizational structure, clinical pathways, and financial planning all aligning seamlessly [8]. The subsequent care pathway developed should be customized to the wide-ranging needs of the local population and adapted to the evolving needs and changing national health agendas, instead of a *one-size-fits-all* model. The prime focus of the integrated diabetes service is the integration of the healthcare system and the coordination of services around a person with diabetes, bringing together primary and specialist care in a setting nearer the person's home, where applicable.

To successfully maintain or even improve clinical outcomes and reduce variation in care, while supporting this shift of care, upskilling of general practitioners, practice nurses, and healthcare assistants and ongoing support from specialists are required. This comprehensive healthcare professional upskilling process needs to be based on psychological theories of learning [9–11] with the necessary knowledge repertoire. This will hopefully equip the diabetes care workforce with the appropriate knowledge and skills to provide them with the confidence to deliver the highest-quality care and improve outcomes for the individual with diabetes.

Possible areas of training could include mentorship and case management at a practice level to support clinical development, training, and care planning. Not only should the education and training be available at differing levels, they need to be provided by multiple alternative and complementary methods, including workplace-based learning, distance learning, a modular format, journal clubs, and mentorship [12]. The multidisciplinary team creates an adaptable and responsive model with a feedback mechanism, which encourages improvement of the quality of care through knowledge of local needs. Furthermore, and crucial for such an educational programme's longevity, it must be developed so that it can reflect continually changing approaches to diabetes management in relation to new therapies and national drivers [12].

Practices that participate and engage in this training process can gain accreditations based on the breadth and level of diabetes care that they provide [12]. A stepwise and ongoing accreditation process could start from the provision of a basic core service, including screening of all individuals at risk of diabetes, diabetes-prevention interventions, regular surveillance of all people with diabetes (i.e. measuring and managing glycated haemoglobin [$\text{HbA}_{1\text{c}}$] according to guidance, blood pressure and cholesterol measurements, and feet examinations), cardiovascular disease risk reduction, evidence-based prescribing, auditing care provided, and evidence of referral to and attendance of all people with diabetes at evidence-based educational interventions/programmes directed to the person with diabetes [12].

A step up the accreditation ladder will be practices that provide elements of an enhanced service, including the management of complex treatment conditions around the person with diabetes on insulin, including in-house initiation and titration for those with type 2 diabetes, management of people with stable type 1 diabetes, initiation and management of glucagon like-peptide 1 (GLP-1) receptor agonist therapies, high-quality care for housebound individuals (including those in nursing/residential homes), and proactive discharge of individuals who may benefit from the treatment and are currently under specialist follow-up [12].

Multidisciplinary team support in structured diabetes self-management education

People with diabetes must live the rest of their lives with the condition and as such need to improve their knowledge, skills, and confidence, enabling them to take better care of their own condition. They must integrate effective self-management into their daily activities. These can be achieved through structured education programmes [13].

The multidisciplinary team will need to consider a range of issues to ensure that their education programmes meet the expected standards. The programme must have a written curriculum, and include areas such as healthcare professional training, quality assurance, and learning needs assessment [14]. Healthcare professional training should incorporate modules around person-centredness. Professional training in cultural diversity awareness in diabetes, self-management initiatives including motivational interviewing and other behaviour change interventions, and psychosocial aspects of diabetes will help multiprofessional teams develop working plans to achieve the desired goals [13].

This structured training for diabetes educators must address the theoretical base and the underlying philosophy of structured diabetes education. The programme itself must therefore be

underpinned by the philosophy that the programme will be adaptable to the needs of the person with diabetes and involve them in its ongoing development. It should be evidence based and have a clear aim and learning objectives, which are shared with the individuals with diabetes, carers, and family. Health professionals must plan *with* the individual with diabetes on issues around the care of their condition.

Local multidisciplinary teams have the responsibility of ensuring that there is an internal quality assurance process in place for the structured education programmes. This ensures that practitioners are carrying out self-reflection during the delivery of the programme with ongoing review of the biometric outcomes, user satisfaction, and experience in order to maintain standards [15].

Like in other chronic diseases, the use of digital health interventions is increasingly becoming integrated into diabetes self-management to improve accessibility for individuals with diabetes, enhance behaviour change, and improve glycaemic management [16, 17]. With people with diabetes able to access web-based programmes at the own time and pace, the problems associated with face-to-face structured education programmes, such as time and transport, can be better addressed with digital interventions [18].

Multidisciplinary teams in diabetes care models

In developing a diabetes service, it is important to know what the components of the service need to be and the mode of implementation required. Even though the models of care delivery in diabetes vary from country to country, the components are broadly similar. The implementation is what varies from place to place. The choice of implementation strategy depends on the local needs and the availability of various component resources. In most high-income countries, there is usually a national strategy for delivering diabetes care.

In a generic service model, there must be integration across all levels of the service to provide a seamless transition for individuals with diabetes and ensure that appropriate referrals take place,

with clear and agreed referral criteria and clinical protocols for chronic and emergency management (Figures 74.1 and 74.2). Good communication links and joint working between the practice diabetes leads and specialist care teams are essential to plan services and to provide a framework for audit, quality assurance, and performance monitoring.

Care provision in community settings (i.e. other than within family doctor practices) requires a collaborative unit of diabetes specialists support teams. These teams are constructed based on the needs of the local population and can comprise a collaborative team of diabetes specialist nurses, diabetes consultants, dieticians, diabetic retinopathy screening teams, and podiatrists. They can offer clinic-based care, outreach support to primary care practices and nursing homes, rapid-access community clinics, development of agreed clinical care pathways for various aspects of diabetes care and referrals, and telephone- and web-based support for complex cases, again depending on the needs of the locality. This support has to be flexible in approach and multistranded to reflect the varying gaps in knowledge of the healthcare professionals. The fundamentals of any such programme should be applicable and transferable to other diabetes care providers.

These components require a coordinated approach between multiple healthcare professionals in different sectors of health and social care. For local populations a local model of care is required, which can be developed in more detail, with roles and responsibilities clearly identified. Ideally, care should be provided within each locality to agreed care pathways, and each care provider should be clear of their role and relationship with other providers. The delivery of integrated diabetes care in any locality requires leadership and teams working through cooperation, coordination, and collaboration, working to a shared vision of healthcare, and drawing together skills and relationships across the healthcare community. This integrated, collaborative approach is effective not only in mental illness, but also in the management of people with mental disease and other chronic physical multimorbidities, including diabetes [19]. Specialist diabetes teams, often with extended roles,

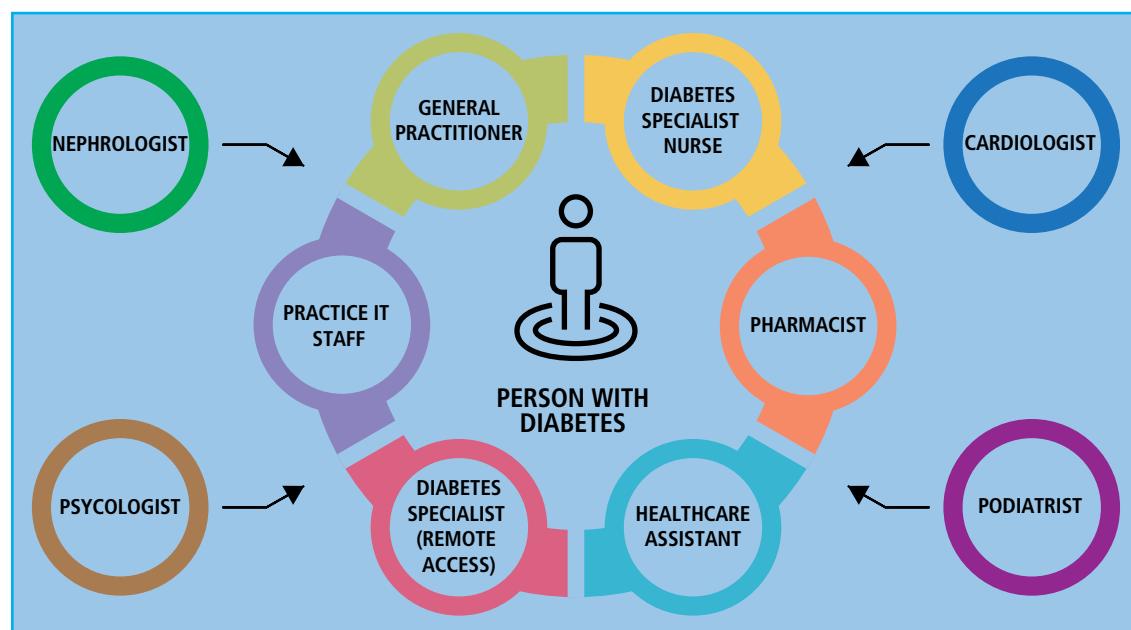

Figure 74.1 Schematic representation of the management of people with multiple long-term conditions in countries with advanced health systems. In areas where resources abound, multidisciplinary primary care teams, supported by specialists, provide holistic care to the person with diabetes. IT, information technology.

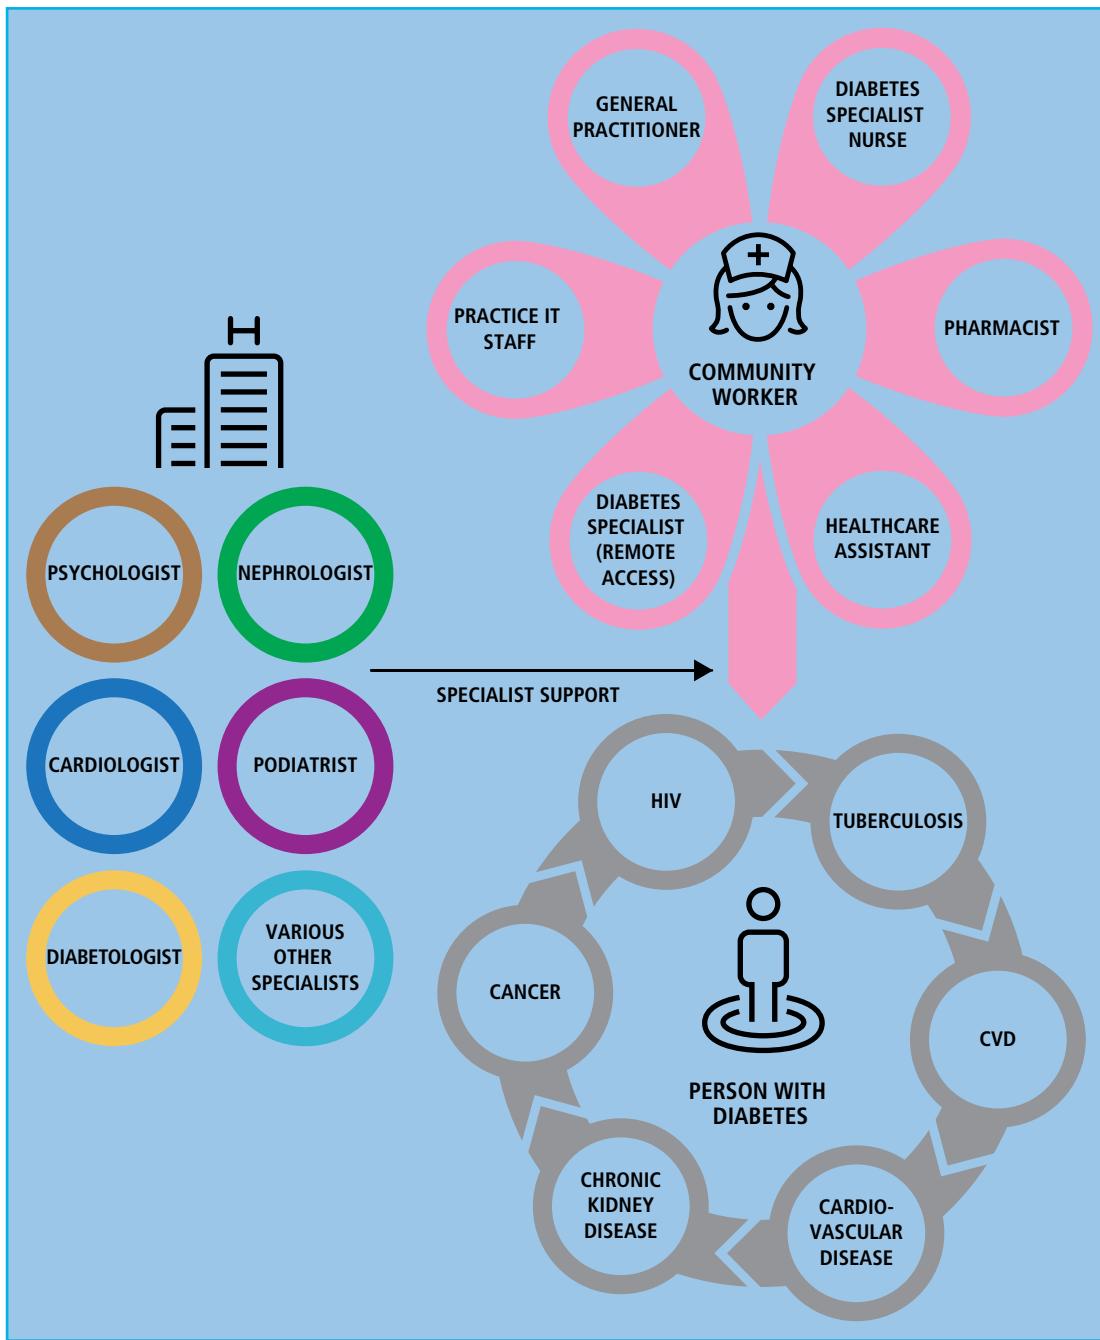

Figure 74.2 Schematic representation of the management of people with multiple long-term conditions in low- and middle-income countries. In the context of multimorbidity and limited human and financial resources, non-specialized nursing and allied health professionals, supported by specialists, provide holistic care to patients. CVD, cardiovascular disease; HIV, human immunodeficiency virus; IT, information technology.

working in primary care through community consultants, form a central *hub* of expertise to support the delivery of high-quality and effective diabetes care (Figure 74.1).

In the USA, there is a drive to incorporate elements of the chronic care model into diabetes care. Systems' redesigns, self-management and decision support, and organization of diabetes care in the community could collectively improve outcomes in diabetes and reduce cost [20]. Organizations like Kaiser Permanente are using these components in diabetes care and showing improvements in admission rates and outpatient clinic attendances [21].

The situation is much more challenging in low- and middle-income countries like sub-Saharan Africa, where diabetes care, largely driven by specialist care, faces competition for resources from the management of infectious diseases (Chapter 75). The lack of financial, infrastructural, and human resources is a major drawback for any effective service implementation in diabetes care, thus leading to lower life expectancy in people with diabetes [22]. Care provision is done using non-specialised nursing and allied health-care professionals in the management of all chronic diseases including diabetes, without disease-focused specialization. In the context

of multimorbidity and limited human and financial resources, this approach seems to be an attractive option worth implementing and evaluating in other areas (Figure 74.2).

Multidisciplinary teams in the management of complexities in cardiovascular risk prevention

The presence of a complex health and illness profile is associated with worse management of cardio-metabolic risk factors independent of regimen intensity and history of cardiovascular disease (Chapter 46) [23]. The medical model of care is structured along system-based specialization, thus necessitating evidence-based guidelines for various conditions to be developed independently [24]. This creates a huge challenge for primary care teams, who must deal with various disease areas without thorough specialization. That is compounded by the fact that management of the major cardiovascular risk factors in diabetes has sometimes raised questions about the benefits of high-risk factor control. In glycaemic management, for example, although early intensive treatment in diabetes results in lasting benefit, including for cardiovascular risk reduction [25], intensive glycaemic management in late diagnosis and in individuals with background cardiovascular disease does not reduce major cardiovascular events and indeed may increase mortality [26]. Similarly, even though major reductions in cardiovascular outcomes are seen in individuals receiving tight control of blood pressure compared with those receiving conventional control if the baseline blood pressure was high [27, 28], tight control of systolic blood pressure among people with diabetes and coronary artery disease does not improve cardiovascular outcomes [29]. Indeed, increased mortality in intensively treated individuals with newly diagnosed diabetes has also been noted and therefore caution in lowering blood pressure too aggressively is recommended in these individuals [30]. Regarding cholesterol, a reduction in 1 mmol/l low-density lipoprotein (LDL) cholesterol leads to a 20–25% reduction in cardiovascular events (major coronary events, coronary revascularization, and ischaemic stroke) [31]. However, among individuals at increased diabetes risk (those with baseline evidence of impaired fasting glucose, metabolic syndrome, severe obesity, and elevated HbA_{1c}), the risk of development of diabetes among statin-treated individuals appears to be raised. However, the overall cardiovascular and mortality benefits of statin therapy exceed the risk for developing diabetes [32]. Nevertheless, this finding introduces another complexity in cardiovascular risk management in people with diabetes. Thus, the management of the various risk factors could potentially require input from other team members with expertise in these areas.

The increasing prevalence of comorbid cardio-renal conditions coupled with the emergence of therapeutic agents that provide cardio- and nephro-protective benefits also calls for integrated, team-based care for the optimal treatment of these individuals with a complex condition. Local information technology (IT) infrastructure enabling shared records between primary care, nephrologists, cardiologists, and diabetologists is required, as well as providing secure data centres to facilitate monitoring of clinical outcomes and service improvement. This can assist people with diabetes, carers, and healthcare professionals with the choice of therapeutic options, understanding of the disease and its complications, and self-management [33]. Using integrated IT systems, provision of therapies and services to people with

diabetes in different healthcare settings is made possible by ensuring responsiveness to the needs and preferences of the individual, improvements in healthcare process and intermediate outcomes, user-clinician communication, and access to medical information [34]. Due consideration, however, needs to be given to potential barriers in access to the IT infrastructure due to older age, low income, education, and cognitive impairment and to consider physicians' concerns about increasing their workload.

The presence of chronic kidney disease increases the risk of cardiovascular morbidity and mortality and increases the risk of progression to end-stage renal failure [35, 36]. Diabetic nephropathy is a progressive disease and as such requires the input of several healthcare professionals at various stages of the disease trajectory. The primary care teams after initial diagnosis of early disease can reduce the progression of renal disease with the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) [37, 38] and sodium–glucose cotransporter 2 (SGLT-2) inhibitors [39, 40].

Additionally, in heart failure, despite the improvements in treatment options, about half of people with the condition die within five years of diagnosis [41]. This and type 2 diabetes are major pandemics of the twenty-first century [42]. The introduction to routine clinical practice of SGLT-2 inhibitors with proven benefits in type 2 diabetes, heart failure [43], and chronic kidney disease [39, 40] will address the residual risk of a worsening of these cardio-reno-metabolic conditions over the coming years.

Specialist assessment should be available to individuals with diabetes with, or at high risk of, renal disease and heart failure for referrals by the primary care teams as the disease progresses. The late management and treatment of complications should be well coordinated between the diabetes and cardio-renal services. Diabetes, nephrology, and heart failure services should have appropriately trained staff and systems in place not just to organize the service effectively in a timely manner during disease deterioration, but to manage acute complications like hypoglycaemia during episodes of dialysis and end-stage heart failure. Multicomponent structured educational intervention programmes are effective in pre-dialysis and dialysis care [44]. The role of the dietitian is invaluable in this group of individuals not only to maintain adequate nutrition, but to prevent abnormal electrolyte excursions [45].

Multidisciplinary teams in the care of people with diabetic retinopathy

The implementation of a retinopathy service should comprise a multidisciplinary team of clinicians who understand the natural history of the condition and options for early detection and treatment (Chapter 43). These will normally be permanent staff at a fixed or mobile retinal screening unit who are engaged in regular professional development updates. The aims of the service should be to improve access to retinopathy screening, particularly for those for whom access has traditionally been limited: the housebound, individuals who are disabled, older, Indigenous, or who do not speak the country's language. In the paediatric and adolescent populations, it is essential to have an ophthalmologist with expertise in diabetic retinopathy, and an understanding of the risk of retinopathy in the paediatric population, backed up by a team that has an experience in counselling young people and their families on the importance of early prevention and intervention [46]. The coordination and

supervision of such a service require proper leadership to identify clinical incidents, safety assessments, and drawing up proper interventions to tackle these deficiencies. The general practitioner keeps an updated register of people with diabetes for a call-recall system for retinopathy screening. This is coordinated through appropriate liaison between the hospital eye service and screening programme.

Successful multidisciplinary coordinated retinal screening services should have the necessary components not just for screening, but for investigation and management. There has to be immediate access to facilities for fluorescein angiography and optical coherence tomography to allow individuals with diabetic maculopathy to be treated within 10 weeks [47] and those with new proliferative retinopathy to be treated with laser within two weeks [48–50]. Individuals needing urgent photocoagulation should be able to have it carried out immediately. For the convenience of the individual, it is essential to have laser treatment carried out on the day of diagnosis, therefore there should be sufficient laser clinics or staff available to undertake the treatment outside laser clinics. Intravitreal drug delivery facilities will be needed at any treatment centre [49], but vitreo-retinal surgery, if not available locally, may require referral to a tertiary referral centre. For individuals with visual impairment, appropriate counselling services should be available.

Multidisciplinary teams in the care of people with diabetes-related foot ulcers

Many people with acute diabetes-related foot ulcers also have other multimorbidities including macrovascular complications and as a result healthcare professionals need to be mindful of these [51]. Foot ulceration has been reported as the leading cause of hospital admission and amputation in people with diabetes (Chapter 53) [52]. Acute diabetes-related foot ulcers require multidisciplinary management and best-practice care, including debridement, offloading, dressing, management of infection, modified footwear, and management of extrinsic factors [53]. Treatment of diabetes-related foot ulcers varies widely, depending on the skills of the attending clinicians. Best practice is deemed to be a multidisciplinary approach, where a holistic view of the individual with the ulcer is sought, and a care plan developed around this person's individual needs. However, these multidisciplinary teams are not always available. The multidisciplinary teams should ideally include appropriately trained staff such as orthoptists, podiatrists or podiatric surgeons or both, vascular surgeons, orthopaedic surgeons, diabetologists, microbiologists, radiologists, diabetes specialist nurses (including a diabetes specialist inpatient nurse), ward link nurses, and consultants in pain management with an interest in diabetic neuropathy [53].

For individuals at no added risk, foot care education is usually all that is required, but as they become at risk, twice-yearly review including foot inspection, footwear assessment, and foot care education become necessary. Individuals at high risk (i.e. those with more than two risk factors) need reviewing every 3–6 months, and may need vascular assessment or referral. Referral to a multidisciplinary foot care team within 24 hours for the management of ulcers and infection is mandatory [54]. To ensure a seamless package of care for people with foot problems, it is important that they are put at the centre of the decision-making process and have access to accurate information and support. The organization of care has to involve appropriate healthcare professionals, including

community podiatrists, who have a clear referral pathway to specialist services. Multidisciplinary specialist teams must endeavour to hold joint clinics in order for the service to be more effective and to reduce duplication of visits [55]. For people in hospital with diabetes, close observation for risk factors and prevention of foot ulceration is crucial, as this can be a vulnerable situation with an increase in pressure-related ulcers.

For the seamless organization of care around the person with a severe diabetes foot condition, there needs to be a ready availability of services to support its management. Facilities for pressure area offloading include orthotic services, foot casting, and prosthetic services. Imaging must also be available, including X-ray, computed tomography, magnetic resonance imaging, and microbiological support services.

Multidisciplinary teams in the care of diabetes in pregnancy

Women of child-bearing age with diabetes should have access to pre-conception services (Chapter 71) [56]. Although they may be managed in primary care, it is essential that there is integration of care between primary care, community services, and specialist services. Specialist services can provide leadership and support to raise awareness and provide education to primary and community services so that women with diabetes are aware of the need for pre-conception counselling and support. Through this leadership, guidance, and auditing of clear documentation of pre-conception counselling, pregnancy care and post-pregnancy management can be carried out.

The components of a multidisciplinary specialist diabetes pregnancy service should include clear signposting to different aspects of care. These should include diet and lifestyle advice, provision of appropriate contraception, alcohol and drug counselling, higher-dose folic acid supplementation, smoking-cessation support, assessment and management of diabetes complications, setting of glycaemic targets, and regular discussion of results of self-monitoring. This will enable the woman to achieve as near-normal glucose levels as possible before conception. There should also be a discussion of diabetes pregnancy risks and expected management strategies and a clear documentation of care and counselling [57]. Once a woman with diabetes is pregnant, they should have access to a specialist multidisciplinary team with interest in diabetes in pregnancy, comprising obstetricians, diabetologists, dieticians, diabetes specialist nurses, and midwives. The role of the specialist multidisciplinary team should be to agree an individualized care plan covering the pregnancy and postnatal period up to six weeks. The details of the contents of such plans will be glycaemic targets, retinal and renal screening schedules, fetal surveillance, a plan for delivery, and plan immediate post-delivery diabetes care [58].

Multidisciplinary teams in the care of people with young-onset type 2 diabetes

With the rising prevalence of overweight and obesity, the prevalence of type 2 diabetes in the younger population is also rising (Chapters 69 and 70). An age of 40 years is a reasonable cut-off to classify the person with diabetes as young or old. People with type 2 diabetes under the age of 40 years have a fourfold increase in the risk of myocardial infarction compared with those diagnosed over

the age of 40 years [58]. This younger age group will also include women of childbearing age who require special care [59]. Diabetes occurring early in adult life appears to lead to more aggressive cardiovascular complications than in age-matched people without diabetes, although the absolute rate of cardiovascular disease is higher in older adults [58]. This cohort of individuals also has other intercurrent conditions such as psychological and mental health problems, non-alcoholic fatty liver disease, sleep apnoea, and vitamin D deficiency. The implications of this are not just the development of complications for these individuals, but a tremendous knock-on effect on the economy as a whole, as this is the age of heightened productivity. Hence strong leadership for the delivery and organization of services and championing of the needs of younger people with diabetes are essential. Younger individuals with type 2 diabetes require tailored management strategies to engage them and intensively manage their cardiovascular risk factors. This is because these risk factors are highly prevalent and insufficiently treated in this extreme phenotype of type 2 diabetes [60].

A service for young people with diabetes should include a consultant dialectologist, a diabetes specialist nurse, a specialist diabetes dietitian, and a clinical psychologist with an interest in diabetes. The collaborative working of these healthcare professionals will ensure that a package of care encompassing the management of psychological issues as well as diet and cardio-metabolic risks is delivered. Younger individuals are likely to be in active employment and so flexibility in the delivery of service at the times conducive to them is essential for engagement, preferably through remote consultations. Telemedicine enhances service provision and quality of care, and mitigates service demand burdens. These individuals are kept connected to the healthcare system regardless of geographical boundaries. They also receive timely access to clinical care, with a reduction in the need for in-hospital care. In the primary care setting, there should be adequate provision for routine care, including diagnosis, initial management, continuing care, surveillance, management of complications, and annual assessment. Access to family planning, contraception, and preconception services must be provided. In working together with consultants, there should also be an agreement for arrangements for shared access to records and ready access to specialist diabetes advice. Targeted glycaemic levels can be aimed for before any attempt at conception is considered [56]. Access to smoking-cessation and substance abuse services should be integrated into any such service design.

Multidisciplinary teams in the care of older people with diabetes

Even though older people with diabetes have as high a risk of developing a spectrum of macrovascular and microvascular complications as their younger counterparts with diabetes, their absolute risk for cardiovascular disease is much higher (Chapter 72). Older adults with diabetes suffer excess morbidity and mortality compared with older individuals without diabetes [61]. Contributing factors to this increased risk include cognitive impairment, functional disabilities, frailty, polypharmacy, depression, urinary incontinence, and persistent pain [62].

The components of a diabetes service for older people should be commissioned, delivered, and monitored to ensure it is delivered as locally as possible, near to families' homes. The multidisciplinary staff members with an interest in diabetes must include a consultant

geriatrician, a consultant old age psychiatrist, a diabetes specialist nurse, a consultant diabetologist, a specialist diabetes dietitian, and a community pharmacist. Specific services aimed at older people with diabetes should include diabetes education programmes targeted to healthcare professionals looking after older people, because of the complexities of varying targets in this population [63]. Older people with diabetes are not a homogenous population; rather, they may include those who are functionally independent and residing in communities, or may be functionally dependent with many comorbidities and in assisted care facilities or nursing homes. Each group will have individualized targets for cardiovascular risk factor control. In frail older individuals with diabetes, avoidance of hypoglycaemia, hypotension, and drug interactions due to polypharmacy are of great concern [64]. This should be achieved without deterioration in HbA_{1c}, and with avoidance of falls and reductions in hospitalization [65]. In addition, management of coexisting medical conditions is important, as it influences the ability to perform self-management.

Suboptimally managed diabetes is associated with an increased risk for dementia, including the vascular and degenerative types. In addition, borderline and undiagnosed diabetes is related to Alzheimer's disease without vascular comorbidities, which suggests a direct link between glucose dysregulation and neurodegeneration [66]. Access to integrated memory clinics with psychological support and local counselling is therefore needed for older people with diabetes. Case management is best delivered by a dedicated community psychiatry nurse and a social worker who ensures that there is adequate provision for routine care, including diagnosis, initial management, continuing care, management of complications, and annual assessment. There should also be provision for rapid access to the service when needed, together with agreements with primary care for arrangements for shared access to records and 24-hour access to specialist diabetes advice. It may well be that due to the older people's multimorbid states and frailties, these services are delivered at home or in residential institutions. To facilitate this goal in this highly vulnerable population while continuing to provide the essential care, telehealth has emerged as a crucial care-delivery mechanism bringing specialty palliative care into the homes of seriously ill individuals [67].

Diabetes management can be discussed in advance and a virtual consultation session arranged later with the person with diabetes and their carer, during which a compliant teleconferencing application can be utilized to allow several healthcare professionals in separate locations to join a single virtual telehealth clinical encounter [68].

Staff composition of a multidisciplinary diabetes team

General or family practitioners

The use of primary care physicians (general or family practitioners) can be as good if not better than hospital outpatient care if regular review of the individual is guaranteed [3]. The enhancement of the generalist's care for people with diabetes by the use of quality improvement strategies, including audit and feedback, is an effective tool for reducing the cardiovascular risk profile [69]. The generalist's role often includes active case management of individuals with multiple conditions. In these groups, continuity of care is of paramount importance. Multidisciplinary primary care teams, led

by the generalist, therefore have a fundamental role in the prevention and identification of diabetes, as well as in routine care at a level that fits with their competencies. They will ensure that an accurate disease register is maintained to enable a call-recall system for annual reviews. They work cooperatively with other members of the team, seeking their views, acknowledging their contribution, and using their skills appropriately. Individuals with cardiovascular risk factors and those with early signs of microvascular complications can be identified and referred on to more specialist centres. The generalist has a more longitudinal relationship with individuals with chronic conditions including diabetes. They have the responsibility of coordinating the management of the person's acute and chronic complications of diabetes over time. They understand the individual in relation to their socioeconomic and cultural background and they recognize the impact of the problem on the individual's family and carers. They will therefore use appropriate support agencies, including primary healthcare team members, targeted to the needs of the person with diabetes.

The pay-for-performance initiative started in the UK in 2004 is probably the most ambitious quality improvement strategy and initially yielded some obvious improvements in the care of people with diabetes [70], but these benefits reached a plateau across the population [71] and did not lead to a reduction in variations in care [72, 73]. The organization of general practitioner specialist clinics in primary care has limited evidence in terms of the reduction of cardiovascular risk factors. The provision of primary care services for people with diabetes, whether from traditional general practitioner clinics or diabetes clinics run by general practitioners with a special interest, is effective in reducing HbA_{1c}, cholesterol, and blood pressure [74]. General practitioners are now managing people with diabetes and other complex comorbidities with complex therapeutic regimens.

Community pharmacists

A sustainable collaborative care approach for people with diabetes should make use of community pharmacists, who provide a local and accessible resource that is increasingly regarded as the first port of call for individuals with diabetes for help with the management of chronic disease. By offering programmes for monitoring therapeutic interventions, improving medication taking, and educating people with diabetes about their lifestyle, community pharmacists play a vital role in managing diabetes and its complications [75, 76]. On average, the community pharmacist consults with people with diabetes 3–8 times more frequently than other individuals [77]. As a result, in addition to bringing medicines expertise to the team-based care of people with diabetes and performing root-cause analyses of adverse events with diabetes medicines that contribute to the safety agenda, the community pharmacist can lead to a collaborative care approach of managing diabetes and reducing associated cardiovascular risk factors. The use of collaboration can bridge the gap between a successful pharmacy screening programme for diabetes and practitioner follow-up of these individuals [78]. This role can be extended to include individuals in residential care and housebound individuals.

Practice nurses

In primary care settings, chronic disease management is increasingly being performed by practice nurses, with general practitioners intervening only in complex cases [79]. In the case of diabetes, this has become even more necessary because of the increasing prevalence and burden of caring for people with the disease. Despite

the worsening of health-related quality of life and an increase in diabetes-related symptoms, practice nurses can achieve results that are comparable to those achieved by a general practitioner in terms of cardio-metabolic risk factor reduction [79]. Individuals being treated by practice nurses also report being more satisfied with their treatment than those being treated by a general practitioner [79]. The care of people with type 2 diabetes can therefore be safely delivered by practice nurses using clinical guidelines. This makes the nursing team an important resource in a multidisciplinary primary care team. The extension of the practice nurse's role to include the initiation and titration of medications complements their other roles like supporting, educating, and enabling individuals to manage diabetes care, thus ensuring holistic delivery of care closer to home. However, practice nurses can potentially overutilize insulin inappropriately, although this can be limited by close collaborative working between nurses and doctors.

Diabetes specialists

Hospital diabetes clinics developed historically from the need for supervision of insulin treatment. Inevitably they also recruited large numbers of individuals not managed with insulin. The workload thus increased over the decades. With most people with diabetes now being managed in primary care, the specialist's role in insulin management has now been limited to acutely ill individuals with diabetes, including those with diabetic ketoacidosis or acute myocardial infarctions, intensive care-treated individuals, and those on renal wards who need meticulous insulin management to foster early recovery. Individuals with type 1 diabetes or type 2 diabetes who require very complex insulin regimens to manage their diabetes, for example those needing very large doses and those requiring insulin in combination with newer therapies, are best managed by a specialist [80, 81]. Most consultants with a specialist interest in diabetes are based in acute hospitals where they also deliver general medicine, alongside training roles, general management, and research. As a result of these multiple roles, they are well placed to provide multidisciplinary diabetes specialist teams with leadership through support and education to community diabetes services. In some areas the integration of services has made necessary the employment of an increasing number of community diabetes consultants who deliver and coordinate services in a community setting only.

Dietitians

The use of dietary education programmes improves anthropometric measures and glycaemic levels and the use of less prescribed medication [82]. By using improvements in people with diabetes' knowledge of how to self-manage their illness, dietitian-led diabetes management programmes can be an effective strategy for glycaemic management and improving dietary habits for individuals with type 2 diabetes [83]. Registered dietitians contribute greatly to the comprehensive care plans of people with diabetes. They work as members of multidisciplinary teams across various healthcare settings, including primary and specialist care. Their caseload might encompass working with children, adults, young people, and individuals with mental health problems. They also have an important role in the management of those with diabetes and severe obesity. The dietitian can offer support for the management of type 1 diabetes in areas around carbohydrate counting. In primary care, their role could be advising those at risk of diabetes and those with newly diagnosed diabetes on the appropriate dietary requirements. In the case of complex treatment conditions around a person with diabetes

needing initialization or augmentation of insulin therapy, dietetic support is normally needed. Within a specialist care setting they support antenatal and postnatal care of women with diabetes. In individuals with diabetes needing bariatric surgery, they can provide dietary support before and after the procedure. For individuals with mental health issues including eating disorders, dietetic support to maintain weight and glycaemic levels can be sought. On dialysis units and hospital wards, people with diabetes will normally need complex nutritional care, including enteral feeding. The dietitian supports people with complex problems such as gastroparesis and pancreatitis.

Community health workers

Diabetes programmes can include community health workers in the multidisciplinary teams in various roles. They usually reside in the target community and are given special training to help bring health services and education as well as health promotion to their local areas. They also mobilize members of the community to adopt behaviours that improve their overall health and living conditions [84, 85]. This important resource can lead to improvements in the individual's knowledge and behaviour and in some cases even improve biochemical outcomes in diabetes and promote health [86]. The optimal role of peer support of community lay educators is

particularly crucial in low-income underserved populations, including racial and ethnic minority communities [87–90]. Community health workers' knowledge of their language, culture, and geographical communities can be used to coordinate care in partnership with healthcare systems [91]. Their functions include activities such as home visits, health education, and outreach activities for ambulatory care sites [85].

Conclusion

The management of diabetes through the integration of care between primary and specialist centres can result in the creation of new healthcare organizations that provide multidisciplinary diabetes care for their local population. These multidisciplinary teams work together around various areas of diabetes, including pregnancy, adolescence, and older people. Other groups of people with diabetes with specific needs are those with diabetes-related foot ulcers, kidney disease, and retinopathies. The teams comprise general or family physicians, community pharmacists, community health advocates, podiatrists, diabetes specialist nurses, and specialist diabetes physicians, all working seamlessly in a coordinated fashion in the different sectors of a diabetes service.

Key points

Overall Context

- Low- and middle-income countries (LMICs) will see the largest increase in diabetes over the coming years.
- These countries are characterized by lack of financial resources for health and weak health systems, resulting in overall low life expectancy.
- Beyond diabetes and non-communicable diseases, LMICs still face an ongoing challenge regarding communicable diseases.
- Different global declarations and strategies have been developed to address the challenge of non-communicable diseases including diabetes.

- Diabetes care in LMICs requires health systems to have a paradigm shift from providing acute to chronic care.
- Given the distinctions in burden, importance of primary prevention, complexity of management, populations affected, and need for insulin, different approaches are needed to respond to type 1 diabetes and type 2 diabetes.
- Health systems in LMICs are currently not prepared for the management of diabetes and other comorbidities.

Current Challenges

- An overall lack in numbers and of appropriately trained human resources is one barrier to diabetes management in LMICs.
- The data generated by the health system are rarely used to inform planning and responses as they are not collected for these purposes, in addition to there being a lack of research into various areas of diabetes in LMIC contexts.
- Availability and affordability of medicines, insulin, syringes, and blood glucose meters are all challenges in LMICs.
- Delivery of diabetes care is centralized in hospitals and main urban areas.
- Most guidelines in LMICs are inadequate in terms of applicability, clarity, and dissemination plan as well as socioeconomic and ethical-legal contextualization.

- As with guidelines, much of the information provided to people with diabetes is not adapted to the context or reality of LMICs.
- Overall financing for health is insufficient in LMICs with, in many cases, funding for healthcare being dependent on donors and their priorities.
- The global policy agenda for non-communicable diseases can be seen as focusing primarily on prevention versus treatment, as well as failing to provide adequate measures that can be implemented in LMICs.
- Specifically for LMICs, co-management and linkages of diabetes and diseases such as HIV/AIDS and tuberculosis need to be integrated into the health system's responses.
- Beyond disease-related factors, the specificities of vulnerable populations need to be considered.

Ways Forward

- Changes to the health system response will require changes at global, national, and health system level, including the driving principles of integration, continuity, universality, responsiveness, quality, and a focus on the individual.
- Global health policies and funding need to include the prevention and control of diabetes, foster civil society involvement, and work closely with communities.
- National policies need to address the issues of access to medicines, organization of care, human resources, and diagnostic tools.

- Health professionals will require training in diabetes and chronic disease management, including communication skills and patient education, with tasks being assigned to different professionals beyond doctors, including nurses, community health workers, pharmacists, and traditional healers.
- New approaches to data collection, analysis, and use are needed to help in programmatic planning, routine surveillance, and resource management.
- Access to affordable insulin and medicines needs to be guaranteed in addition to diagnostic tests and self-monitoring tools.

- Continuity of care for diabetes includes the provision of comprehensive services and interventions addressing the health needs and the well-being of a person, from their diagnosis to possible provision of palliative care.
- Technology and innovations have the potential to have impacts on all aspects of diabetes care in LMICs, from data collection to education for individuals and possibly service delivery.
- Guidelines, information, and education on self-management for people with diabetes need to be adapted to the context between and within countries.
- Diabetes care in LMICs should be part of a universal healthcare package providing access to medicines and care at affordable or no cost to all individuals, including vulnerable populations.
- Quality mechanisms are required at the policy level and within the health system to guarantee quality control, including accountability measures for the health system and providers, as well as user-related outcomes and performance-based payments.
- The health system should be focused and organized around people, rather than diseases.
- Users of the health system should be included as active participants in the delivery of services and should have channels to actively voice their concerns, to shape health services and policies, as well as to hold health providers and policy makers accountable.

Low- and middle-income countries (LMICs) are defined by the World Bank as countries with an income per capita of less than US\$4045 per person per year [1]. This group comprises 79 countries including Afghanistan, Algeria, Ecuador, Kyrgyzstan, India, Malawi, and Vietnam, with 53% of all countries in the category being located in the World Health Organization (WHO) Africa region. LMICs represented 47% of the total global population in 2019 and in 2018 average life expectancy at birth in these countries was 66.1 years, in contrast to 72.6 years globally and 80.7 in high-income countries (HICs) [2]. There is a noteworthy difference in health expenditure per capita between LMICs and HICs, with on average LMICs spending US\$93.4 (range US\$19.4 in the Democratic Republic of Congo to US\$424.8 in the Federated States of Micronesia) in contrast to US\$5244.1 for HICs.

Globally, it is estimated that 463.0 million people had diabetes in 2019, with this predicted to increase to 578.4 million in 2030 and further to 700.2 million in 2045, with the largest increase in LMICs [3] due to ageing populations, lack of physical activity, and unhealthy nutrition attributed to rapid urbanization [4]. People with type 2 diabetes in LMICs represented 33% of global cases in 2019, and 30% of the estimated 1.1 million children and adolescents (aged 0–19 years) with type 1 diabetes live in LMICs. Therefore, the countries facing the largest increase in the diabetes burden are also those with the health systems that are the least prepared to face this challenge [5].

To respond to the diabetes challenge different global initiatives have been developed. This includes the United Nations' Sustainable Development Goals (SDG) and the WHO's Global Action Plan for the prevention and control of non-communicable diseases (NCDs). At a global level the diabetes agenda is combined with that of NCDs, which for the WHO includes cardiovascular diseases, cancers, chronic respiratory diseases, and mental health conditions. Targets included in these documents include access to medicines, universal health coverage, and decreases in premature mortality. However, very little focus is given to addressing the weaknesses that exist with regard to delivery of diabetes care by health systems in the global diabetes response [6–8]. Therefore, LMICs and their health systems need to address the increasing burden of NCDs in parallel to managing the existing populations with diabetes [4, 6]. This is especially challenging as health systems in LMICs are not adapted to manage chronic conditions, but rather acute diseases [8, 9]. The coexistence of NCDs and communicable diseases, the so-called double burden of disease, means that different needs and health system approaches are required to address the healthcare of populations [10]. However, there are synergies, as many communicable diseases can be

viewed as chronic, such as HIV/AIDS, or have chronic sequelae, such as some neglected tropical diseases [11, 12].

The WHO defines the primary role of the health system as 'to promote, restore and maintain health' [13]. Six components, or building blocks, make up the health system [13]:

- *Healthcare workforce*: the human resources and how they are trained and used to deliver specific services to the population.
- *Information*: data collection and generation by the health system and how these data are used to inform different decisions, as well as how research can help guide health system responses.
- *Medical products, vaccines, and technologies*: how medicines and necessary products are delivered to individuals and issues around their availability and affordability.
- *Service delivery*: how care is delivered.
- *Financing*: how healthcare is financed in a given context – people paying out of pocket for their care, tax-based systems, insurance schemes, etc.
- *Leadership and governance*: how the health system acts as a political actor in shaping health-related policies beyond the immediate health sector.

Each health system is different and its organization is linked to other sociopolitical factors in a given country, meaning that countries take different approaches in delivering each of these components [8].

In responding to diabetes as a whole, it is important to distinguish the health system response for type 1 diabetes and type 2 diabetes. The burden of type 2 diabetes is much more significant than that of type 1 diabetes. For every person with type 1 diabetes there are 455 with type 2 diabetes in LMICs [3]. Different approaches are needed from the health system perspective in addressing these two types of diabetes. First and foremost is the health system's role in prevention. Type 2 diabetes, given its close links with obesity and other common NCD risk factors, requires the health system to play an active role with regard to influencing policies external to the delivery of care, as well as the system playing a vital role in prevention. There is a push by the WHO to decentralize the care of type 2 diabetes to primary healthcare settings and involve the community [14, 15]. Beyond this, there is also the need to ensure that quality of care is improved and that health systems are capable of responding to the complex needs of the populations they serve [16].

In contrast, prevention of type 1 diabetes is not feasible and, in many settings, it remains a condition managed by specialists in tertiary facilities [17, 18]. There are two other important differences between type 1 diabetes and type 2 diabetes from a health system perspective. First, type 1 diabetes is mainly diagnosed in younger populations, although an increase in obesity and type 2 diabetes in

children has been reported even in LMICs [19]. Next, for type 1 diabetes access to insulin is a life-or-death situation, in contrast to type 2 diabetes where insulin is needed for better management. Given these differences, approaches to managing type 1 diabetes and type 2 diabetes from a health system perspective need to address the six building blocks in different ways. That said, many similarities exist with regard to the need for continuous access to medicines, trained health personnel, and the importance of education and empowerment [20]. Another key component is guaranteeing that the financial cost of care and medicines is not a barrier.

What are the current challenges of managing diabetes in low- and middle-income country settings?

Management of diabetes and its coexisting conditions requires long-term care and follow-up of individuals by a trained interprofessional team of healthcare workers, access to medicines and diagnostic tests, empowerment and education of people with diabetes and communities, prevention of cardiovascular disease, information and data management, treatment of complications with referrals between different levels of the healthcare system, including end-of-life care, and coordination between all stakeholders [8, 21]. In comparison to HICs, additional challenges in the management of diabetes in LMICs include low implementation of policies, the lack of trained health professionals and staff shortages, low availability and high prices of medicines and diagnostic devices, consultation fees, and the general economic vulnerability of populations [6, 8, 22–24]. Beyond these factors the overall health systems in LMICs require a paradigm shift to move from providing acute to chronic care [25–28]. Although this challenge is global, the main barrier to implementing the changes needed in LMICs to improve chronic care is linked to the availability of resources [29].

Human resources, information, and medical products

Looking at human resources, the issue faced by LMICs is both in connection to numbers of professionals within the system and the

training they have with regard to diabetes [30]. This is especially true for specialists, with few diabetologists present and these mainly being in major urban areas [20]. In addition, due to its low prevalence many health professionals will be unfamiliar with type 1 diabetes. Surveillance systems are scarce in many LMICs. Much of the data collected at facilities and for individual patients are paper based, with the data generated by the system rarely used to inform planning and responses [8, 30, 31]. Beyond this information generated within the health system, studies are lacking on the diabetes burden, especially type 1 diabetes, and understanding this condition in LMIC contexts [6, 32].

Availability and affordability of medicines, insulin, syringes, and blood glucose meters are challenges in LMICs [23, 33–35]. Availability has been found to be affected by the level of the health system (hospital vs primary healthcare), location (urban vs rural), and sector (public vs private) [6, 23] (Figure 75.1). A wide variation in ministry of health/government purchasing prices has been found [34, 36] (Figure 75.1), which can have an impact on the affordability to the health system [37]. For the individual, mark-ups in the system further affect the affordability of medicines [38]. Affordability for the individual can vary widely, with prices in the private sector being significantly higher than in the public sector. In contrast to HICs, people in LMICs are less able to afford medicines for diabetes, with 27% of households in LMICs unable to afford metformin in contrast to 0.7% in HICs [35]. The same is also true for insulin, with 63% of people with diabetes unable to afford insulin in LMICs, versus 2.8% of people in HICs. The difference in affordability of metformin versus insulin also raises the issue of the impact of different treatment regimens on the overall cost of care for the individual. Globally, one in two people with type 2 diabetes requiring insulin cannot access it, whereas in sub-Saharan Africa this is one in seven people [39]. This highlights a variety of health system factors, including the existence and use of guidelines, healthcare worker training, and the availability and affordability of insulin, which influence overall access and ultimately management and outcomes.

Delivering diabetes care

With regard to the delivery of diabetes care, there is a need to look at the overall organization of care within the health system as well as the organization of the consultation. In many LMICs the

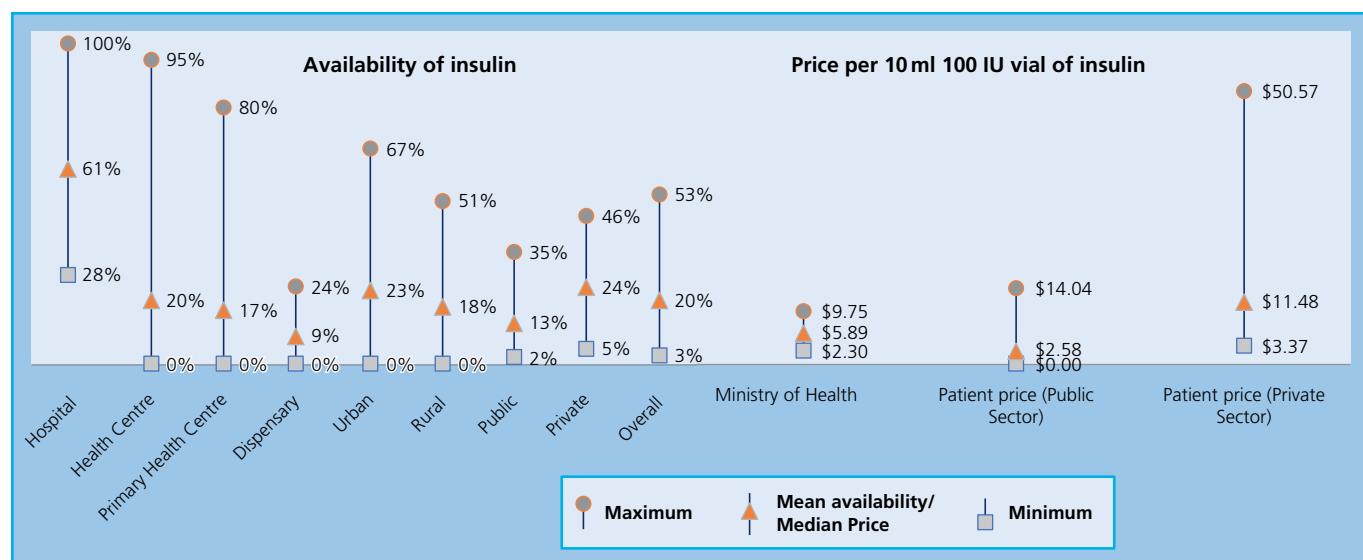

Figure 75.1 Availability and price of insulin at different levels of the health system. Source: Data from Atun et al. 2017 [6].

management of diabetes is centred at hospitals [17, 40], despite WHO guidance focusing on the importance of primary healthcare [14, 15]. Although primary healthcare is seen as a tool to address the majority of the health needs of an individual throughout their life [41], as well as being the focus of renewed political interest in 2018 with the Astana Declaration [42] to celebrate the 40th anniversary of the Alma-Ata Declaration, there has been insufficient investment in primary healthcare and human and material resources are lacking at this level of the health system for appropriate diabetes care [16, 43, 44]. Beyond defining the role of each level of the health system and ensuring that the appropriate resources are available to manage diabetes, challenges exist with regard to the referral system from primary healthcare to hospitals, as well as counter-referrals from hospitals back to primary care [20, 43]. This is especially important for the management of diabetes-related complications. Many services for the diagnosis and care of diabetes are lacking in most LMICs at primary healthcare level and are only available in major hospitals [6].

One issue with the delivery of diabetes care in LMICs is the adaptation and use of clinical guidelines. The WHO's Global Diabetes Report highlights that 71% of countries have a national guideline for diabetes management that is either fully or partially implemented [4]. It has also been reported that most LMIC guidelines are inadequate in terms of applicability, clarity, and dissemination plan, as well as socioeconomic and ethical-legal contextualization [45]. In comparison to guidelines developed and used in HICs, the range of elements included in LMIC guidelines was seen to be limited and the process of development as suboptimal, as well as not following guidance as to what should be included in guidelines.

A key component of diabetes care is information and education about diabetes and how the individual needs to manage their condition for proper self-management. As with guidelines, much of the information provided is not adapted to the context or reality of many individuals with diabetes in LMICs [46, 47]. This was especially true with regard to dietary and physical activity recommendations [46], as well as there being a lack of focus on psychosocial issues [47]. The result of this is that people with diabetes are less likely to follow advice about self-monitoring of blood glucose, physical activity, diet, and medications [47]. Many of these factors are also linked to the availability and affordability of medicines and care. Another factor to consider is the importance of traditional healers and their role in the overall health system [20].

Specifically for type 1 diabetes, different initiatives have enabled the establishment of specific delivery of services, but these focus on children and adolescents and rely on external donations and support for their implementation [48]. This is a problem, as when these young people graduate from these programmes they are unable to afford insulin or other supplies.

Financing and leadership

Overall financing for health is insufficient in LMICs [2] and this is a key element to be able to deliver adequate diabetes care [29]. Funds for healthcare in many LMICs are also dependent on donors and their priorities. Development assistance for health represented 25% of health expenditure in LMICs, totalling US\$38.9 billion in 2018 [49]. However, 2% of this amount was allocated to NCDs, with the majority of this funding being apportioned to maternal and child health and communicable diseases. Much of the funding allows for treatments, for example for HIV/AIDS, to be provided for free, in contrast to diabetes care that needs to be paid for out of pocket [6, 50]. In LMICs 60% of healthcare costs are borne by the

individual through out-of-pocket payments, in contrast to 20% in HICs [29]. Beyond this funding for care, budgets to address NCDs and diabetes within national programmes are lacking. For example, in 2010 only US\$97 000 was allocated to the NCD Department within the Ministry of Health in Mozambique [51] and in Peru 3.2% of the total budget was allocated to NCD programmes, despite this group of diseases representing 66% of overall mortality.

The global policy agenda for NCDs can be seen as focusing primarily on prevention versus treatment, as well as failing to provide adequate measures that can be implemented in LMICs [7]. A study found that 88% of 156 countries examined reported having a national diabetes policy, plan, or strategy [4]. Overall, only 77% of these were funded and implemented, but for LMICs this was less than 60%. A summary of all the challenges present for the health system response in diabetes in LMICs is presented in Table 75.1.

The health response cannot only focus on diabetes

In responding to the challenge of diabetes, the health system response needs to include other health challenges that people with diabetes will face, as well as specific responses to certain populations.

Diabetes and comorbidities

Comorbidities are frequent in individuals with type 2 diabetes, as well as being more numerous in socially deprived individuals, and influence their quality of life [52, 53]. Due to the shared risk factors between type 2 diabetes and other NCDs, people with type 2 diabetes have a higher risk of developing another NCD as well as mental health problems. While the negative interaction between depression and diabetes has been widely studied in HICs, only a few studies have examined the comorbidity of depression in people with diabetes in LMICs, which have an estimated average prevalence of depression of 36%, higher than in HICs (25%) [54].

Beyond this interaction between diabetes and another NCD, there is the additional challenge of the links between diabetes and communicable diseases, such as tuberculosis and HIV/AIDS. People with diabetes are more susceptible to tuberculosis infection [55]; and the actual treatment regimen for HIV/AIDS can lead to the development of diabetes [56]. There is not only the increased risk of these disease interactions, there are also poorer outcomes for people with diabetes affected by communicable diseases [55]. Part of this is due to the fragmentation of care for diabetes and communicable diseases, with diabetes and tuberculosis management for example in Kyrgyzstan being completely separate, leading to increased cost and burden of care for individuals [57].

The Covid-19 pandemic has brought to the forefront the challenges of the continuity of diabetes care as well as the increased risk of people with diabetes suffering negative consequences from a concomitant disease [58–60]. A rapid assessment conducted by the WHO highlighted a disruption to NCD services in three-quarters of countries in all regions and income groups [61]. The impact of Covid-19 was manifold. It affected continuity of access to care due to lack of protective equipment, stocks of medicines, and lack of health workers, in addition to lockdowns prohibiting movement of staff and people and leading to closure of health facilities. In addition, the Covid-19 pandemic influenced the ability of countries to continue to give access to essential health services providing care for diabetes, putting people with diabetes at risk of interruption of treatment and complications. Confinement also meant impacts on diet, physical activity, and mental health, as well as possible delays in seeking care or accessing necessary medicines and supplies,

Table 75.1 Summary of barriers to diabetes management in low- and middle-income countries.

	Healthcare workforce	Information	Medical products	Service delivery	Financing	Leadership and governance
Health system building block	<ul style="list-style-type: none"> • Lack of human resources • Lack of training • Lack of task shifting/sharing • Non-inclusion of traditional healers/medicine in health system responses • Lack of role for pharmacists 	<ul style="list-style-type: none"> • Lack of tools for data collection, analysis, and use 	<ul style="list-style-type: none"> • Availability and affordability of medicines • Availability of diagnostic and monitoring tools 	<ul style="list-style-type: none"> • Overall organization of care • Centralized care in urban areas • Hospitals versus primary care • Lack of adapted guidelines and implementation • Poor integration of education and empowerment activities 	<ul style="list-style-type: none"> • Predominantly out of pocket • Lack of funding of national programmes 	<ul style="list-style-type: none"> • Health system's role in prevention • Lack of policies and strategies • Poor integration of other sectors
Underlying factors						
<ul style="list-style-type: none"> • Overall rates of poverty and socioeconomic conditions with competing priorities • Rapid epidemiological changes • Environmental factors, e.g. access to food and opportunities to be physically active • Low health literacy • Cultural constructs of diabetes as a disease/stigma • Low healthcare funding • Donor agendas • Persistence of communicable diseases 						

either due to government lockdown measures limiting movement or individuals' fears of contracting Covid-19 within the health system [59, 60]. An additional challenge is that the Covid-19 response focused on hospitals, which are usually where diabetes care is provided, thus further limiting access. Beyond these factors specific to diabetes, vulnerable populations also faced financial hardships due to the pandemic further affecting their access to medicines and care.

Specific challenges for vulnerable populations

Covid-19 also brought a spotlight to the challenge of specific populations who can be considered vulnerable and who are often forgotten by health systems, who face additional challenges due to 'individual factors such as sex, age, race, gender, ethnicity, displacement, disability and health status' [62]. For example, in sub-Saharan Africa a higher prevalence of overweight, obesity, and diabetes is found in women versus men [6]. Differences are also seen between men and women when it comes to health-seeking behaviour [63]. Ageing populations are a challenge in LMICs, with a faster rate of ageing than that seen in HICs as well as a lack of mechanisms in place to support this growing proportion of the population with a wide range of health and social needs [64].

Although a paucity of data exists in LMICs for specific vulnerable populations, studies from other contexts shed light on the challenges, for example for Indigenous populations with regard to access to services. In Guatemala a variety of challenges were faced by Indigenous populations in their access to diabetes care, ranging from preference for Indigenous languages over Spanish, lack of knowledge and medical constructs around diabetes and chronic disease, access to medicines, and use of traditional medicine [65].

Migrants are another vulnerable group. Migration has an impact both on the development of diabetes and on access to services [66, 67], with some studies showing that rural-to-urban migration leads to an increased prevalence of diabetes [68] in LMICs. Most studies

on migration and diabetes are from HICs, showing higher rates of diabetes and poorer access to services for migrant versus host populations. These phenomena are probably also present in LMICs for both internal migration as well as people migrating across borders.

Another population to consider is the 125 million people affected by humanitarian emergencies [69]. In these settings, health actors and individuals face challenges providing health services with security and safety concerns, destruction of health facilities, migration and death of health personnel, interruptions in supply chains, and sanctions preventing import of certain equipment and supplies [70].

Inter- and intra-country disparities exist and are driven by the social determinants of health, which are themselves clear drivers of the diabetes epidemic and need to be addressed by the health system [71]. The WHO defines social determinants of health as 'the conditions in which people are born, grow, live, work and age. These circumstances are shaped by the distribution of money, power and resources at global, national and local levels' [72]. In tackling the social determinants of health, the health system actually plays a small role (10–15%) in influencing health outcomes, in contrast to 50–60% that is shaped by social and environmental factors [73, 74].

The issue of equality and the impact of health system gaps

From a global perspective, the situation of both type 1 diabetes and type 2 diabetes highlights global inequalities in access to medicines and care as well as financial protection [75]. This is especially striking for type 1 diabetes, where 2021 marked the centenary of insulin's discovery, yet lack of access to this life-saving medicine still results in life expectancy in LMICs being substantially lower than in HICs [18, 33]. Beyond global inequalities, national inequalities also exist, with better access to diabetes care and medicines in urban versus rural areas [24].

Many HICs provide care for free or at least financial protections to their populations to try to reduce these inequalities [37]. In many LMICs these protections do not exist, and if they do they do not cover all those with diabetes, as many are undiagnosed. In addition, financial protections will be challenged in the future by the increasing burden of diabetes [37]. For example, in Nicaragua care is provided for free to individuals with diabetes. However, diabetes accounted for 5% of the total healthcare budget, even though only one in five people with diabetes was actually diagnosed and managed by the system.

The impact of these gaps results in 48% of NCD-related mortality in LMICs being premature (occurring before the age of 70 years) in contrast to 42% globally, with diabetes causing 4% of these deaths [76]. For type 1 diabetes life expectancy is extremely low in LMICs [20], with for instance one in six people with type 1 diabetes dying within five years of their diagnosis in the Democratic Republic of Congo [77].

This high rate of mortality is due to poor control and lack of access to medicines and care [20] affecting diabetes self-management. For example, in a cohort of people with type 1 diabetes in Tanzania, glycated haemoglobin (HbA_{1c}) was rarely done, but for those individuals where this was measured, the mean HbA_{1c} was 11.1% [78]. This sub-optimal glycaemic management resulted in 22% of this group of individuals having retinopathy and 29% neuropathy, even though the cohort was young (mean age 21.1 years) and had had type 1 diabetes for a relatively short period of time (6.2 years). For type 2 diabetes diagnosis may happen later in the disease progression, with many people being diagnosed already having a complication [6]. In sub-Saharan Africa a wide range of rates of complications has been found, ranging from 7% in Kenya to 63% in South Africa for retinopathy, from 27% in Cameroon to 66% in Sudan for neuropathy, and from 10% in Tanzania to 83% in Nigeria for microalbuminuria.

There are differences in the cascades of care for type 2 diabetes between people who are aware of their diabetes status, those treated for their diabetes, and those who have well-managed diabetes. Figure 75.2 shows that for many LMICs under 60% of people with diabetes are actually aware they have diabetes, and many of those under treatment are not reaching glycaemic targets [79, 80]. In looking at the data in Figure 75.2 for India, sex and geographical

differences can be seen, with women being more likely to be aware, treated, and within target in comparison to men, and people in urban areas faring better than people in rural areas [79]. This highlights the different challenges faced by different populations within the same context, as discussed in what follows.

What are the ways forward?

Looking at the cascades of care, the focus could be on increasing detection of people with type 2 diabetes through screening programmes, although this is not recommended by the WHO [81]. Another approach could be to ensure that all those diagnosed with diabetes are given treatment, but as presented in the previous section, the challenges are significant. The final approach for type 2 diabetes would be to improve services for those already accessing care and medicines and improve overall rates of optimal diabetes management. This would ensure that the investment by the health system and/or the individual in spending resources on medicines, testing, and consultations is utilized optimally, in parallel to building and strengthening the foundations of the delivery of diabetes care for the benefit of people with both type 1 diabetes and type 2 diabetes. Guaranteeing access to insulin and strengthening services for type 1 diabetes through different support programmes has shown a positive impact in terms of survival [82], but challenges remain with regard to glycaemic management [78, 83, 84]. Besides improving care, there is also clearly a need to stem the rising prevalence of type 2 diabetes in LMICs, and this requires the health system to widen its remit and stewardship in influencing other sectors to address the determinants of diabetes.

First and foremost, global health policies and funding need to include the prevention and control of NCDs, including diabetes. The WHO's 2016 Global Diabetes Report (Box 75.1) provides a list of recommendations building on the Sustainable Development Goals and other global commitments. These are far ranging, but highlight the complexity of the issues at hand and that a holistic global policy approach is needed, including early childhood interventions, fiscal policies, and guaranteed access to essential

Box 75.1 World Health Organization global diabetes report

Prepared in 2016 to commemorate World Health Day, the World Health Organization's Global Diabetes Report proposed the following recommendations.

At a policy level

- Create multisectoral commissions at a national level.
- Strengthen ministries of health in their capacity to engage different partners.
- Monitor and evaluate processes established to increase accountability.
- Develop and implement national policies and plans.
- Prioritize preventive measures to address overweight and obesity, including before birth and in early childhood.
- Promote healthy policies and programmes including breastfeeding, addressing the consumption of unhealthy products, such as sugar-sweetened beverages, the built environment, and physical activity.
- Use taxation as a tool to help with this.

At a health system level

- Reinforce health systems, specifically in primary care.
- Develop guidelines and protocols.
- Improve access to medicines and technologies for diabetes management.
- Improve data collection systems and establish diabetes registers.

Source: World Health Organization 2016 [4].

medicines and technologies. Although these are proposed for individual countries, they require global support in order for them to be implemented. At a global level the inclusion of insulin in the WHO's prequalification programme to guarantee quality products on the market and increase competition [85] is a good example of a global measure with possible wide ramifications in particular countries.

For LMICs, changes to the health system response to diabetes will require changes at global, national, and health system level. At each of these levels addressing the growing burden of diabetes as well as access to effective care, including of vulnerable populations, will be needed, with aspects of integration, continuity, universality, responsiveness, quality, and a focus on the individual as driving principles to change the way health systems operate.

Integration as a solution

There are different perspectives on the concept of integration. Integration can happen at policy, health system, or individual levels [86]. From the global level, integration is how to ensure that different health problems are addressed together rather than in silos [87]. Many successes in LMICs, for example regarding HIV/AIDS, have taken a vertical approach where all elements of the health system were strengthened for this health issue, versus taking a horizontal approach and using the resources for HIV/AIDS for all health needs [88]. Any solution will require a health system strengthening versus a health system support approach [89]. Strengthening a health system requires depth in providing more than simple inputs and breadth so to address more than one specific issue,

as well as ensuring that all elements are integrated into the formal health system. One example of health system support activities is the various donation programmes for type 1 diabetes that exist and, although they have had an impact, have yet to be fully integrated into the health system response for diabetes [48].

At a national level, integration needs to happen at the policy, health system, and community levels [9]. The WHO has developed the concept of 'health in all policies' [90], which for diabetes would mean that a wide range of other sectors would be involved in addressing this challenge. This integration of different stakeholders and sectors to address some of the complex issues at hand would also need to include the private sector when looking at issues of access to medicines and technologies. For other diseases affecting LMICs the private sector has played an active role in addressing the challenge [91] and it might be able to also do this for diabetes. It has been proposed in general with regard to delivering health services that private healthcare providers could also play a part in delivering universal health coverage [92].

NCD policies at a national level need to expand beyond health and experts, and foster civil society in order to develop a broader and more inclusive governance structure [7]. Most NCDs, including diabetes, cannot be solved without addressing their determinants, and these determinants lie beyond the health sector and require the involvement of other sectors [93]. In order to operationalize and foster accountability, it is important to invest resources in the development and implementation of policies with clearly established indicators [4]. For example, in order to achieve its goal to improve the health of the population by reducing premature mortality from NCDs by 15% by 2020, Azerbaijan established a high-level national intersectoral coordination mechanism with the involvement of the following sectors: social, agriculture, finance, trade, transport, urban planning, education, and recreation [93]. Interactions with civil society and the private sector are also part of this platform.

There are two main measures at the policy level to prevent diabetes and NCDs that have been implemented in LMICs, and especially in Latin America, which call for such intersectoral collaboration. One policy intervention is front-of-package nutrition labelling and secondary taxation of sugar-sweetened beverages and non-essential energy-dense foods. Another area is the removal of different tariffs and taxes on medicines [38]. These policies require the health sector to work with, for example, the ministry of finance both to use these policy measures to prevent diabetes as well as to generate additional income. The examples of Hungary and Mexico show that taxes on sugar-sweetened beverages were able to decrease the consumption of these products as well as generate additional resources for health [94–99].

In focusing on integration and the delivery of care, the WHO proposes two definitions that include access to care when needed. Care should be user-friendly, focusing on the individual's needs, including a range of preventive and curative services delivered over time and at different levels of the health system, and it should result in positive outcomes and be affordable [87]. This would mean that integrated diabetes care would provide a one-stop shop for all the needs of the individual through a package of defined services that would be made available [87]. In HICs, integration of care often focuses on the delivery of health services in conjunction with social care [86, 100–102]. The areas of integration in HICs include human resources, for example the role of nurses [103–110]; how complementary and alternative medicine can be integrated with allopathic approaches [111];

or the role technology can play in integration [112–123]. In contrast, studies on integration in LMICs have focused on four main areas of integration: integration between services for two separate health issues [124, 125]; using existing services to integrate a new response [126–130]; integrating communities as providers of health services [131–133]; and use of primary healthcare as a platform for integration between different diseases [134, 135].

Looking at the specificities of integration for type 1 diabetes, the focus of integration is around seamless transition through services catering to the different ages of people with diabetes, from paediatric to adolescent and finally adult care [136]. The two other elements addressed with regard to integration are specialists [137] and addressing psychosocial issues [138]. At the level of the health system, one such example of integration from Cameroon was integrating traditional healers in a wide range of roles in diabetes care [139].

To move diabetes care forward in LMICs, integration is needed in its most holistic sense, with the concept of packages of services being delivered, a focus on the individual, links between what is provided by the health system and the population's needs, and the use of inter-professional teams [140]. This can also include bundling of interventions, services, and even medicines and tools. That requires both horizontal integration to link different services within the same facility as well as vertical integration between different levels of the health system. The aim of this integration is to address not only diabetes, but also the full range of health needs an individual may have.

Continuity in addressing the needs of the individual and continuity of care

The aim of integration of care is to ensure continuity of care [86], which from a health system response is another guiding principle for diabetes care in LMICs. This continuity can be seen as continuity over the life course of the individual to avoid exposures to diabetes risk factors at different ages, for instance proper maternal nutrition, breastfeeding, access to food, and proper living conditions during childhood, adolescence, and adulthood. This can be seen as the public health role of the health system. In parallel, there is a continuum of care, an element defined as 'Access to comprehensive services and interventions that address the health needs and the well-being of a person, from the identification of a health condition until the recovery of a functional state consistent with the context' [141]. It focuses on ensuring that those individuals receiving treatment within the health system do so in an optimal way.

Continuity of care is also valued by individuals with diabetes with regard to having regular periodic checks, support and education, developing a relationship with their providers, the services they receive adapting to their needs, and having the same staff care for them and coordinate the services they receive in different health facilities [142]. Such continuity requires the health system to provide continuous access to care, medicines, and diagnostic tools over time and at different levels of the health system [29]. While most people with type 2 diabetes can be followed within primary care, there is still a need to guarantee access to ancillary and specialized services. These services should include for example mental health support, referral to hospital, rehabilitation, and palliative services. Due to access issues especially in rural areas, telemedicine and other options are needed. Palliative care for diabetes in LMICs should be included, due to the lack of services to manage complex complications such as end-stage renal failure. This continuity also needs to go beyond the health system and incorporate the community, which can play a role in the promotion of healthy lifestyles, initiation of treatment, continued monitoring and medication taking,

and long-term follow-up [143]. This role for the community needs to be integrated within the health system and also allow for certain tasks to be shared or shifted from healthcare providers to community members, given the human resource challenges in LMICs. Many national programmes for NCDs in LMICs involve community health workers, who are lay health workers based in the local community. They are frequently involved in prevention (lifestyle modifications) and possibly screening as part of early diagnosis and management [144]. Their involvement together with peer supporters in the self-management of diabetes appears to show some improvements in outcomes. However, the effectiveness of the intervention of this heterogeneous group, with differences in training, supervision, and type of peer support (e.g. face-to-face home visits vs telephone) needs to be further evaluated [145].

Universality in access

Diabetes-related tools should be part of the defined universal health coverage package. In order to achieve this additional funding is necessary in LMICs, but with the aim of caring for the highest possible number of people by making rational choices in using resources. For example, in Kyrgyzstan in 2009 close to US\$740 000 was spent on analogue insulin, which at this time was not included on the WHO's Model Essential Medicines List, equivalent to government spending for 20 000 people. The United Nations (UN) in the Sustainable Development Goals as well as during a special high-level meeting in 2019 has called for universal health coverage to be a driving force of the global health agenda [146]. Within the Sustainable Development Goals, the target is to 'Achieve universal health coverage, including financial risk protection, access to quality essential health-care services and access to safe, effective, quality and affordable essential medicines and vaccines for all'. Within this element two components are important, namely financial protection and coverage of services [147], as well as the funds made available for universal health coverage through different sources [148].

Beyond universal coverage there is also the issue of universality of access in a given context, with different diseases given different priority in different settings. For example, in Cambodia the inequity between people receiving free treatment for HIV/AIDS versus people with diabetes needing to pay for their own care out of pocket resulted in people with diabetes 'wishing they had AIDS' [149].

Quality and responsiveness as driving principles

Improving quality requires policy and system responses [16]. There is a need to have quality mechanisms in place at the policy level and within the health system in order to guarantee quality control, including accountability measures for the health system and providers, as well as user-related outcomes and performance-based payments [9, 16]. Supportive supervision is a key to guaranteeing quality and reinforcing training [150]. This includes measuring the patient experience [88] as well as audits [125]. With regard to healthcare services, quality of care is having present all the elements needed for the proper management of diabetes, from guidelines to trained health professionals, diagnostic tests, and so on, but also the experience of receiving healthcare by the individual [16]. Quality of care includes the notions of being valued, trusted, and adapting to the different needs of people using the health system. Quality of care needs to enhance the services provided to address these three elements.

Aligned with quality improvement is the concept of responsiveness put forward by the WHO, which addresses how well health

systems respond to the expectations of the populations they serve, focusing on the experience of care [151]. Responsiveness, as defined by the WHO, is the 'outcome that can be achieved when institutions and institutional relationships are designed in such a way that they are cognizant and respond appropriately to the universally legitimate expectations of individuals' [151]. Responsiveness includes eight elements: dignity, autonomy, confidentiality, clear communication, prompt attention, quality of amenities, access to social support networks, and choice of self-provider. The concept of trust is also sometimes included as a further element of responsiveness [152]. The main aim of this approach is to focus health system responses on the service experience of individuals [151].

There are four types of continuity that have been described and all of these have a link to the delivery of quality services and guaranteeing that services are responsive. There is longitudinal continuity (the follow-up over time of the individual); relational continuity (having a relationship with the provider[s] that goes beyond just a clinical consultation); flexible continuity (services evolving with the individual); and team continuity (coordination between the different providers and services that the individual needs) [142]. All of these require a quality focus as well as being essential for quality healthcare to be delivered.

A focus on the individual

Health system responses need to focus on the individual, as chronic diseases can be described from the perspective of the individual as a biographical disruption [153], with all elements of daily life being affected by diabetes, such as taking medicines, changing lifestyles, and so on. These changes have been described as needing three 'overlapping galaxies' [154, 155]. The first galaxy is the role individuals themselves need to assume in caring for themselves, taking medicines, and changing their lifestyle. Health professionals comprise the second galaxy by working in interprofessional teams meeting the wide range of care needs the individual may have. Society as a whole is the third galaxy, which has to provide a propitious environment for the individual to manage their chronic disease. These three galaxies and the focus on the individual are important, as for example in Zambia various stressors had an impact on diabetes management [156]. These stressors included poverty, discrimination, keeping diabetes a secret, stigma, lack of family support, and worrying about the future, emphasizing the importance of wider issues that go beyond the health system in having an impact on diabetes. For diabetes and specifically for type 1 diabetes in children, there is a need to involve parents and families. This family outreach has been part and parcel of many HIV/AIDS programmes and can be seen as an area that could be important for diabetes [157].

In addressing the care of people with diabetes, there needs to be a focus on the individual. Managing a child with type 1 diabetes in a rural area of an LMIC is very different to a bank executive in the capital city with type 2 diabetes. Many of the requirements an individual will have for managing their diabetes daily have traditionally been seen as external to the health system [158], but they do have to be addressed to appropriately manage their diabetes. For this, people with diabetes need to be part of the solutions that are developed by the health system to meet their needs [88]. This requires the delivery of quality and responsive care as well as a focus on the individual. With this there is a need to have people-centred health systems [159, 160]. People-centred care involves not only focusing on the delivery of care and involving people in this, but also the governance and decision-making processes [161]. The health system

should be focused and organized around people, rather than diseases. The aim is to address the needs and expectations of people and communities considering the context of people's family, community, and culture [162]. Given that the actual burden of care is on the individual in managing their condition on a daily basis outside the formal health system, this is a challenge for health professionals in the way they provide information and knowledge to the person with diabetes [163]. It requires training, allocating or defining different roles for different health professionals, a team approach to care, and a shift in the role of the health professional from being an expert and providing directives to an individual, to being a mode of support and providing guidance and recommendations to the individual as they care for their diabetes [164].

Within this framework, users of the health system are seen as active participants in the delivery of services and should have channels to actively voice their concerns, to shape health services and policies, as well as to hold health providers and policy makers accountable [165]. Beyond including the individual, there is also an active role for families and the community [9]. The WHO's Innovative Care for Chronic Conditions Framework (ICCCF), a model developed to help health systems transition from acute to chronic care and highlight the different components necessary for this, states that individuals, families, and communities are under-used as resources for the health system [9]. Within the ICCC model individuals, families, and communities are seen as partners to the health system rather than recipients. That is viewed as essential, given that people with diabetes need to be active in their care to ensure proper outcomes. This role given to individuals, families, and communities not only needs to be integral to the interaction between the provider and the person with diabetes, but also engrained within the system and policy context.

In Thailand and Jamaica, different peer-led support interventions with the aim of improving diabetes knowledge have been implemented, including group meetings, education, as well as home visits [166]. Other approaches used community health workers for outreach activities. Community involvement is also an essential component of HIV/AIDS care in LMICs, with care being devolved outside the formal health system to the community and even to people's homes, with lay people trained to provide some elements of care and support [157].

Within addressing the needs of the population, two approaches could be integrated into those developed by the health system. The first is to take a needs-based approach. This has been described for type 1 diabetes [158, 167]. The focus would be laid on the more pressing needs first and a hierarchical approach taken to meeting these. For example, ensuring that insulin is available, because it is necessary for survival, could be done through different means, including universal health coverage policies and policies beyond the ministry of health, which might address the cost of insulin, supply systems, organization of care, and so on. At a later stage, once the essential survival needs are met, more complex needs around tailoring of education and fully integrating the community would be addressed.

Another approach is to involve people with diabetes in developing solutions within the health system to meet their needs, instead of these being driven by policy makers, healthcare providers, or other experts. So called co-creation or co-design approaches where the beneficiaries are directly involved in developing solutions [168] can also be a tool for involving people with diabetes in addressing the challenges they face, as has been done in HICs [169]. Involvement of communities in the organization of services

delivered by primary healthcare leads to these being of better quality, more frequently used, with increased accountability, as well as improved health outcomes [161]. In HIV/AIDS programmes developed and implemented in LMICs, people living with HIV/AIDS played an important role in supporting the health system, their peers, and advocacy-related activities [157]. Through this involvement not only were these initiatives focused on the individual, they also addressed many challenges around the stigma associated with HIV/AIDS.

How can this be achieved?

Lessons from Mozambique and Kyrgyzstan show that in order to improve the health system for diabetes certain elements are needed [8]. First, it is important to have wide-ranging legal and policy documents to address the issues of access to medicines, organization of care, human resources, and diagnostic tools. Secondly, with regard to organization of care, for type 2 diabetes both countries are trying to shift diabetes care to primary healthcare with a focus on training of health personnel. In tackling the issue of access to medicines, the role of diabetes associations, professionals, and research has assisted in documenting and then acting on the barriers present.

Human resources are a key component in addressing diabetes in LMICs. Thus, training should be integrated into the curricula of doctors and nurses in medical and nursing faculties as well as in continuing professional development [21]. This would include clear definitions of tasks, including task sharing or shifting [170], with redistribution of certain tasks from doctors to nurses as well as from specialists to primary care physicians [171]. This would allow a redistribution of the workload and would benefit from the complementary strengths of each professional in the provision of care. Task sharing is effective in other fields such as antenatal care and in HIV/AIDS and tuberculosis programmes [166]. The role of nurses and other health professionals should be fostered, with this training being based on clear, applicable, and socioeconomically contextualized guidelines [45]. In addition, the inclusion of pharmacists in interprofessional teams could also be used to improve access to care [172]; the same applied to traditional healers [20].

A recent systematic review and meta-analysis of health system interventions in LMICs aiming to improve outcomes in people with diabetes found that health system interventions for type 2

diabetes may be effective in improving glycaemic management. Multicomponent clinic-based interventions had the strongest evidence for glycaemic benefit among intervention types [32]. Other examples of health system interventions were pharmacist task sharing, diabetes education or support alone, and nursing case management interventions, among others. The WHO's Package of Essential Noncommunicable Disease Interventions (WHO-PEN) for primary care settings includes protocols for the management of major NCDs, as well as a list of diagnostic tools and medicines required at this level of the health system [14] (Box 75.2). Some lessons learnt during the Covid-19 pandemic, such as triage to select those most in need of face-to-face consultations, use of telemedicine, task sharing/shifting, decentralized distribution of medicines, and redirection to alternate facilities, could become the new normal to address current challenges in access to care [59].

In linking training with the delivery of services, there is also a need for training in the management of chronic conditions, patient education, and communication [173]. This requires not only clinical competencies, but also organizational and personal skills development. Each element of service delivery needs to be organized with the individual in mind, from the consultation to the diabetes clinic if a special clinic is part of the services provided, to the given facility as well as referrals and counter-referrals. Diabetes care needs to be incorporated into the services offered within primary care, in addition to providing general primary care services, in facilities that are safe and of good quality. Care provided covers basic chronic care including health promotion, identification and management of risks, and patient education in self-care and treatment of diabetes and comorbidities, with the possibility of referring on in case of need [174].

A key element of the delivery of care is the collection of data at different levels of the health system and for different purposes. This goes from patient data to help in the management and follow-up of an individual to facility and even subnational and national data as part of a routine surveillance system, allowing for the improvement of programmatic planning and resource management (e.g. human, medicines, laboratory), as well as helping in the planning and procurement of medicines and other supplies. For patient-related data, creation of health passports containing medical information and appointment dates might be an option to guarantee continuity of information for a given individual [22]. Research is also needed to further document the burden as well as to test adapted solutions for LMICs [6].

The final component to the delivery of care is of course access to medicines, which is especially important for type 1 diabetes, as access to insulin is vital for survival. Medicines for diabetes should be available as close as possible to the individual at an affordable price, if not for free. This requires policies to be in place around universal health coverage as well as regulation of prices and mark-ups within the health system. In parallel to medicines there is also a need to have different laboratory tools and tests available (Box 75.2), with these being adapted to the level of the health system as well as affordable to individuals.

Innovation and new technologies = new opportunities?

Technology and innovations have the potential to affect all aspects of diabetes care in LMICs, from data collection to education for individuals and possibly service delivery. LMICs need to create and implement new information technologies to take decisions based on their own evidence. However, data collection, periodic analysis,

Box 75.2 Elements of the World Health Organization Package of Essential Noncommunicable disease interventions (WHO-PEN) for diabetes.

WHO-PEN provides a comprehensive set of tools for the management and care of non-communicable diseases, including diabetes, in primary healthcare.

interpretation, and use have to be systematic and if possible automated [8]. The introduction of technological innovations such as digital health strategies with decision support tools [175], including patient reminders with health education messages through text messages, or automated monitoring and self-care support calls, is facilitated by mobile phones, which are easy to use and widely available, even in LMICs [22]. While access to care might be challenging in remote areas, provision of contextualized digital technology services to patients, such as text messages, improves diabetes outcomes (i.e. HbA_{1c}) and gives patients a feeling of being cared for [176]. Telehealth gained traction during Covid-19 for the management of diabetes [177] and in HICs has been used to address the shortage of healthcare specialists [178]. Electronic records are also a tool that can address a gap in the health system environment in LMICs in collecting data and in ensuring their use to improve the quality of care [179].

One area where innovation has been described is with regard to diagnostic tests, either standalone or in conjunction with other mobile devices [6]. Devices attached to mobile phones, for example for eye complication screening, are other innovations that can help improve diabetes care in LMICs. Many of these new technologies or solutions have only been piloted in LMICs, requiring further evidence as well as the feasibility of scaling up [180], for instance the use of foot thermometry and mHealth for the prevention of foot ulcers [181]. Innovation could include heat-stable insulin and self-monitoring equipment, in addition to monitoring tools adapted to LMIC contexts. Beyond innovation in new technologies, innovation in delivery of care should not be neglected [182], as well as ensuring that innovations are equitably accessible, as even though insulin was discovered 100 years ago it remains inaccessible to many.

Conclusion

The WHO defines health as total social, psychological, and physical well-being [183]. In order to achieve health for the populations they serve, health systems need to adapt their role to meet the needs of their populations. Despite having seen success in addressing a variety of health challenges for populations in LMICs, such as maternal

and child health and HIV/AIDS, the responses to date for diabetes have been insufficient. This is due to the various barriers described (Table 75.1). Clearly, one issue to be addressed is funding for diabetes in order to ensure that the financial burden does not fall on the individual. For LMICs this requires both governments and donors to act together. Although there have been global calls regarding diabetes and NCDs, as of yet these have not been answered with adequate resources and approaches. Much focus has been given to addressing the increasing burden of type 2 diabetes, to the detriment of addressing the challenges within the health system. Evidently there is a need to stem the rising prevalence of type 2 diabetes, but this should both involve the health system and not avoid the complex issues around addressing access to care.

This focus on health systems and diabetes care both is an issue of equality and needs to differentiate between type 1 diabetes and type 2 diabetes. For type 1 diabetes, without access to insulin and care survival cannot be guaranteed. Given that 2021 was the centenary of insulin access, this needs to feature prominently on both global and national agendas. The approach should focus on ensuring that people who have been diagnosed with type 1 diabetes can access care in an optimal way. This would guarantee that the investment in providing care that both the health system and the individual pay for is optimized. It would also benefit people with type 1 diabetes and type 2 diabetes in laying the foundations for improved access to care.

In developing global and national health system and community responses, there is a need to understand the current situation with regard to the health system and its capacity to deliver diabetes care. Using the six health system building blocks as pillars for this response, policy makers, professionals in the health system, diabetes associations and advocates, and individuals with diabetes need to ensure that the principles of integration, continuity, universality, responsiveness, quality, and a focus on the individual are all part of the solutions proposed to address this complex issue (Table 75.2).

All these components will be needed for better use of resources to guarantee access to diabetes care for all, including vulnerable populations. Diabetes in LMICs is a global health problem that can no longer be ignored and will require global, national, health system, community, and individual responses. All these responses

Table 75.2 Overview of solutions.

Healthcare workforce	Information	Medical products	Service delivery	Financing	Leadership and governance
Integration					
Optimally use human resources: nurses, community health workers, pharmacists, traditional healers	New technologies Data for programmatic planning, routine surveillance, and resource management Registers	Role of pharmacists Point-of-care devices available at different levels of care Bundling	Packages of services beyond diabetes	Public and private sources of funding Strengthening primary healthcare Removal of different tariffs and taxes on medicines Collaboration between ministry of health and other government sectors Taxes on sugar-sweetened beverages as a means of resource generation	Multisectoral approaches Strengthening primary healthcare and health system's role in prevention and beyond the health sector

(continued)

Table 75.2 (Continued)

Healthcare workforce	Information	Medical products	Service delivery	Financing	Leadership and governance
Continuity of care					
Training in chronic disease management Task sharing	Data follow the individual and are available where care is provided	Ensure continuous access and affordability	Models of care guarantee continuity of care across diseases and levels of the health system	Financial coverage from prevention to treatment rehabilitation and palliative care, with a specific focus on primary healthcare	Focus on primary healthcare, defining complications covered by universal health coverage
Universality					
Healthcare workers sensitized to issues of universality	Health system data assist in guaranteeing universal access	Equitable access	Non-discriminatory health system Decentralization	Financial protection from the costs of care	Universal health coverage features prominently on the agenda
Quality and responsiveness					
Training in provision of care Training in organization of care Training in management of primary healthcare Supportive supervision Focus on the individual Training in communication skills Training in patient education	Data collection allows for monitoring of quality and responsiveness Digital support tools for decision making Data follow the individual Digital support tools	Prequalification, essential medicines, and technologies Self-management and control Simplified guidelines/ modes of delivery/storage User-friendly, adapted, and thermostable medicines and devices	Implementation of chronic care services with referral mechanisms Audit of services Tailoring of services to meet the individual's needs	Performance-based payments Health insurance schemes covering care for non-communicable diseases	Accountability measures for the health system and providers Better primary healthcare management Accountability to the individual Involvement of individuals, families, and communities in defining priorities and models of care

should actively involve individuals with diabetes in order to ensure that the strategies developed address specific challenges that are context and person specific. Margaret Chan, the former Director-General of the WHO, stated in 2011: 'Building a health system takes time, and improvements are difficult to measure. But this is the one area where investments are most desperately needed. . . . Health

systems are social institutions. They do far more for society than deliver babies and pills, like a post office delivering parcels. Properly managed and adequately financed, a fair and equitable health system contributes to social cohesion and stability' [184]. Therefore, for the reality of diabetes to fundamentally change in LMICs, health systems need to be at the centre of the response.

Key points

- Type 1 diabetes is a chronic immune-mediated disease causing death of the insulin-producing pancreatic β cells. The progressive loss of β cells is mainly caused by autoimmune inflammation.
- An even deeper understanding of the immunopathological processes of type 1 diabetes is needed to tailor innovative and more efficient immunotherapies.
- One of the major obstacles to success is that increasing data suggest that type 1 diabetes is a heterogeneous disease.
- Current preventive immunomodulating therapies close to the clinical onset of type 1 diabetes seem, at best, to induce a temporary effect, with the long-term outcome being less satisfactory.
- Not all participants in the preventive type 1 diabetes trials conducted so far have benefited from the tested intervention. New strategies are warranted to identify responders versus non-responders and the development of better biomarkers.
- The timing of the immunotherapy in relation to the different stages of type 1 diabetes progression needs further exploration.
- Immunotherapy, as combination treatment designed to interact with different targets involved in the type 1 diabetes pathogenesis, has potential advantages over monotherapy: it allows lower doses of *riskier* agents, and has fewer side effects, as seen within other complex diseases.

Type 1 diabetes is a chronic immune-mediated disease, causing attrition and death of the insulin-producing pancreatic β cells, resulting in a life-long requirement for exogenous insulin. The progressive loss of β cells is mainly caused by autoimmune inflammation. The aetiology and pathological mechanisms remain to be completely understood. Type 1 diabetes has a strong genetic component, where contributions from several genes influence disease development [1]. In addition to genetic predisposition, environmental and epigenetic factors influence disease susceptibility [2, 3]. Worldwide more than 20 million people are afflicted with type 1 diabetes and in most countries type 1 diabetes incidence is increasing by 3–4% every year, most notably in children and adolescents [4]. This globally rising incidence of type 1 diabetes calls for effective preventive measures. The main obstacles to the successful prevention of type 1 diabetes are:

- Incomplete understanding of the disease pathogenesis.
- Heterogeneity of type 1 diabetes.
- Lack of biomarkers for cost-effective screening of first-degree type 1 diabetes relatives and within the general population.

The dilemma is that in the early stages of the disease process more effective interventions may be used, but the disease prediction is poorer, and a larger population is predisposed to potential side effects of the treatment. In contrast, in later stages the disease prediction is more precise, but applicable interventions are less effective due to the already advanced disease process.

The presence of genetic polymorphisms of human leucocyte antigen (HLA) complex and multiple autoantibodies, which appear

early in life, are highly predictive of type 1 diabetes [5]. Currently, best-practice genetic screening for HLA risk haplotypes identifies individuals at risk of type 1 diabetes and the presence of autoantibodies informs its progression.

Despite modern treatment regimens that increasingly embrace advanced technology [6], mortality in people type 1 diabetes with excellent glycaemic indices (glycated haemoglobin [$\text{HbA}_{1\text{c}}$] <6.9%; 52 mmol/mol) is still twice that of matched individuals without diabetes, increasing to more than eight times higher risk in severely dysregulated type 1 diabetes [7]. Hence, there is an urgent need to explore disease-modifying strategies [8].

Type 1 diabetes as an autoimmune disease

As described in depth in Chapter 14, the β -cell autoimmunity in type 1 diabetes is characterized by an inflammatory response with a progressive infiltration of several immune cells within the pancreatic islet [9]. This disease process typically begins years prior to the presentation of overt type 1 diabetes [10]. The immune cells involved in the process are CD4 $^{+}$, CD8 $^{+}$ positive T cells, macrophages, dendritic cells, and B cells [8]. However, a reported lack of T-cell infiltrates in human pancreata implicates the heterogeneous nature of the immunopathology [11]. This is supported clinically by the rapid and severe type 1 diabetes development in children and adolescents [12], with a broader and more aggressive

β -cell-specific T-cell response as opposed to the development of type 1 diabetes in adults [13, 14]. There is an imbalance between the T-regulator (Treg) cells and T-effector cells [15], as well as dysregulation of the antigen-presenting cells [16], exhibiting proinflammatory properties driving a skewed differentiation of naïve T cells towards pathogenic T-effector cells, as well as directly being part of the islet inflammation and β -cell destruction by interleukin-1 (IL-1), tumour necrosis factor- α (TNF- α), and interferon γ (IFN γ) production [17, 18]. Type 1 diabetes autoantibodies against multiple targets include insulin (IAA), glutamate decarboxylase (GAD), islet antigen 2 (IA-2), and the zinc transporter 8 (ZnT8); these are merely disease markers and do not damage the β cells [19]. Notably, the CD4 and CD8 T cells recognize the same epitopes. Furthermore, there seems to be a critical role of the β cells functioning as antigen-presenting cells [19, 20], especially as part of the cellular infiltrate before the age of 7 years [21]. Finally, the contribution of the β cell itself in type 1 diabetes seems to be complex, as the β cells are involved by the upregulation of HLA, self-antigen presentation, and secretion of chemoattractant molecules attracting and focusing T cells with a cytotoxic potential [18, 22]. This leads to β -cell damage, probably giving rise to post-transcriptional or post-translational modified islet proteins acting as strong triggers of T-cell activation [23], giving the islet infiltrate and β -cell damage further momentum; hence the β cell seems to interact with the immune system in an unfavourable way.

Definition of the natural history, staging, and how to evaluate disease progression by different biomarkers

Genetic characterization in terms of genome-wide association studies can be used to identify individuals at risk of developing type 1 diabetes, where the HLA system (in particular DR-DQ) is attributed to approximately half the genetic risk [1]. A combination of HLA and non-HLA gene polymorphisms in polygenic risk scores improves prediction, and it has been estimated that 77% of future cases could be identified by following 9.6% of screened children [24]. Using this approach, population-based screening identifies newborns with ~10% risk of developing autoimmunity before the age of 6 years.

Type 1 diabetes is the common endpoint of T cell-mediated destruction of pancreatic β cells, but the variability in clinical phenotype and pre- and post-onset rate of β -cell decline suggests the presence of multiple underlying pathways. Age is a strong but imperfect predictor of C-peptide decline [21]. Variability in β -cell decline mandates longer and larger clinical trials to power the most common primary outcome measure of stimulated C-peptide area under the curve (AUC). Early identification of *rapid progressors* would permit shorter studies with fewer participants and reduce the risk-to-benefit ratio.

Finally, there is increasing recognition of distinct endo-types in those with recent-onset type 1 diabetes, reflective of varied pathology. Improved understanding of these endo-types and the development of relevant biomarkers will permit targeted therapeutic interventions [14, 25].

The pre-clinical phase of type 1 diabetes is divided into two distinct stages:

- Stage 1: defined as β -cell autoimmunity with two or more positive islet autoantibodies with normal glucose metabolism.

- Stage 2: characterized by autoantibody positivity and glucose intolerance.

Stage 3 (phase two) defines the clinical diagnosis with clinical manifestations of type 1 diabetes [26] (Figure 76.1). This staging may pave the way for better-targeted intervention strategies. As demonstrated within The Environmental Determinants of Diabetes in the Young (TEDDY) and the Finnish Diabetes Prediction and Prevention (DIPP) studies, a clear relationship exists between the number of positive autoantibodies and the risk of later clinical type 1 diabetes, with a five-year risk of progression to overt type 1 diabetes of 11%, 36%, and 47% in individuals with one, two, or three autoantibodies, respectively [27]. At stage 3 more than 90% are positive for at least one autoantibody against either IAA, GAD, IA-2, or ZnT8 [28].

Beyond genetics and autoantibody positivity, T-cell biomarkers have the potential to characterize the underlying pre-type 1 diabetes progression, onset, and response to intervention initiatives [29]. A better understanding of the T-cell receptor repertoire of the pathogenic T cells has the potential to serve as a surrogate marker reflecting the efficacy of forthcoming immunotherapy interventions.

The β cells themselves may have an important role in driving the autoimmune process leading to clinical type 1 diabetes. As described earlier, a complex interaction takes place between the β cells and the immune system during the pathogenic processes [23, 30, 31]. As a cell type with a high biosynthesis rate, the β cell seems especially vulnerable to stress-induced changes during inflammatory events and altered β -cell physiology has been noted once the autoimmune process is ongoing, which might accelerate β -cell killing [32]. Furthermore, immune-histopathological human studies demonstrate a disconnection between β -cell function and β -cell mass in the pancreas of humans with type 1 diabetes. Despite a severe decrease in C-peptide production, insulin-positive cells can still be identified in significant numbers in many individuals with type 1 diabetes in the years following diagnosis [33, 34]. Hence, all the β cells may not be destroyed; instead, the remaining β cells might be dysfunctional [35], and the balance between β -cell loss and β -cell dysfunction could be individual.

Prevention of type 1 diabetes

The prevention of type 1 diabetes can be divided into four stages (Figure 76.1):

1. Primary prevention before the onset of islet autoimmunity.
2. Secondary prevention before the diagnosis of type 1 diabetes.
3. Tertiary prevention in individuals with newly diagnosed type 1 diabetes to preserve residual β -cell function.
4. Late prevention of secondary complications in established type 1 diabetes and attempts to revive lost β -cell function.

The vision is to discover a primary prevention approach safe enough to be administered to the general childhood population without the evaluation of disease risk [26]. A lead candidate for such a measure would be a preventive vaccine for early immunization [36]. To date, prevention trials carried out in human populations have demonstrated only limited success in achieving their goal [37]. Some past and ongoing trials are summarized in Table 76.1. The most promising results have been achieved in studies of teplizumab [49], rituximab [54], alefacept [59], abatacept [60], and anti-thymocyte globulin [57]. A transient benefit after the administration of oral insulin was seen in a subgroup of individuals with high IAA levels in the Diabetes Prevention Trial-Type 1 [61], details of which are given later.

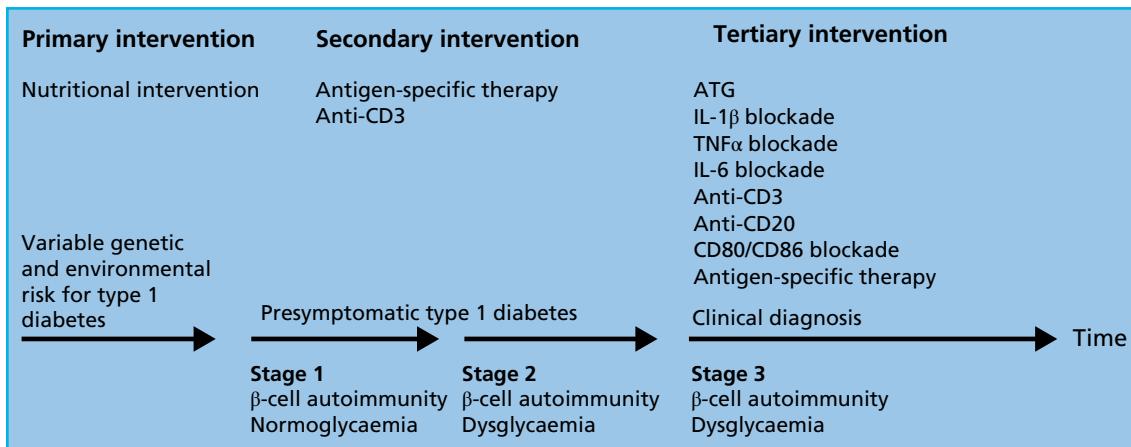

Figure 76.1 Stages of type 1 diabetes, with corresponding interventions and intervention approaches. Type 1 diabetes is a continuum that begins prior to symptomatic disease with well-defined, reproducible early stages. Stages 1 and 2 are defined by the presence of multiple autoantibodies. Different intervention strategies apply to these stages. Examples of immune therapy approaches used at the different stages are shown. ATG, anti-thymocyte globulin; IL, interleukin; TNF- α , tumour necrosis factor α .

Table 76.1 Some previous and ongoing trials aimed at preventing type 1 diabetes.

Study	Intervention	Stage	Outcome achieved	Reference/ClinicalTrials.gov identifier
TRIGR	Hydrolysed casein formula	Primary	No	[38]
BABYDIET	Gluten-free diet during first year	Primary	No	[39]
Pre-POINT	Oral/intranasal insulin	Primary	Yes (immune response to insulin)	[40]
DIPP	Intranasal insulin	Secondary	No	[41]
DPT-1	Oral insulin	Secondary	Transient benefit in subgroup with high IAA levels	[42]
DPT-1	Parenteral insulin	Secondary	No	[43]
Belgian Diabetes Registry	Subcutaneous insulin	Secondary	No	[44]
TrialNet	Oral insulin	Secondary	No	[45]
INIT-II	Intranasal insulin	Secondary	Ongoing – rate of new diabetes	NCT00336674
ENDIT	Nicotinamide (vitamin B ₃)	Secondary	No	[46]
DENIS	Nicotinamide	Secondary	No	[47]

DIAPREV-IT2	Alum-GAD + vitamin D ₃ 2000IU/d	Secondary	Ongoing – rate of new diabetes	NCT02387164
TrialNet	Teplizumab	Secondary	Yes – rate of new diabetes	[49]
TrialNet	Teplizumab	Tertiary	Yes	[50]
TrialNet	Abatacept	Tertiary	Yes – Stimulated C-peptide at the 2-yr visit	[51]
TrialNet, AIDA	Canakinumab, anakinra	Tertiary	No	[52]
TrialNet	GAD vaccine	Tertiary	No	[8]
TrialNet	Mycophenolate mofetil/dacizumab	Tertiary	No	[53]
TrialNet	Rituximab	Tertiary	No long-term effect	[54]
DEFEND-1	Otelixizumab	Tertiary	No	[55]
T1DAL	Alefacept	Tertiary	Yes – stimulated C-peptide	[56]
TrialNet	Anti-thymocyte globulin	Tertiary	Yes – stimulated C-peptide at 1- and 2-yr visits	[57]
T1GER	Golimumab	Tertiary	Yes – stimulated C-peptide at 1-yr visit	[58]

GAD, glutamate decarboxylase; IAA, insulin.

Immunotherapy approaches

The first proof-of-concept studies indicating that immunotherapy could be a way of preserving β -cell function came from the use of cyclosporine in new-onset type 1 diabetes, which was first tested in the 1980s [62, 63] and successfully prolonged the remission phase.

However, due to severe side effects, mainly nephrotoxicity, the use of cyclosporine ceased. Later on anti-lymphocyte globulin and small molecules (cyclosporine, azathioprine, and glucocorticoids) were commonly used in a regimen as a means of non-specific immunosuppression for β -cell preservation in individuals with type 1 diabetes or in islet transplantation [64]. While glucocorticoids are widely used as an immunosuppressive steroid to treat autoimmunity [65], it is

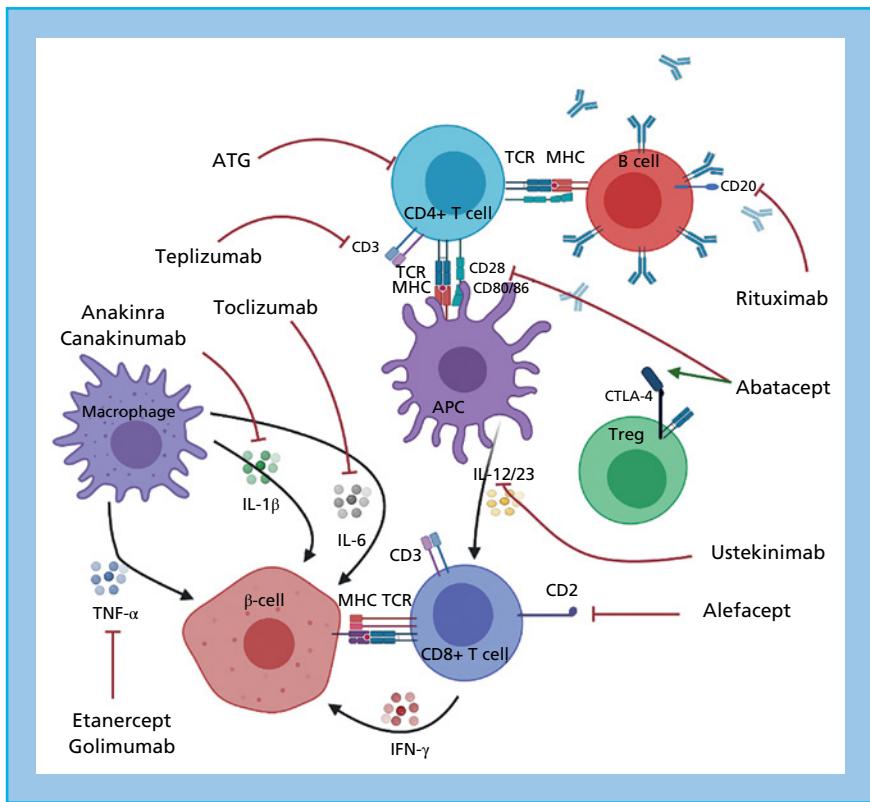

Figure 76.2 Mechanisms of immunotherapy in type 1 diabetes. A simplified model of the pathogenesis of type 1 diabetes showing the β cell and immune cells with the targets of different immunotherapies. Immune therapy targets are shown on one cell only despite the targeted receptor, e.g. CD3, potentially being expressed on several cell types. ATG, anti-thymocyte globulin; IL, interleukin; MHC, major histocompatibility complex; TCR, T-cell receptor; TNF- α , tumour necrosis factor α .

increasingly clear that glucocorticoids adversely stimulate gluconeogenesis in the liver and antagonize the insulin-mediated uptake of glucose [66]. The induction of peripheral insulin resistance is counterproductive to the desired effect of β -cell preservation. A major improvement in immune suppression treatment was introduced with the Edmonton protocol, which used a glucocorticoid-free regimen comprising sirolimus, tacrolimus, and daclizumab [67].

Today most immunotherapies in type 1 diabetes are based on the known pathogenetic mechanisms underlying the development of the disease (Figure 76.2). These targeted therapies and their outcome at various stages of type 1 diabetes development are detailed in what follows. They can broadly be divided into non-antigen or antigen-specific intervention strategies, the former including T-cell and B-cell as well anti-cytokine targeting modalities.

Targeting T cells

CD3 blockade (teplizumab and otelixizumab)

Mode of action

Teplizumab and otelixizumab are non-activating, Fc-modified, anti-CD3 monoclonal antibodies thought to attenuate activated autoreactive T cells. Such T cells disappear from the peripheral circulation during immunotherapy, but return within weeks after the end of treatment. Pre-clinical and clinical studies in type 1 diabetes suggest that the drug may induce Treg activity, indicating augmented immune tolerance. Hagopian et al. demonstrated that the effect of the anti-CD3 monoclonal antibody seems to be mediated by transient reduction in the CD4 $^{+}$ and CD8 $^{+}$ cells during the cycle of treatment. Both may be relevant mechanisms of action of teplizumab, wherein the T-effector cells, which are maintaining an inflammatory environment in the pancreas, are preferentially

depleted while Tregs are favoured [68]. Later, expansion of CD8 $^{+}$ Tregs and CD8 $^{+}$ T-effector cells exhibiting an exhausted phenotype has been reported [69].

Pre-diabetes studies

The use of teplizumab in TrialNet (TN-10) in first-degree relatives of individuals with type 1 diabetes was the first trial to meet its clinical endpoint of delaying the onset of type 1 diabetes [49]. At the end of the trial, 25 of the 44 participants in the intervention group (57%) were diabetes free. The longest follow-up was >5 years (88 months). The annual incidence rates of type 1 diabetes were 14.9% and 35.9% in the teplizumab versus placebo groups, respectively ($p = 0.006$). The two-year delay in diagnosis is clinically important, as any time without clinical diabetes has significance, particularly for children, who were ~70% of the study participants ($n = 76$ in total). Notably, biomarkers identified those participants most likely to respond to the treatment. Repeated dosing, or combinations of teplizumab with other agents with complementary mechanisms of action likely to increase the ability to delay or prevent the progression of clinical disease, are warranted in the future. In November 2022, the FDA approved teplizumab injection to delay the onset of stage 3 type 1 diabetes in adults and children aged 8 years and older who currently have stage 2 type 1 diabetes.

New-onset studies

Anti-CD3 treatment has been tested in individuals with newly diagnosed type 1 diabetes in various formulations (teplizumab and otelixizumab), designs (one or multiple administrations), and doses. Generally, a greater β -cell preservation with a slower decline in C-peptide over time was demonstrated; however, dose dependency in relation to C-peptide preservation and adverse effects seems to exist. A recent meta-analysis including eight randomized

trials comprising 866 participants demonstrated a higher value of C-peptide AUC at 24 months, but no difference in HbA_{1c} could be demonstrated at any time point (onset to 24 months) between the teplizumab group versus placebo [70].

In a study by Keymeulen testing 48 mg otelixizumab in 80 randomized individuals with type 1 diabetes aged 12–39 years, higher C-peptide release at 18 months was demonstrated in the intervention group versus placebo, but no difference in HbA_{1c} between the groups was seen [71]. In a four-year follow-up study, lower exogenous insulin doses were observed within the intervention group, with higher C-peptide response to a glucose clamp among the youngest age groups within the otelixizumab-treated individuals [72]. The dose of 3.1 mg otelixizumab has also been tested in the Durable-response therapy Evaluation For Early- or New-onset type 1 Diabetes (DEFEND-1 and DEFEND-2) studies, but C-peptide preservation was not demonstrated [55, 73]. A recent randomized, single-blind, placebo-controlled, 24-month, dose-response study (16–27 years old, <32 days from diagnosis of type 1 diabetes) using otelixizumab (cumulative intravenous [IV] dose 9, 18, or 27 mg over 6 d) demonstrated that the adverse effects were dose dependent and only the dose of 9 mg otelixizumab led to a change from baseline mixed-meal tolerance test C-peptide weighted mean AUC at 18 months (difference from placebo 0.39; $p = 0.023$); no β -cell function preservation was seen with otelixizumab 18 and 27 mg [74].

The other CD3 blocking agent, teplizumab, was tested in a two-course administration design (Autoimmunity-blocking Antibody for TolErance in recently diagnosed type 1 diabetes [AbATE] study; cumulative dose 11.6 mg and 12.4 mg at baseline and after one year) comprising 52 actively treated versus 25 placebo individuals with newly diagnosed type 1 diabetes (aged 8–30 years), with the first dose being given within eight weeks post-diagnosis. At 24 months the baseline (at entry) adjusted mean C-peptide AUC levels were 75% higher in the intervention group versus control; however, no difference in HbA_{1c} between the groups was demonstrated at 24-month follow-up. Within the group defined as responders (45% of the total intervention group who had lost less C-peptide than the control group), lower HbA_{1c} at entry of the study was demonstrated [50]. These findings were confirmed within the Protégé study comprising >500 participants [68]. The one-year responders from the 2013 Herold et al. study maintained a higher C-peptide at the seven-year follow-up compared to the placebo group, still without any difference in HbA_{1c} [75].

Safety

Adverse drug-related events were transient and resolved spontaneously. Fever, nausea, vomiting, rash, and headaches as well as mild forms of cytokine release syndrome were observed, and transient increases in the viral load of cytomegalovirus (CMV) and Epstein-Barr virus (EBV) were measured in drug-treated participants who were seropositive at study entry. Mild transient cytopaenia and small increases in transaminases were also seen.

CD2 blockade (alefacept)

Mode of action

Alefacept (LFA3-Ig) is a dimeric fusion protein that was the first biological US Food and Drug Administration (FDA)-approved drug for moderate to severe plaque psoriasis [76]. It comprises two LFA-3 molecules bound to the Fc portion of immunoglobulin (Ig) G1 that binds CD2, which is expressed most prominently on CD4⁺ and CD8⁺ effector memory T cells (Tem cells), the cells thought to

be primarily responsible for β -cell destruction in type 1 diabetes. In the Rigby study, alefacept was associated with an increase in the Treg/CD4⁺ Tem and Treg/CD8⁺ Tem ratios, possibly leading to a higher ratio of Tregs to cytotoxic T cells. The effect of alefacept may be mediated by an increased expression of the programmed death-1 (PD-1) receptor demonstrated in the CD4⁺ cells, mediating downregulation of its effector functions [59].

Pre-diabetes studies

None.

New-onset studies

The Inducing remission in Type 1 Diabetes with Alefacept (T1DAL) study is a phase II, double-blind, placebo-controlled trial that randomized individuals with newly diagnosed type 1 diabetes, aged 12–35 years, to alefacept ($n = 33$; two 12-wk courses of 15 mg intramuscularly [IM]/wk, separated by a 12-wk pause) or to placebo ($n = 16$). The primary outcome of higher change from baseline 2 h C-peptide AUC during a mixed-meal tolerance test was not met when comparing the intervention group to the control group (delta 2 h AUC: +0.015 nmol/l vs -0.115 nmol/l [$p = 0.065$] intervention vs placebo), despite the mean 4 h C-peptide AUC being higher (delta 4 h AUC: +0.015 nmol/l vs -0.156 nmol/l [$p = 0.019$] intervention vs placebo) and lower insulin requirements being reported. There was no difference in HbA_{1c} at 12 months (6.9% vs 7.2%; 52 mmol/mol vs 55 mmol/mol [$p = 0.75$] alefacept vs placebo, respectively) [56]. At the 24-month follow-up, both the 2 h and 4 h C-peptide AUC demonstrated higher C-peptide production within the alefacept-treated group compared to placebo (delta 2 h AUC: -0.185 nmol/l vs -0.334 nmol/l [$p = 0.015$] intervention vs placebo; delta 4 h AUC: -0.134 nmol/l vs -0.368 nmol/l [$p = 0.002$] intervention vs placebo). Furthermore, exogenous insulin need and prevalence of severe hypoglycaemic episodes were markedly reduced; however, no difference in HbA_{1c} was observed (7.4–7.5%) (57–58 mmol/mol in both groups) [59]. A *post hoc* analysis demonstrated a strong inverse association between the 4 h C-peptide AUC and risk of severe hypoglycaemia, glucose variability, and insulin dose-adjusted HbA_{1c} values, with no difference between the alefacept treated and placebo, suggesting that natural variability as well as immune intervention with alefacept-induced preserved β -cell function benefits the person with new-onset type 1 diabetes [77].

Safety

Although this trial was too small to detect uncommon adverse events, alefacept has been widely used in psoriasis for many years with a strong safety record; it does not blunt immune responses to novel and recall antigens and does not increase susceptibility to infectious disease or malignancy [59].

CD80 and CD86 blockade (abatacept, CTLA4-Ig)

Mode of action

For the full activation of T cells from an antigen-presenting cell, two signals are required. The first signal results from the interaction between the T-cell receptor and an antigen peptide presented on a major histocompatibility complex (MHC) by an antigen-presenting cell. The second and most crucial signal for the full activation of the T cell comes from the interaction between the T-cell receptor and specific ligands on the antigen-presenting cells. These ligands are CD80 and CD86, which are found on

antigen-presenting cells, and CD28 located on the surface of the T cell. This interaction results in a strong co-stimulatory signal required for the full activation of the T cell. T-cell activation can be inhibited by binding of the CD80/CD86 of the antigen-presenting cell to the CTLA4 ligand on the T cell. Hence, a therapeutic strategy to hinder autoimmunity was proposed by inhibiting the second signal to block the stimulation of the T cell by saturating the CD80/CD86 receptor of the T cells with soluble CTLA4-Ig [78]. It is speculated that the effect of abatacept relates to a decline in T-cell activation over time of at least of the initial activated T cells, alone or in combination with later components of the type 1 diabetes disease process, that might interfere with or use alternative means of T-cell activation.

Pre-diabetes studies

TrialNet is currently conducting a trial testing abatacept in type 1 diabetes, stage 1 (NCT01773707).

New-onset studies

In 2011 in a multicentre, double-masked, randomized controlled trial, Orban et al. demonstrated higher C-peptide levels in 77 abatacept-treated individuals with newly diagnosed type 1 diabetes (aged 6–36 years) than in 35 people receiving placebo. Abatacept (10 mg/kg, maximum 1000 mg/dose) or placebo was administered by IV infusion on days 1, 14, 28, and monthly thereafter for a total of 27 infusions over two years. The primary outcome was baseline-adjusted mean 2 h AUC for serum C-peptide during a mixed-meal tolerance test after two years' treatment. The adjusted C-peptide AUC was 59% higher at two years in the abatacept group (0.378 nmol/l) versus placebo (0.238 nmol/l) ($p = 0.003$). This difference was present throughout the study period, with an estimated 9.6 months' delay in decline in the abatacept treatment arm. Furthermore, at the 24-month assessment, 34 (47%) abatacept-treated individuals had $\text{HbA}_{1c} < 7\%$ (53 mmol/mol), compared to 8 (26%) placebo participants ($p < 0.002$), although the exogenous insulin requirement was similar [60]. A follow-up study one year post-treatment (36 months) demonstrated a sustained C-peptide decline from a baseline of 9.5 months within the abatacept arm in parallel to the placebo group, and the HbA_{1c} also remained lower in the abatacept group (7.6%; 60 mmol/mol) versus placebo (8.6%; 70 mmol/mol) ($p < 0.005$) [51].

Safety

A few, clinically insignificant infusion-related adverse events and minimal overall adverse events were reported. A more detailed description of adverse events has been documented from the use of abatacept tested in other diseases such as rheumatic arthritis [78, 79].

Low-dose anti-thymocyte globulin

Mode of action

The efficacy of anti-thymocyte globulin (ATG) relies on its capacity to deplete lymphocytes and it has been used successfully in preventing graft-versus-host disease and suppressing allograft rejection [80]. An explanation of why higher doses of ATG (6.5 mg/kg) in monotherapy did not preserve C-peptide in new-onset type 1 diabetes has not been fully elucidated; however, flow cytometry demonstrated a significant reduction of the CD4 : CD8 ratio, and while absolute numbers of Tregs decreased, increases in Treg : Tconv (conventional T cell) ratios were observed in low-dose ATG.

In contrast, flow cytometry data from a previous trial using higher-dose ATG (6.5 mg/kg) in people with new-onset type 1 diabetes demonstrated marked reductions in Treg : Tconv ratios [81, 82].

Pre-diabetes studies

None.

New-onset studies

ATG was a part of early protocols using autologous non-myeloablative haematopoietic stem cell transplantation in people with newly diagnosed type 1 diabetes [83]. ATG has also been tested in combination with prednisolone in a pilot study by Eisenbarth [84] and, more recently, retested in 38 and 20 adults with newly diagnosed type 1 diabetes receiving 6.5 mg ATG versus placebo, respectively. Neither primary endpoint of baseline-adjusted change in 2 h C-peptide AUC during a mixed-meal tolerance test from baseline to 12 and 24 months, respectively, was reached in an intention-to-treat analysis [81, 82]. In a different setting, ATG was tested at low dose in combination with pegylated granulocyte colony-stimulating factor (GCSF) in a randomized design comprising 25 individuals, mean age 23 years, on average 12 months after the diagnosis of type 1 diabetes (duration of type 1 diabetes >4 mo and <2 yr) [85, 86]. The intervention group ($n = 17$) received low-dose ATG 2.5 mg/kg IV followed by GCSF (6 mg subcutaneously [SC] every 2 wk for 6 doses) and eight participants received placebo. The primary outcome was the one-year change in AUC C-peptide following a 2 h mixed-meal tolerance test. Combination ATG/GCSF treatment tended to preserve β -cell function in individuals with established type 1 diabetes. The mean difference in the stimulated AUC C-peptide between treated and placebo participants was 0.28 nmol/l/min at 12 months, and HbA_{1c} was lower in those treated with ATG/GCSF at the six-month study visit.

Finally, the ATG/GCSF therapy was associated with relative preservation of Tregs. In a follow-up study, Haller et al. tested the same protocol in individuals with newly diagnosed type 1 diabetes, average age 17 years (range 12–42 years), comparing low-dose ATG/GCSF versus low-dose ATG alone and placebo in a three-arm, randomized, double-masked, placebo-controlled trial in 89 participants. There were 29 participants randomized to ATG (2.5 mg/kg IV) followed by pegylated GCSF (6 mg SC every 2 wk for 6 doses), 29 to ATG alone (2.5 mg/kg), and 31 to placebo. Low-dose ATG alone slowed the decline of C-peptide (AUC C-peptide ATG 0.646 nmol/l/min vs placebo 0.406 nmol/l/min) and reduced HbA_{1c} , whereas no difference could be demonstrated comparing ATG/GCSF (0.528 nmol/l/min) versus placebo [87]. This effect was sustained after 24 months, where lower HbA_{1c} was also observed in participants treated with ATG and ATG/GCSF.

Safety

Adverse events with ATG are an issue; in particular, cytokine release at infusion and serum sickness during the following two weeks are reported in approximately 70–80% of cases [87]. Within the low-dose ATG studies, no participants required extended hospitalization or readmission due to cytokine release or serum sickness. There were no reported cases of grade 4 or 5 adverse events (life threatening or death). In addition, no participants who received ATG/GCSF or ATG alone developed serious infections. Furthermore, between the first- and second-year endpoints, there were no increases in adverse events in ATG- or ATG/GCSF-treated participants. There were nearly twice as many adverse events reported in the placebo group than in either the

ATG or the ATG/GCSF group between the first- and second-year endpoints. No cases of EBV reactivation or severe hypoglycaemia were reported [57].

Targeting B cells

CD20 blockade (rituximab)

Mode of action

Rituximab is an anti-CD20 monoclonal antibody [88]. Because pancreatic β -cell destruction has been traditionally considered to be T cell mediated, many interventions have targeted the T-cell response. However, a role for B lymphocytes in accelerating the autoimmune β -cell destruction by T cells has also been demonstrated. In humans, increased B-lymphocyte infiltration of islets corresponds with more aggressive and earlier disease onset. B-lymphocyte depletion through a short course of an anti-CD20 monoclonal antibody temporarily preserved β -cell function in individuals with recent type 1 diabetes onset, solidifying a role for B lymphocytes in human type 1 diabetes. Orchestration of a successful autoimmune attack requires T–B cell cross-talk, and disruption of this cross-talk between antigen-specific B and T lymphocytes remains an unrealized therapeutic goal [89].

The mode of action of rituximab in type 1 diabetes is unknown. It has been proposed that rituximab reduces the production of cytokines that augment the immune response locally within the pancreas or the peripancreatic lymph nodes. It has also been suggested that the antigen presentation provided by B lymphocytes, which is required for continued T-lymphocyte action, is altered by rituximab [54].

Pre-diabetes studies

None.

New-onset studies

The Type 1 Diabetes TrialNet Anti CD-20 Study Group has orchestrated a randomized, double-blind study comprising 87 individuals with newly diagnosed type 1 diabetes (aged 8–40 years), who were assigned to receive infusions of rituximab (375 mg/m^2 body surface area [BSA]) or placebo on days 1, 8, 15, and 22, no more than three months post-diagnosis. At one-year follow-up, the primary goal was achieved of higher baseline-adjusted 2 h C-peptide AUC during a mixed-meal tolerance test for the rituximab arm (0.56 nmol/l) versus placebo (0.47 nmol/l ; $p = 0.03$). Lower HbA_{1c} (rituximab 6.8% [51 mmol/mol] vs placebo 7.0% [53 mmol/mol]; $p < 0.001$) and lower exogenous insulin use (rituximab 0.39 IU/kg vs placebo 0.48 IU; $p < 0.001$) were also demonstrated in the intervention group [54]. At the two-year follow-up, the baseline-adjusted 2 h C-peptide AUC during a mixed-meal tolerance test was still higher for the rituximab versus placebo; however, the difference was no longer significant and no differences in HbA_{1c} and insulin dose were seen [90]. The B lymphocytes recovered to baseline levels at 18 months within the rituximab-treated participants.

Safety

Rituximab is considered safe in type 1 diabetes with mostly grade 1 and 2 adverse events reported (mild and moderate), and no grade 4 (life threatening). Unsurprisingly, the IgM levels were lower within the rituximab-treated individuals, an effect that persisted at 24 months, whereas the IgG levels did not differ significantly between the two groups. Increased rates of neutropaenia and infection were not seen [54, 90].

Summary of studies targeting T and B cells

The main philosophy of the studies discussed has been that the remaining β -cell capacity at onset of type 1 diabetes provides a window of opportunity to preserve the endogenous insulin production and to extend the remission phase, as individuals having a long remission phase as part of the natural history experience less severe hypoglycaemia and fewer long-term complications [91]. Most studies include a mixed population of adolescents, young adults, and adults, which potentially may harbour a bias, as increasing evidence points towards heterogeneity within the type 1 diabetes pathogenic process, especially when adjusting for age [8].

Taken together, the studies targeting immune T- or B-cell function seem to demonstrate a delay of 8–9 months in loss of C-peptide production; however, the rate of decline seems to be unaffected. Recently, Jacobsen et al. compared the latest results of teplizumab, alefacept, abatacept, high-dose ATG, low-dose ATG, low-dose ATG/GCSF, and rituximab trials in an attempt to rank the effectiveness of the agents [92]. The baseline-adjusted 2 h C-peptide AUC was modelled using analysis of covariance. Percentage increases in C-peptide over placebo and absolute within-study difference were calculated for each study for inter-study comparison. Ranking the 2 h C-peptide AUC by (i) *percentage change relative to control* at one- and two-year follow-up were high-dose ATG (9% and 16%), rituximab (18% and 15%), alefacept (18% and 36%), abatacept (22% and 37%), low-dose ATG/G-CSF (30% and 49%), teplizumab (48% and 63%), and low-dose ATG (55% and 103%); and (ii) *absolute difference* presented as a point estimate for years 1 and 2 was slightly different: high-dose ATG (0.0347 and 0.0517), rituximab (0.0666 and 0.0465), alefacept (0.0817 and 0.112), abatacept (0.0839 and 0.0967), low-dose ATG/G-CSF (0.0889 and 0.0888), low-dose ATG (0.162 and 0.184), and teplizumab (0.166 and 0.144), indicating most potential for low-dose ATG and teplizumab [92]. Finally, only anti-CD3 intervention (teplizumab) has been tested in pre-diabetes stage 2 [49].

Targeting inflammation

The use of various cytokine blockers has been inspired by the positive outcome in other autoimmune conditions such as inflammatory bowel disease and rheumatoid arthritis [93].

Interleukin-1 blockade (anakinra, canakinumab)

Mode of action

Both canakinumab and anakinra induce blockade of IL-1, a key innate immune mediator. Canakinumab is a human monoclonal anti-IL-1 antibody, and anakinra is a human IL-1 receptor antagonist. Because of its direct β -cell pro-apoptotic action and mediatory effects on pancreatic β -cell glucotoxicity, IL-1 β has been implicated in the pathogenesis of both type 1 diabetes and type 2 diabetes. No data have been reported so far regarding altered serum levels of IL-1 or other mechanistic outcome measures in studies including individuals with type 1 diabetes.

Pre-diabetes studies

None.

New-onset studies

An exploratory pilot study in 15 children aged 6–18 years tested anakinra 50–100 mg for 28 days in comparison to a historical control group. As a lower insulin dose-adjusted HbA_{1c} was demonstrated after one month's treatment and lower insulin need at

one and four months' treatment [94], the following two randomized placebo-controlled trials in two groups of individuals with recent-onset type 1 diabetes were conducted. Both trials used the baseline-adjusted 2 h AUC C-peptide response to a mixed-meal tolerance test at the end of the study as the primary endpoint.

The individuals in the canakinumab trial were aged 6–45 years and enrolled at 12 sites in the USA and Canada. They were randomized to an SC injection of 2 mg/kg (maximum 300 mg) canakinumab ($n = 47$) or placebo ($n = 22$) monthly for 12 months. The difference in 2 h C peptide AUC between the canakinumab and placebo groups at 12 months was 0.01 nmol/l ($p = 0.86$) [52].

Individuals with type 1 diabetes in the anakinra trial were aged 18–35 years and enrolled at 14 sites across Europe, and randomized to 100 mg anakinra ($n = 35$) or placebo ($n = 34$) daily for nine months. The difference in the 2 h C-peptide AUC between the anakinra and the placebo groups at nine months was 0.02 nmol/L ($p = 0.71$) [52].

No difference was observed in HbA_{1c} comparing the intervention groups to their respective placebo groups.

Safety

In the canakinumab trial the number and severity of adverse events did not differ between groups; however, in the anakinra trial, the individuals receiving anakinra had significantly higher grades of adverse events than the placebo group ($p = 0.018$), mainly because of a higher number of injection-site reactions.

Tumour necrosis factor α blockade (etanercept, golimumab)

Mode of action

Etanercept is a recombinant soluble TNF- α receptor fusion protein that binds to the TNF- α receptor. It acts by clearing TNF- α from the circulation, thereby blocking the biological activity of this inflammatory cytokine. Golimumab is a monoclonal antibody that binds to both soluble and transmembrane forms of TNF- α and thereby inhibits the effect of TNF- α . No data have been reported regarding altered serum levels of TNF- α or other mechanistic outcome measures in studies including individuals with type 1 diabetes.

Pre-diabetes studies

None.

New-onset studies

A 24-week double-blind, randomized, placebo-controlled pilot study was carried out involving 18 individuals aged 7.8–18.2 years who were randomly assigned to receive either etanercept (0.4 mg/kg max 25 mg SC twice weekly; $n = 10$) or placebo ($n = 8$). The percent change in a 2 h C-peptide AUC during a mixed-meal tolerance test from baseline to week 24 showed a 39% increase in the etanercept group and a 20% decrease in the placebo group ($p < 0.05$). HbA_{1c} at week 24 was lower in the etanercept group (5.9% [41 mmol/mol]) compared with the placebo group (7.0% [53 mmol/mol]; $p < 0.05$), with a higher absolute percentage decrease from baseline than in the placebo group (etanercept 0.41% vs placebo 0.18%; $p < 0.01$) [95].

A recent study testing the TNF- α receptor blocker golimumab reached its primary goal [58]. This phase 2, multicentre, placebo-controlled, double-blind, parallel-group trial randomly assigned in a 2:1 ratio children and young adults (age 6–21 years) with newly diagnosed type 1 diabetes to SC golimumab (induction dose 60 mg/m²

or 100 mg followed by 30 mg/m² or 50 mg every second week, depending on weight below or above 45 kg, respectively; $n = 56$) or placebo ($n = 28$) for 52 weeks. The 4 h C-peptide AUC (primary goal) differed significantly (golimumab 0.64 nmol/l vs placebo 0.43 nmol/l, $p < 0.001$). A higher percentage of the golimumab group (43%) was in partial remission defined as insulin dose-adjusted HbA_{1c} <9% (75 mmol/mol) than the placebo group (7%, 53 mmol/mol); however, no difference in HbA_{1c} was demonstrated after 52 weeks (HbA_{1c} change from baseline golimumab 0.47% [5 mmol/mol] vs placebo 0.56% [5 mmol/mol]; $p < 0.8$).

Safety

The use of etanercept is considered safe. There were concerns that TNF- α blockade was associated with an increased risk of hypoglycaemic episodes, but this was not confirmed in a large recent study [96]. No severe adverse events were reported in the studies mentioned and frequency of events was similar. Cold symptoms were reported twice as frequently in the etanercept group than the placebo group. Six of nine episodes of abdominal pain were reported by one participant receiving etanercept [95]. This safety profile has been confirmed in trials testing the effect of etanercept in rheumatoid arthritis [97]. Finally, TNF- α blockers are approved for individuals as young as 2 years who have an autoimmune condition [98].

Interleukin-6 blockade (tocilizumab/NCT02293837)

Mode of action

Tocilizumab is a recombinant humanized anti-IL-6 receptor monoclonal antibody [99].

Pre-diabetes studies

None.

New-onset studies

A phase II/III study has been conducted: EXTEND, a randomized trial of IV tocilizumab (8–10 mg/kg) every 4 weeks for 24 months in 136 individuals with newly diagnosed type 1 diabetes (aged 6–45 years). The primary outcome is 2h C-peptide AUC during a mixed-meal tolerance test at 12-month follow-up. This study has been completed, but the results are still awaited.

Safety

Overall the use of tocilizumab has a good safety profile, although an increased risk of infections and a negative influence on the lipid profile have been reported [99].

Interleukin-12/23 blockade (ustekinumab/NCT02117765)

Mode of action

Ustekinumab is a fully human IgG1κ monoclonal antibody blocking the biological activity of IL-12 and IL-23 through their common p40 subunit [100, 101].

Pre-diabetes studies

None.

New-onset studies

Two studies are ongoing. The first is a pilot clinical trial testing different doses of ustekinumab (45 or 90 mg SC) at various time points (0, 4, 16, 28, and 40 weeks or 0, 4, and 16 weeks) in 20 adults with

newly diagnosed type 1 diabetes with a primary outcome of safety. The second study is a phase II/III, randomized trial in 66 adults with newly diagnosed type 1 diabetes (aged 18–25 years) given an IV loading dose of ustekinumab (6 mg/kg) followed by seven SC injections of 90 mg over 48 weeks. The primary outcome is 2 h C-peptide AUC during a mixed-meal tolerance test at 12-month follow-up.

Safety

The safety profile of ustekinumab is considered good, with similar infection rates between placebo and intervention groups and uncommon infusion reactions [100].

Interleukin-21 blockade (+liraglutide) NCT02443155

Mode of action

A human recombinant monoclonal antibody that binds and neutralizes IL-21 [102, 103].

Pre-diabetes studies

None.

New-onset studies

Anti-IL-21 (12 mg/kg IV every 6 wk) and liraglutide (1.8 mg SC daily injection) are being tested in a 2×2 factorial design phase II clinical trial involving 308 adults with newly diagnosed type 1 diabetes (aged 18–45 years). The primary outcome is 4 h C-peptide AUC during a mixed-meal tolerance test at week 54 compared to baseline. The trial has been completed, but no study results have been posted.

Safety

In the first-in-human trial, no clear differences in adverse events were observed between participants treated with active drug versus placebo [102].

Antigen-specific therapy

Antigen-specific immunotherapy is not a standard of care in other autoimmune diseases, where a strong need to control disease activity and symptoms has resulted in the pragmatic use of generalized immune modulation. Type 1 diabetes, by contrast, can be managed by exogenous insulin administration. Antigen-specific immunotherapy that suppresses the autoimmune response – that is, by the induction of tolerance – is an attractive approach in type 1 diabetes as it may avoid the off-target effects seen with systemic immunotherapies. Antigen-specific immunotherapies have good safety track records that could support their long-term use.

There is strong evidence for a loss of immunological tolerance at all stages of type 1 diabetes development as the major immunopathological feature of the disease. Several tolerance-inducing strategies for type 1 diabetes have been approached. The antigen can be given orally, intranasally, or by injection (IV, dermal, or SC), although some routes are favoured for being more tolerogenic (e.g. the oral or nasal route).

Antigen delivery in type 1 diabetes may be by whole antigens, peptides, or as carrier complexes, for instance on nanoparticles or as plasmid-encoded DNA vaccine. The precise mode of tolerance induction might be different in each case. Notably, most antigen-based therapies in type 1 diabetes have been administered as

native proteins, but emerging data on hybrid peptides and other post-translational and post-transcriptional modifications suggest that modified proteins could be used as tolerogens.

Insulin and glutamic acid decarboxylase 65 (GAD65) have served as the major antigen targets in these approaches. Insulin-based intervention is used as primary and secondary intervention approaches, whereas GAD65 immunization is for secondary and tertiary interventions.

Insulin as a primary antigen was targeted in clinical trials with oral insulin [104], intranasal insulin [41], altered insulin epitopes [105], proinsulin peptides [106], or as IM injection of DNA plasmids encoding proinsulin [107], but has shown limited success. *Post hoc* analysis of trial data has identified subgroups that may benefit from this intervention and more studies are needed to clarify the potential of insulin as a tolerogenic treatment.

Immunization with the islet autoantigen GAD65 conjugated to alum has been tested in several trials [108–110] with different administration routes and in combination with other compounds. GAD-alum has been tested in combination with vitamin D alone [111] or with vitamin D and etanercept [112]. GAD-alum is also being tested in combination with gamma aminobutyric acid (GABA), but overall the different GAD-alum immunization trials have not reached their primary outcome, though findings from subgroup analyses suggest beneficial effects [113].

Antigen-based therapies are appealing for use in combination with other intervention strategies. An example might be synergistic use with a non-specific, immune-modulatory drug designed to act as a tolerogenic adjuvant for the antigen.

Current status of immunomodulatory therapies

The current status of preventive immunomodulatory therapies shortly after the clinical onset of type 1 diabetes (stage 3) is that they demonstrate at best a temporary effect and the long-term outcome is still unsatisfactory. This may be related to various factors, such as the design and timing of the intervention, the target of modulation, and whom to target. Most studies today have focused on individuals with new-onset type 1 diabetes, testing a single drug selected based on a pathogenetic model of the development of type 1 diabetes in a predefined timespan with endogenous secreted C-peptide as the primary endpoint. Increasing data are emerging that this could turn out to be too simplistic an approach. The accumulating evidence that type 1 diabetes is much more heterogeneous than previously assumed should be reflected in future preventive strategies of type 1 diabetes.

Type 1 diabetes as a heterogeneous disease

The heterogeneous nature of type 1 diabetes is a major obstacle to the success of immunotherapies. The progression of type 1 diabetes varies with age, with young children having a more aggressive form. From the DIPP study, nearly all children developing multiple autoantibodies go on to develop type 1 diabetes by 15 years old (>85%) and those developing multiple autoantibodies before the age of 3 years had a further increased rate of disease progression compared with children who developed autoantibodies at older ages [27]. Identification of biomarkers defining rapid and slow progressors within the natural history of type 1 diabetes development is important and will add to the perception of heterogeneity in type 1 diabetes [114]. Similar data have been demonstrated by

the TrialNet Pathway to Prevention Study, where age was identified as the single most important factor for rapid progression in individuals with multiple antibodies, with a significant difference between children and adults [8]. In parallel, the same group observed a similar rate of decline in C-peptide after the clinical onset of type 1 diabetes among individuals aged 7–21 years, whereas participants aged over 21 years had a slower decline in C-peptide [115].

Finally, the significant effect of the intervention with rituximab (anti CD-20) [54] and abatacept (CTLA4-Ig) [60] was mostly driven by the positive response from the paediatric participants. Hence, it is important to note that if the initial intervention studies had been performed exclusively within adults with new-onset type 1 diabetes, a negative result might have been the most likely outcome. The chance of retesting such an intervention within the paediatric population would have been unlikely, thereby discarding a putative positive effect in children. On the other hand, if the trial did not reach the primary goal, typically neither adults nor children achieved any benefit, exemplified by the GAD-alum trial [116]. Furthermore, data related to the insulitis lesion also point towards heterogeneity, as demonstrated among 45 cadaveric type 1 diabetes pancreata with massive variation within the insulitis process [11, 117]. These studies also seem to confirm the apparent discrepancy between β -cell mass and endogenous C-peptide production, as insulin-producing β cells may persist even in individuals who have no detectable levels of C-peptide and with up to 56 years of disease [117]. Within the immune system, there is increasing recognition of distinct endo-types in those with recent-onset type 1 diabetes, reflective of various unique pathobiologies [13, 14]. Finally, even at the β -cell level, several endo-types as a result of various combinations of the autoimmune versus β cell interaction have been hypothesized, spanning from a state of *benign* islet autoimmunity to progression to type 1 diabetes relying on more highly vulnerable β cells [30].

As not all participants in the preventive type 1 diabetes trials have benefited from the tested intervention, new strategies to identify responders versus non-responders are urgently needed and hence the development of better biomarkers is warranted [8]. Also, further characterization of immune phenotypes seems to be of importance in relation to outcome [118].

When to intervene?

It is possible that the modest impact of interventions at clinical onset (stage 3) could be due to the clinical design of mainly testing single drugs in an ineffective dose and not using combination treatment. It is also simply possible that by the time of clinical onset the disease has progressed beyond the point of no return. From the various current trials it has been suggested that individuals with higher baseline C-peptide perform better and the eventual outcome after cessation seems inevitable, suggesting that intervention at an earlier stage as well as possible retreatment might improve the overall outcome [114], the former exemplified by teplizumab intervention in relatives at risk of type 1 diabetes [49].

Future strategies

Preserving β -cell function is an obvious and mandatory endpoint of success in preventing type 1 diabetes from progressing to the clinical phenotype known today. However, it could be speculated

that the other side of the coin – that is, insulin sensitivity – plays a role in type 1 diabetes rather than solely the insulin secretion capacity of the remaining β cells. It is thought-provoking that improvement in C-peptide capacity does not always lead to a reduction in HbA_{1c}, indicating, at best, a limited effect of the metabolic outcome exemplified by the teplizumab studies [50, 75]. A more recent observational study evaluated insulin sensitivity before and after treatment with abatacept in individuals with rheumatoid arthritis. Insulin sensitivity, evaluated by the Matsuda Insulin Stimulation Index (ISI), significantly improved after six months of abatacept treatment ($p = 0.003$) [119]. Such observations argue in favour of testing various combinations of interventions aiming at different targets. Testing various combinations of interventions is currently being adopted in long-term follow-ups of NCT02293837 (T1DES): five-year follow-up of AbAte (teplizumab/antiCD3), T1DAL (alefacept/CTLA 4 Ig), and EXTEND (tocilizumab/IL-6 blockade), $n = 80$ in total. These studies are currently recruiting.

Conclusion

Despite tremendous progress in type 1 diabetes disease-modifying approaches, none of the current immunotherapies discussed in this chapter is sufficiently effective alone in preventing or managing type 1 diabetes. An even deeper understanding of the immunopathological processes of type 1 diabetes is needed to tailor innovative and more efficient immunotherapies.

Combination treatment has several potential advantages over monotherapy. It would allow a lower dose of riskier agents as well as rational combinations for complex disease, and has proven efficacy in for instance cancer, HIV, and transplantation. Combination therapy that works through two mechanistic targets seems attractive. One option may be a combination of antigen-specific and systemic immune-modulatory treatment; the latter could target T cells (e.g. anti-CD3) or be anti-inflammatory. Alternatives could be combining immune-modulatory treatment with a β cell-specific treatment or an insulin sensitizer.

It seems reasonable to assume that the lack of success in most of the immunotherapy trials to date relates to the fact that type 1 diabetes is a heterogeneous disease with different disease stages (Figure 76.1). This suggests that a given immunotherapy may not work equally well in all individuals, for example due to genetic or biochemical interindividual variation. Furthermore, a given immunotherapy may not work equally well at different stages of the disease process.

To ensure the efficacy of future trials, an intelligent trial design is critical. Improved biomarkers, including genetic profiling, that reflect disease activity may assist in predicting who is likely to respond to a given immunotherapy (Figure 76.3).

Increased knowledge of the pathogenesis of type 1 diabetes has provided us with better options for more specific prevention of the disease. Currently, therapies targeting effector and regulatory T cells show most promise, but combination therapies, for instance targeting both the immune system and the β cell, may have even larger potential. More extensive biomarker screening to identify likely responders and non-responders to a given therapy will be crucial. Together, this will bring us closer not only to treating type 1 diabetes, but also to preventing and reversing it.

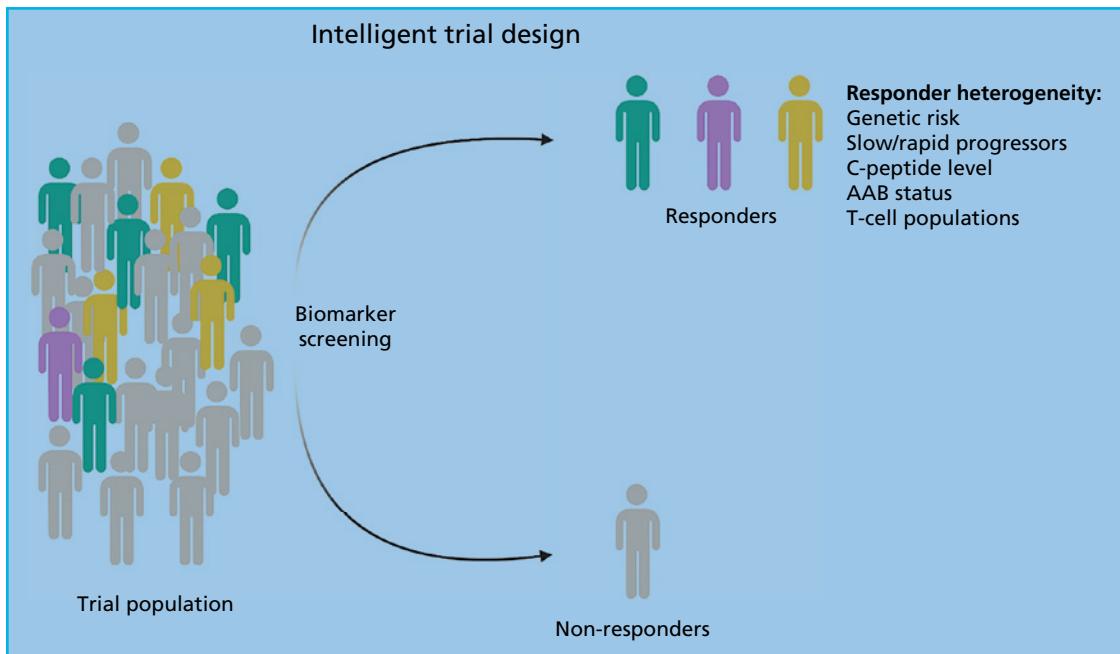

Figure 76.3 The trial population is critical for efficacy of a trial. Improved biomarker signatures will reflect disease activity and will allow for prediction of who will respond to or may have potential severe adverse effects from a particular immunotherapy. AAB, auto-antibody.

Angelo Avogaro and Gian Paolo Fadini

Department of Medicine, University of Padova, Padova, Italy

Key points

- Stem cells divide asymmetrically to produce self-renewing cells and daughter cells that differentiate; they can also divide symmetrically to expand the stem cell pool.
- A β cell can be formed by an α cell following the allocation towards the pancreatic lineage.
- A functional β cell can be reprogrammed from adult cell types through an inducible pluripotent state cell.

- Angiogenesis occurs as the sprouting of a small endothelial tube from pre-existing capillary beds in response to local hypoxia, while arteriogenesis is the transformation of pre-existent collateral arterioles into functional collaterals.
- Renal progenitor cells and organoids represent an alternative to modulate kidney regeneration.

Why use stem cells in people with diabetes?

Despite optimal diabetes management, diabetes is associated with the development of chronic complications, reduced quality of life, and an 3.1-fold increased relative risk for mortality for people with type 1 diabetes. The primary unmet clinical needs in diabetes care are:

- To develop a cure for the disease by recreating physiological insulin secretion and normal blood glucose levels to avoid long-term complications.
- To reverse long-term complications in individuals who already have these disabilities.

The treatment for people with type 1 diabetes is daily intensive insulin therapy, with as many as 20% of individuals with type 2 diabetes requiring insulin therapy. The treatment of diabetes with exogenous insulin is often problematic due to unavoidable recurrent hyper- and hypoglycaemic episodes. Therefore, pancreas or isolated islet transplantation is needed to restore normal glucose metabolism in selected individuals with recurrent and often asymptomatic severe hypoglycaemic episodes despite optimal medical therapy and education (Chapter 34). However, pancreas transplantation requires major abdominal surgery and immunosuppression. Islet transplantation is more acceptable because it is less invasive and repeatable, and is indicated for individuals who are ineligible for pancreas transplantation. Unfortunately, these approaches are limited by the number of donor organs and the need for immunosuppression. For these

reasons, strategies for β -cell replacement based on stem cells to create insulin-producing cells have been proposed.

What is a stem cell?

Stem cells are undifferentiated cells that give rise to differentiated cells, the *bricks* for building tissue and organs (Figure 77.1). In the postnatal and adult stages of life, tissue-specific stem cells can be found in differentiated organs and are extremely important in tissue repair following injury. Characteristics of stem cells include self-renewal, clonality, and potency (the ability to differentiate into different cell phenotypes) [1]. Stem cells usually reside in a niche environment, which regulates the stem cells by providing short-range signals. In terms of the potential to differentiate, stem cells can be categorized into totipotent, pluripotent, multipotent, oligopotent, and unipotent. Totipotent or omnipotent cells, such as fertilized oocytes, are the most undifferentiated cells in early development. Pluripotent stem cells can differentiate into cells that arise from the three germ layers – ectoderm, endoderm, and mesoderm – from which all tissues develop. Pluripotent stem cells can be generated from reprogrammed somatic cells, called induced pluripotent stem cells (iPSCs). Unlike human embryonic stem cells (hESCs), iPSCs can be generated from tissue biopsies, thus providing a limitless source of person-specific material that can be used to produce specific cell types, such as insulin-producing cells. iPSCs can be generated from different cell types, though many obstacles remain to be resolved before taking full advantage of this technology in therapy [2].

Multipotent cells, such as mesenchymal stem cells (MSCs), are ubiquitous and can differentiate into cells from a single germ layer. Oligopotent stem cells can self-renew and form two or more lineages within a specific tissue; haematopoietic stem cells are oligopotent stem cells, as they can differentiate into myeloid and lymphoid lineages. Unipotent stem cells can self-renew and differentiate into only one specific cell type and form a single lineage, such as endothelial progenitor cells (EPCs) [3].

Stem cells for insulin replacement

Many protocols for efficient differentiation of stem cells into functional endocrine cells have been developed [4], but most have not generated fully functional β cells [5]. The differentiation of human pluripotent stem cells to pancreatic cells is obtained through a series of steps mimicking *in vivo* development (Figure 77.2).

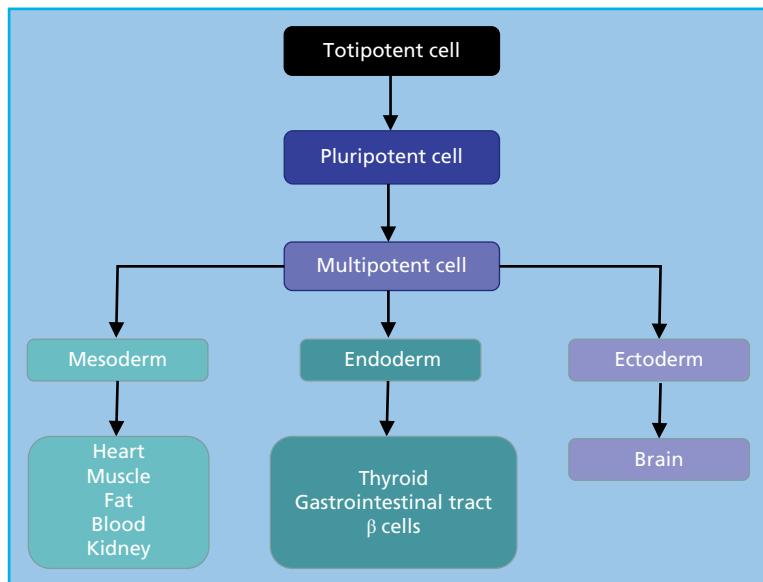

Figure 77.1 Pluripotent stem cells can differentiate into cells that arise from the three germ layers – ectoderm, endoderm, and mesoderm – from which all tissues develop. Pluripotent stem cells can be generated from reprogrammed somatic cells, called induced pluripotent stem cells.

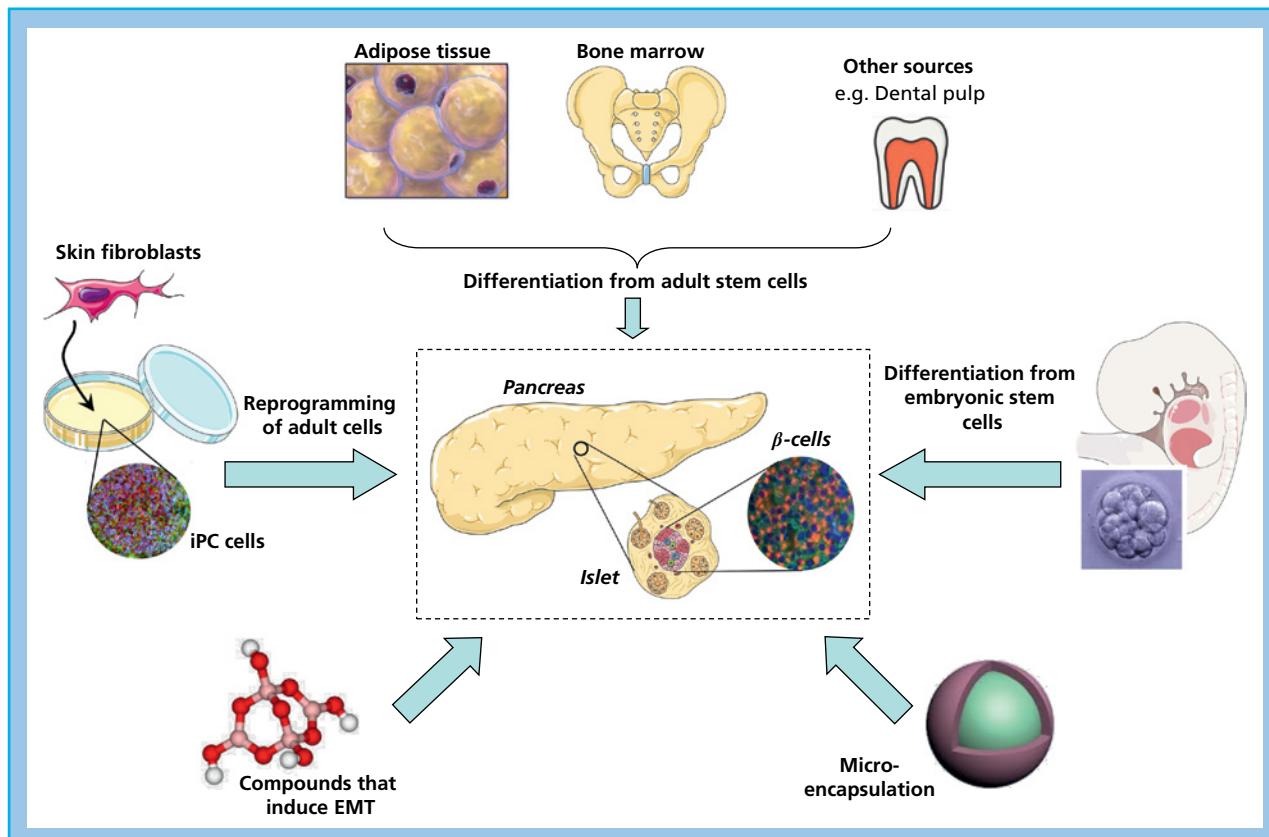

Figure 77.2 Cell phenotypes and organ able to generate functional β cells. EMT, epithelial-to-mesenchymal transition; iPC, induced pluripotent cell.

These steps lead to the formation of definitive endoderm, characterized by:

- Expression of the transcription factors forkhead box A2 (FOXA2) and SRY-box transcription factor 17 (SOX17) and the cell surface marker C-X-C motif chemokine receptor 4 (CXCR4).
- Patterning of the posterior foregut to generate pancreatic and duodenal homeobox 1 (PDX1)-expressing endoderm.
- Specification of the PDX1+ endoderm to pancreatic progenitors expressing PDX1 and NK6 homeobox 1.

Endocrine commitment is characterized by the upregulation of neurogenin-3 and NK2 homeobox 2, followed by the expression of lineage-specific genes, including the hormones insulin expressed by β -like cells, glucagon expressed by α -like cells, and somatostatin expressed by δ -like cells [6]. Each step is controlled by the activation and/or inhibition of specific pathways. Activin/nodal and canonical Wnt signalling are required to form definite endoderm, whereas retinoic acid and fibroblast growth factor 10 signalling are essential for PDX1 induction (Figure 77.3). Endocrine lineage commitment is achieved in the presence of bone morphogenetic protein (BMP)/transforming growth factor β (TGF- β)/Notch inhibition. Cultures obtained with these sequential procedures are composed of β -like cells and other cell phenotypes such as endocrine cells, uncommitted progenitors, and enterochromaffin cells.

Cells generated with these protocols secrete human C-peptide in response to glucose, and can rescue hyperglycaemia in streptozotocin-diabetic mice [7]. MSCs have also been used to generate insulin-producing cells [8], as well as to enhance islet engraftment and survival, and to improve metabolic control in experimental diabetes [9]. Trials performed in type 2 diabetes suggest a positive impact of bone marrow-derived mononuclear cells on metabolic measures in the absence of adverse events, following intra-arterial injection by selective cannulation of the pancreatic vasculature [10]. Rezania et al. have demonstrated that pancreatic progenitor cells can produce glucose-responsive, insulin-secreting cells and prevent or reverse diabetes in mice [11]. An alternative strategy is the reprogramming of terminally differentiated cell types into β cells. Zhou and Melton showed a direct conversion of mouse acinar cells to β cells *in vivo* via viral expression of particular genes; these induced cells were able to improve glycaemic levels in diabetic mice [12]. A further example of adult cell reprogramming to β cells has been described for adult mouse α cells. Following the allocation to the pancreatic lineage, the endocrine differentiation program is initiated through the expression of neurogenin-3 (NGN3), and NGN3+ cells can become α cells or bipotential β/δ precursors [13]. Combining several lineage-tracing approaches, authors have shown

that pancreatic duct-lining precursor cells are continuously mobilized, re-express the developmental gene NGN3, and successively adopt a glucagon-expressing and β -like cell identity through mechanisms involving the reawakening of the epithelial-to-mesenchymal transition [14]. The restoration of insulin-producing cells from non- β -cell origins is enabled throughout life via δ - or α -cell spontaneous reprogramming, suggesting a condition with multiple intra-islet cell interconversion events. A further approach to make functional β cells is to reprogram adult cell types towards β cells; any tissue could be reprogrammed to iPSCs. Differentiation protocols can be applied to human iPSCs; cell lines derived from reprogrammed human fibroblasts have been successfully differentiated to insulin-producing cells *in vitro* [15, 16].

Maehr et al. have shown that fibroblasts obtained from skin biopsies from two individuals with type 1 diabetes were reprogrammed to pluripotency and differentiated to insulin-producing cells, although their functionality needs further validation [17]. In this context, Hua et al. generated iPSCs from people with maturity-onset diabetes of the young type 2 (MODY-2); these stem cells differentiated into β cells with an efficiency comparable to that of controls and expressed markers of mature β cells.

β -cell replacement therapy can be considered a viable treatment option for individuals with β -cell failure and severe and persistent glycaemic instability despite optimal high-quality medical care and education. After the transplant, β -cell survival is crucial and still represents a significant barrier to cell replacement therapy. There is a 60% loss within the first few days after transplant, probably determined by hypoxia following alteration in the vascularization of transplanted cells. Another challenge is the allo-rejection and autoimmune reaction, which can be present when hiPSC-derived cells are transplanted into individuals with type 1 diabetes. Encapsulation could potentially overcome this challenge, since it would provide a physical barrier between the host and the transplanted β cells [18]; these devices should contain pore sizes that permit the exchange of oxygen, glucose, and insulin, but at the same time would not allow the transit of immune-competent cells and molecules responsible for mediating the immune rejection. The potential drawback is the presence of hypoxia in the centre of the device and the host-mediated fibrosis around the capsule. ViaCyte's Encaptra device comprises a single immuno-isolating membrane that protects cells from direct physical contact with host immune cells; this device is currently in clinical trials with hPSC-derived progenitor cells (ClinicalTrials.gov identifier NCT02239354).

While macrocapsules have shown adequate vascularization, limited fibrosis, and immunoprotection, microcapsules, made by

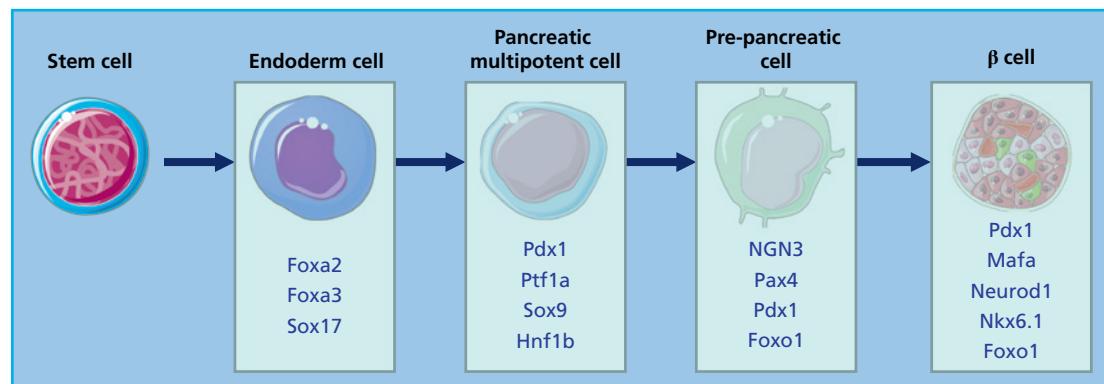

Figure 77.3 Transcription factors responsible for transition from stem cells to fully functional β cells.

alginate, a natural polysaccharide with good biocompatibility, contain 1–3 islets, are approximately 300–1500 mm in diameter, should confer improved diffusion characteristics compared to extravascular macrocapsules, and involve minimally invasive procedures to be implanted [19]. Since microcapsules are tiny, one potential problem is their retrievability after implantation, raising safety concerns. Semma Therapeutics/Vertex received approval to launch a clinical trial to test its human pluripotent stem cell-derived β -cell product's (VX-880) safety, tolerability, and efficacy when infused into the hepatic portal vein of individuals with type 1 diabetes (ClinicalTrials.gov identifier NCT04786262).

For islet transplantation, 5000 islet equivalents (IEQs)/kg of the recipient body mass should be transplanted for adequate glycaemia, with yields of >7000 IEQ/kg from a single donor correlating with a higher likelihood of resulting in insulin independence [20]. For an adult weighing 75 kg, this would represent a fraction of the total mass of an endogenous β cell, meaning that only a small cell population may guarantee insulin independence. Multiple transplantation sites are being pursued as options for stem cell-derived insulin-producing cells. Microcapsules are often transplanted into the peritoneal cavity. Intravascular macrocapsules are connected as a shunt to the systemic blood circulation, whereas extravascular microcapsules are typically implanted subcutaneously or intraperitoneally.

Subcutaneous, intramuscular, and omental/intraperitoneal sites are similar candidates for hPSC-derived insulin-producing cells. Subcutaneous implantation offers the advantages of retrievability and simplicity of delivery, but the major challenge can be poor spontaneous vascularization. A significant aim is the tolerance of transplanted human pluripotent stem cell-derived β -like cells. Genetic approaches are being developed to enable human pluripotent stem cell-derived and differentiated progeny to escape detection from alloimmune effectors following transplantation. Gene editing techniques have been proposed to decrease the expression of human leucocyte antigen (HLA) proteins on the surface of human pluripotent stem cell-derived cells and their progeny. The same approach can be used to control the expression of various immunomodulatory factors by the implanted human pluripotent stem cell-derived cells. Other strategies include cellular immunotherapy by using monoclonal antibodies targeting T-cell co-stimulatory pathways.

Two companies have initiated clinical trials with stem β cells. A European consortium started a trial where pancreatic progenitor cells (PEC 01) cells are encapsulated into an open device, allowing the growth of new blood vessels while administering both anti-inflammatory agents and standard immunosuppression [21]. The β -Cell Therapy Consortium announced that VC-02TM had been implanted into people with type 1 diabetes for the first time in Europe, meaning that human-induced pluripotent stem cell-derived insulin-producing cells can survive, engraft, differentiate, and mature into human islet-like cells when implanted subcutaneously. Vertex also announced that a new approach based on fully differentiated and functional stem cell-derived islet-like organoids (VX-880) delivered through the portal vein combined with immunosuppression would be tested in humans [22].

microvascular complications. As a consequence of coronary heart disease, heart failure is also more prevalent in people with diabetes. For these reasons, cardiac regenerative medicine is of primary importance in diabetes. During an acute myocardial infarction, billions of cardiomyocytes are lost, and current therapies cannot re-establish such a loss. Ageing also causes cardiomyocyte loss. Myocyte apoptosis in the normal human heart involves at least 1 in 100 000 cells at any time, which equals a decrease of 2.2% of myocytes per year [23]. Ischaemia is determined by significant obstruction of the coronary blood flow during myocardial infarction with an irreversible loss of cardiomyocytes. Because the heart is a terminally differentiated organ with little to no regenerative capacity, the remaining cardiomyocytes cannot replace the lost cells. Therefore, compensatory scarring replaces the dead tissue, leading to compromised cardiac function and heart failure.

The approach to cardiac regenerative medicine with stem cells has been disappointing to date. However, in light of the rising incidence of heart failure and a simultaneous shortage of organs, the option of a regenerative approach remains more relevant than ever [24]. Stem cells, defined by their ability to self-renew and differentiate into at least one other cell type, were investigated for their ability to replace lost myocardium directly. In pre-clinical models, stem cell therapy improves left ventricular ejection fraction by 7.5% in large animal models and from 2% to 5% in clinical trials. The stem cells used for cardiac regenerative purposes are divided into first, second, and subsequent stem cells. First-generation stem cell therapy was based on skeletal myoblasts, bone marrow mononuclear cells, adipose tissue-derived regenerative cells, mesenchymal stem cells, and haematopoietic stem cells (CD134⁺/CD133⁺). Second-generation stem cells include purified cardiac cell populations such as ckit⁺ cardiac stem cells, cardiosphere-derived cells, pluripotent cells, and allogeneic cells. Next-generation stem cells have modified and lineage-directed stem cells, such as cardiopoietic stem cells derived from mesenchymal stem cells; this generation also includes combination therapy of specific cell types. Several trials have been completed, but the results were, at best, unequivocal in terms of left ventricular ejection fraction, scar size, or left ventricular volume improvement [25].

As an alternative to cell therapy, the use of drugs is being considered to modulate stem/progenitor cell availability and homing. Zaruba et al. proposed a combined strategy of granulocyte colony-stimulating factor (G-CSF) plus dipeptidyl peptidase 4 (DPP-4) inhibition to improve cardiac homing of mobilized stem/progenitor cells, which is currently under clinical investigation in the SITAGliptin plus GRanulocyte colony-stimulating factor in patients suffering from Acute Myocardial Infarction (SITAGRAMI) trial in individuals after acute myocardial infarction [26]. This approach stems from the concept that inhibition of DPP-4, which cleaves the primary stem cell attracting chemokines, stromal-derived factor-1 α (SDF-1 α), will improve the homing of mobilized stem/progenitor cells. Endogenous stem cell mobilization can also be achieved using the CXCR4 antagonist plerixafor. The cardiac stem/progenitor cells (CSPC) compartment is involved in diabetic cardiac dysfunction by activating the cell death pathways and inhibiting cell replication [27]. Glucose-induced dysfunction of the pool of CSPCs leads to insufficient replacement of old, dying cells and acquisition of the heart senescent phenotype. A protein that appears to be implicated in CSPC cell damage is p66shc, an adaptor protein, which is linked to premature ageing, oxidative stress, and apoptosis. Exposure of human CSPCs to hydrogen peroxide results in increased caspase-3 cleavage and apoptosis, mediated by the activation of the c-jun

Healing the heart

Diabetes doubles the risk of cardiovascular disease, regardless of other risk factors, with the risk being more significant in women, those of a younger age, and those with long-lasting diabetes and

N-terminal protein kinase (JNK) pathway [28]. Regarding cell bioenergetics, CSCPs exposed to a diabetic environment show remarkably reduced activity of key enzymes of the pentose phosphate pathway (G6PD and transketolase), resulting in decreased antioxidant defence mechanisms and activation of apoptosis [29]. Inflammation is also being implicated [30].

Creating new vessels

Peripheral arterial disease is highly prevalent among people with diabetes and is associated with significant morbidity and mortality. Peripheral arterial disease can lead to critical limb ischaemia, resulting in substantial amputations and death. Angiogenesis and arteriogenesis should represent compensatory mechanisms to increase vessel growth in individuals with peripheral arterial disease. Angiogenesis occurs as the sprouting of the small endothelial tube from pre-existing capillary beds in response to local hypoxia. It is mainly mediated by vascular epithelial growth factor (VEGF), with no need for non-tissue-resident cells. The resulting capillaries are tiny, and cannot compensate for any sizeable occluded conduit artery. Arteriogenesis is the transformation of pre-existent collateral arterioles into functional collateral arteries. This implies an increase in the diameter of existing arterial vessels capable of compensating for the loss of function of occluded arteries. Ischaemia itself induces elevated plasma stem and progenitor cell-activating cytokines, including sKitL (soluble Kit ligand) thrombopoietin, and G-CSF. Together with hypoxia, these in turn generate the release of SDF-1, thereby stimulating the mobilization of proangiogenic cells that accelerate revascularization of the ischaemic site [31].

One approach to stimulate angiogenesis is to administer locally proangiogenic factors such as growth factors and cytokines, including vascular endothelial growth factor, fibroblast growth factor 2, and TGF- β . Unfortunately, this approach has essential drawbacks, such as dosing problems, poor local retention, and high cost. Another method is based on the administration of genes rather than proteins by using plasmid-based or viral carriers, but, similarly, dosing problems and tissue retention remain significant issues. An additional approach is the administration of bone marrow-derived and adipose-derived stem cells. Traditional circulating EPCs originated from the monocyte-macrophage lineage [32]. Circulating stem cells (CSCs) are a heterogeneous cellular population within peripheral blood with different anatomical and developmental origins. Haematopoietic stem and progenitor cells (HSCs/HSPCs) constitute the most abundant and best-characterized CSC type [33]. HSCs/HSPCs retain migratory activity during adulthood. They circulate in the blood and can be found in various organs such intestine, liver, lungs, kidneys, and skin. HSPCs contribute to peripheral tissue homeostasis by regulating vascular repair and regeneration [34]. This hypothesis, which is relevant to the relationship between CSCs and cardiovascular outcomes, is supported by the aforementioned ontological overlap between the haematopoietic and vascular systems. Over the last two decades, CSCs have been extensively studied in three main areas of cardiovascular research:

- Physiological contribution to myocardial and vascular homeostasis.
- Experimental and human cell therapies for the treatment of cardiac or peripheral ischaemia.
- Clinical biomarkers for diagnosis and prognosis.

Beyond their ability to physically repair the damaged blood vessels, CSCs exert much of their activity via paracrine signals; most proangiogenic effects of CSCs in peripheral ischaemia appear to be mediated by secretory activity. Pre-clinical findings with bone marrow-derived CSCs, mainly HSPCs and EPCs, have propagated several clinical trials of bone marrow-derived cell therapy for cardiac or peripheral arterial disease. Overall, positive results of cell therapy in chronic ischaemic heart and peripheral arterial diseases support the scientific claim that CSCs are involved in cardiovascular homeostasis [35]. Exposure to virtually any known modifiable cardiovascular risk factors impacts CSC- or EPC-like phenotypes: accelerated CSC senescence and impaired endothelial repair capacity have been demonstrated among people with essential hypertension, cigarette smoking, hypercholesterolaemia, and diabetes. Indeed, diabetes is one of the traditional risk factors most strongly associated with quantitative defects and functional impairment of CSCs, including EPCs. Several studies have consistently reported a reduction of CD34 $^{+}$ CSCs and other progenitor cell phenotypes in the peripheral blood of individuals with type 1 diabetes or type 2 diabetes compared with those without diabetes. This alteration occurs early in the natural history of type 2 diabetes, is only partially reversible with glucose management, and becomes more profound in long-standing complicated diabetes. Reversal of these risk factors may overcome the intrinsic deficiencies of autologous EPCs. Attention should be paid to the application of EPCs in advanced cardiovascular states, with a special effort to optimize cell therapy's metabolic and mechanical context. Standard treatment for severe cases of peripheral arterial disease is surgical or endovascular revascularization. Nonetheless, up to 30% of individuals are not candidates for such interventions due to high operative risk or adverse vascular anatomy. Bone marrow-derived stem and progenitor cells have been identified as potential therapeutic options to induce angiogenesis.

In humans, two different approaches have been proposed, based on (i) unselected autologous mononuclear bone marrow-derived stem cells (BM-MNCs) directly sampled from bone marrow; or (ii) autologous CD34 $^{+}$ or CD133 $^{+}$ BM-MNCs sampled from peripheral circulation after G-CSF stimulation of the bone marrow. Cells can be administered intra-muscularly, intra-arterially, or topically (Figure 77.4). The intramuscular approach is easily performed and allows a significant amount of cells to be injected in the proximity of the ischaemic area; theoretically, this approach may result in a cell depot, which would allow local paracrine activity.

The first clinical trial of stem cell therapy in peripheral arterial disease was the Therapeutic Angiogenesis using Cell Transplantation (TACT) study, with unselected BM-MNCs injected intramuscularly into the ischaemic limbs of individuals with critical limb ischaemia; it proved safe and improved rest pain, perfusion, oxygen pressure, and pain-free walking distance at 24-week follow-up compared with placebo [36]. One clinical trial using unselected BM-MNCs delivered intra-arterially demonstrated a similar improvement in ankle-brachial index (ABI) compared with previous trials of intramuscular BM-MNC administration [37]. Notably, an intra-arterial study in people with diabetes suggested much more significant ABI improvements, as well as an improvement in wound healing and blood flow. The Intraarterial Progenitor Cell Transplantation of Bone Marrow Mononuclear Cells for Induction of Neovascularization in Persons With Peripheral Arterial Occlusive Disease study has been a multicentre, randomized trial of intra-arterial BM-MNC therapy in people with critical limb ischaemia [38]. The study reported improvements in wound healing and

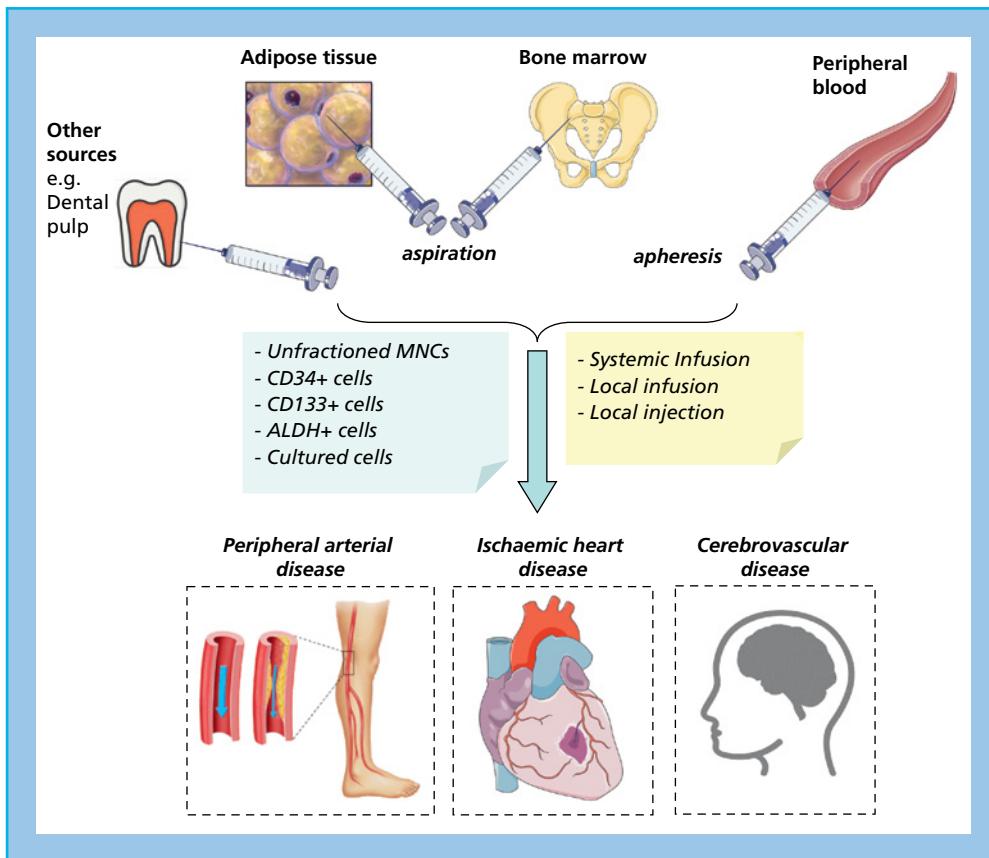

Figure 77.4 Stem cell–based and growth- and chemokine-based therapeutic approaches to regenerate the cardiovascular system. ALDH, aldehyde dehydrogenase; MNC, mononuclear cell.

reductions in rest pain, despite no effect on ABI and limb salvage rates. Both intramuscular injection and intraarterial injection of G-CSF mobilized peripheral MNCs, resulting in a >0.1-point improvement in ABI and a twofold increase in maximum walking distance in small clinical series.

A meta-analysis by Fadini et al. from 37 cell therapy trials indicates that cell therapy can significantly improve ABI, transcutaneous oxygen, rest pain, pain-free walking distance, ulcer healing, and limb salvage [35]. In contrast, G-CSF monotherapy was not associated with significant improvement of these endpoints, albeit conclusions should be deferred because the number of G-CSF testing trials was limited. High aldehyde dehydrogenase (ALDH) activity identifies a subset of blood-derived progenitor cells with high vascular regenerative potential; ALDH is an intracellular detoxification enzyme highly expressed by progenitor cells from multiple mesodermal lineages that protects differentiating progenitor cells from damage by alkylating agents or oxidative stress [39]. A clinical trial performed for severe critical limb ischaemia demonstrated that intramuscular implantation of autologous bone marrow ALDH cells improved Rutherford category scores and ABI at 12 weeks post-transplantation [40].

Lately, attention has been devoted to the role of extracellular vesicles produced by human EPCs and MSCs; these extracellular vesicles contain potent regenerative cargo in the form of proteins, lipids, and microRNAs. They are released by membrane blebbing or exocytotic mechanisms and may have a potential role for vascular repair since they release CD34⁺ cells. Mathiyalagan and colleagues injected mice with purified CD34⁺ cell exosomes and showed improved hindlimb perfusion and preserved muscle mass [41]; they demonstrated that

CD34⁺ cell-derived exosomes contained high levels of miR-10a and miR-130, with previously demonstrated antifibrotic activities in the ischaemic myocardium. Future studies will reveal the potential of extracellular vesicles in vascular repair and regeneration.

Stem cell–based therapy for kidney disease

An estimated 840 million people worldwide have chronic kidney disease, which was responsible for 1.2 million deaths and 35.8 million disability-adjusted life years in 2017. Diabetes is a significant risk factor for chronic kidney disease, and ~20–40% of people with diabetes have evidence of chronic kidney disease. Chronic kidney disease does not remit spontaneously and gradually progresses to end-stage renal disease (ESRD) without intervention. The adult human kidney has a limited number of nephrons, determined during embryonic development by many genetic and environmental factors that cannot be modified after the 36th week of gestation. This inherent incapability of total kidney regeneration pushes towards the application of strategies for kidney regeneration. ESCs represent a strategy for kidney regenerative therapies. They are capable of differentiation into different kidney mature cell types. Most protocols of human ESC differentiation to kidney cells have been translated from studies in mice; however, significant concerns such as ethical issues have significantly limited their use. They also are at high risk of degenerating in neoplasms, especially teratomas, and eventually, since differentiated cells are allogeneic, they suffer from all the issues related to allografts and immunocompatibility.

iPSCs can generate cells that resemble renal progenitors and their progenitors, such as podocytes and tubular epithelial cells [42]. Although iPSCs have the advantage of having the same genetic background as the individual they are derived from, a major concern is the presence of an epigenetic memory, such as methylation/demethylation, which may affect the ability of iPSC-derived mature cells to reliably recapitulate the disease pathophysiology, but also the differentiation capability. One possibility is the generation of kidney-derived iPSCs that would retain the specific renal epigenetic memory of the cell of origin.

Kidney organoids are essential tools for studying the development of the human kidney [43]. Organoids are self-organizing 3D aggregations of cells representing the structure and function of organs. They can be derived from ESCs or induced by iPSCs. Many protocols have been proposed for the induction of kidney organoids from iPSCs; the availability of technologies such as single-cell RNA sequencing has provided insights into the relevance of kidney organoids to the process of kidney development. Kidney organoids can advance the field of nephrology for regenerative therapy. Nevertheless, significant barriers remain to using organoids for any of these purposes.

Kidney organoids have been successfully used to model glomerular and tubular diseases. Advances in single-cell RNA sequencing have led to identifying various cell types in the organoids. They have been shown to be similar to, but more immature than, human kidney cells *in vivo*. Now protocols are available that enable the successful generation of ureteric bud from mouse ESCs and human iPSCs. Combining nephron progenitor cells and ureteric bud generated from mouse ESCs with mouse embryo-derived stromal cells makes it possible to create kidney organoids that show both ureteric bud branching and differentiated nephrons [44]. Although

promising, significant obstacles remain: scRNA-seq and transcriptional profiling studies have demonstrated that organoids represent a very immature kidney system. Therefore, kidney organoids do not generate the full complement of renal cells. A better understanding of organ development and the molecular mechanisms of maturation will be able to be used to develop more mature organs containing a complete complement of renal cell types.

Conclusion

Significant advances have been made recently in stem cell biology and its therapeutic application in the treatment of diabetes and its complications. A tremendous amount of work is still ahead to apply stem cell therapy to people with diabetes on a widespread basis. Common therapeutic strategies for the replacement of β cells and for the rescue of blood vessels and myocardium require totally safe cellular approaches. This is particularly relevant to the deployment of the iPSC approach. However, great uncertainties remain over which precise lineage to employ and the proper conditions that need to be created to yield the optimal therapeutic approach. This is important to new vessel formation since, as described in detail by Fadini et al., the endothelial progenitor is a dynamic phenotype in space and time [45]. Furthermore, other phenomena such as endothelial-to-hematopoietic or epithelial-to-mesenchymal transitions should also be considered, which needless to say underlie the incredible challenges we have ahead before definitively implementing cellular treatment for people with diabetes. Even so, the gap is progressively closing.

- The term gene therapy defines any therapeutic strategy based on the genetic modification of a cell by introduction of exogenous genetic material to prevent, correct, or ameliorate the symptoms of a disease.
- The selection of one gene transfer vector over another depends on the indication, the target tissue in the case of *in vivo* gene therapy, and the period of time during which the expression of the transferred genetic material is required.
- The use of gene transfer technologies has allowed the development of potential therapeutic strategies for the treatment of type 1 diabetes and type 2 diabetes, as well as the performance of proof-of-concept studies in small and large animal models to understand the pathophysiology of these diseases better.
- For type 1 diabetes, most gene therapy strategies have focused on restoring insulin production by islets or surrogate cells, enhancing glucose disposal, or preventing the destruction of the remaining β cells.
- For type 2 diabetes, gene therapy approaches have been directed towards ameliorating insulin resistance and glucose tolerance, enhancing energy expenditure, and improving adipose tissue dysfunction and inflammation.
- Extensive studies are required to demonstrate the efficacy and safety in large animal models of the approaches that have shown therapeutic potential in small diabetic animals before any of these gene therapies are brought to the clinic to treat diabetes in humans.

Gene therapy is a therapeutic strategy based on the genetic modification of a cell by introduction of exogenous genetic material to prevent, correct, or ameliorate the symptoms of a disease. Originally, gene therapy was conceived to supplement or replace the function of a defective gene by delivering to the target cell a functional copy that could mediate the production of the desired therapeutic protein. Progress in the field has led to a broadening of gene therapy applications, and nowadays the introduction of genetic material to a cell is not only limited to gene addition, but also includes induction, repression, and modulation of gene expression at transcriptional and post-transcriptional levels and, more recently, genome editing. To these ends, full-length genes, cDNAs, mRNA, a variety of modulatory and interfering RNA and DNA molecules – including antisense RNA, short-hairpin RNA (shRNA), microRNA (miRNA), and microRNA target sequences (miRT) – and genome editing endonucleases – zinc-finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and the clustered regularly interspaced short palindromic repeats-associated Cas protein system (CRISPR/Cas) – have been used. Furthermore, the vast range of technologies that the field has developed over recent years for therapeutic purposes are also being exploited in proof-of-concept studies to demonstrate gene function.

On the basis of the strategy used, gene therapy can be classified into the following two subtypes: *ex vivo* gene therapy, in which tar-

get cells are genetically modified *in vitro* before transplantation into the patient; and *in vivo* gene transfer, in which cells are genetically modified *in situ* in the individual [1].

The success of gene therapy depends on the existence of gene transfer vehicles capable of safely and efficiently introducing genetic material into target cells either *ex vivo* or *in vivo*. To achieve this goal, a wide variety of vectors have been developed over the past few years; these are divided in two main categories: non-viral and viral vectors. Delivery systems based on non-viral vectors include both the direct administration of naked nucleic acids and the use of physico-chemical means to ferry the genetic material into the target cell, such as electrotransfer or incorporation of nucleic acids into liposomes or cationic polymers. The use of viral vectors exploits the natural ability of viruses to enter cells, transfer their genetic material to the nucleus, and express proteins. So far the vast majority of gene therapy strategies developed for the treatment of diabetes have been based on the use of viral vectors as gene transfer vehicles.

Viral vectors

Several naturally occurring viruses have been subjected to numerous genetic modifications to allow their use as safe gene transfer vehicles. Viral vectors cannot develop a pathogenic infection after

delivery to cells or animals due to the genetic deletion of genes essential for the life cycle of the wild-type virus. Therefore, recombinant viral particles contain a genetically modified viral genome that may be partially or completely devoid of viral genes and is unable to generate new virions on infection. They retain, however, the infectivity of the wild-type virus and its ability to mediate introduction of the genetic material into the cell nucleus (a process known as transduction), because these functions are conferred by the capsid itself [2].

The selection of one vector over another depends on the gene transfer application, the target tissue in the case of *in vivo* gene therapy, and the period of time during which the expression of the transferred genetic material is required. For example, for proof-of-concept studies or if short-term expression is sufficient, adenoviral vectors (AdV) show great efficiency of transduction *in vitro* and *in vivo*. However, the immunogenicity of these vectors precludes their use for therapeutic purposes [3], particularly in the context of chronic diseases such as diabetes.

For therapeutic, *in vivo* approaches in which long-term gene expression is desired, adeno-associated vectors (AAV) stand out as the vectors of choice. The wild-type virus is non-pathogenic and the different serotypes of vectors have the ability to transduce a wide variety of cell types, mediating long-term expression of the gene of interest in non-dividing tissues. In addition, the simple composition of AAV vectors, and their low efficiency in transducing antigen-presenting cells (APCs), may contribute to their generally low immunogenicity [4]. These gene transfer vectors have been used in clinical trials since the mid-1990s, and no serious adverse events related to the vectors have been described so far. More than 3000 individuals have been enrolled in these studies, comprising adults and children affected by different pathologies, generally all serious illnesses, and administered with recombinant AAV at different doses and through different routes to target different organs, mainly liver, skeletal muscle, brain, and eye [5–7]. Thus, recombinant AAV vectors are regarded as having a strong safety record after both local and systemic administration [5–7]. Indeed, three out of the seven gene therapy treatments approved for commercialization are AAV-based therapies [6]. In 2012 the European Medicines Agency (EMA) gave marketing approval to alipogene tiparvovec, the first gene therapy product for the management of lipoprotein lipase deficiency based on the administration of lipoprotein lipase-expressing AAV vectors of serotype 1 (AAV1) to the muscle [6]. In 2017, the AAV2-based voretigene neparvovec-rzyl became the first Food and Drug Administration (FDA)-approved gene therapy for RPE65-mediated inherited retinal dystrophy; in 2018, this product also received market authorization from the EMA [8]. In 2019, the AAV9-based onasemnogene abeparvovec to treat spinal muscular atrophy in children was also authorized by the FDA [6]. Moreover, dozens of other AAV-based treatments are under clinical trial [6, 7].

The only limitations to the use of these vectors are their limited cloning capacity, the presence in the general population of pre-existing anti-AAV humoral immunity due to natural infection that may preclude transduction of certain organs, and the subclinical activation of capsid-specific T cells when vectors are administered to peripheral organs that can limit expression of the therapeutic transgene, although this has so far been efficiently controlled with short-course immunosuppression [9–11].

The main properties of the viral vectors most commonly used in gene therapy are summarized in Table 78.1.

Gene therapy for diabetes

Both type 1 diabetes and type 2 diabetes are characterized by hyperglycaemia, which, when not properly managed, may ultimately lead to the development of long-term complications with high morbidity and mortality. Although the management of hyperglycaemia remains the main target of strategies developed so far for diabetes, several approaches target other components of the disease pathogenesis, which are different in type 1 diabetes and type 2 diabetes, as discussed later.

Gene therapy for type 1 diabetes

The hyperglycaemia of type 1 diabetes results from an absolute deficiency of insulin secretion due to the autoimmune destruction of the β cells of the pancreas. Therefore, the main gene therapy approaches developed for type 1 diabetes have focused on restoring insulin production by islets or surrogate cells, enhancing glucose disposal, or avoiding the destruction of the remaining β cells.

Ex Vivo genetic engineering of islets for transplantation

Islet transplantation has demonstrable therapeutic benefit in people with type 1 diabetes, particularly with the Edmonton Protocol [12]. However, the scarcity of cadaveric donors and the large quantities of functional islets required for amelioration of diabetes in each single individual have limited the broad clinical application of this approach. Moreover, the processes of islet isolation, purification, and transplantation, together with the host's immune response, greatly impair islet function and promote islet apoptosis, limiting the long-term survival of the grafts [12]. To overcome these limitations, several studies have explored gene therapy strategies based on the *ex vivo* genetic engineering of islets prior to transplantation. Adenoviral vectors have been the most extensively used vectors to this end because of their high efficiency for *ex vivo* transduction of islets of different species, including humans [13–15]. Recently, the generation of a chimeric AAV vector displaying markedly enhanced human islet transduction efficiency has been reported [16]. The transgenes used to improve the outcome after transplantation can fall into three main categories:

1. Mitogenic and/or pro-survival/anti-apoptotic factors aimed at promoting islet survival, such as hepatocyte growth factor (HGF), X-linked inhibitor of apoptosis (XIAP), manganese superoxide dismutase (MnSOD), B-cell lymphoma 2 (Bcl-2), and haem oxygenase-1 (HO-1) [17–19].
2. Immunoregulatory genes to counteract the immune response that destroys β cells, such as interleukin-1 receptor antagonist protein (IRAP), interleukin (IL)-10, IL-4, the chemokine CCL22, US2 protein of human cytomegalovirus, serpin-9, and transforming growth factor β (TGF- β) [20–23].
3. Factors that promote vascularization, such as HGF and vascular endothelial growth factor (VEGF), given that hypovascularization, hypoxia, and nutrient deprivation have been deemed likely culprits for the short-term survival of transplanted islets [24, 25].

In general, these strategies have enhanced the viability and function of the transplanted islets and attenuated β -cell death, preventing graft failure and reversing hyperglycaemia. In addition to the *ex vivo* genetic manipulation of islets, AAV vectors have been used *in vivo* to deliver immunomodulatory genes, such as the immunosuppressive IL-10 or Epstein–Barr-derived BCRF-1, to the muscle of the recipient of the islet graft prior to the transplant [26, 27].

Table 78.1 General characteristics of the most commonly used viral vectors.

Viral vector	Retroviral (RV)	Lentiviral (LV)	Adenoviral (Ad)	Adeno-associated (AAV)	Herpes simplex (HSV)
Family	<i>Retroviridae</i>	<i>Retroviridae</i>	<i>Adenoviridae</i>	<i>Parvoviridae</i>	<i>Herpesviridae</i>
Pathogenicity of parental virus	Yes	Yes	Yes	No	Yes
Genome	ssRNA, lineal	ssRNA, lineal	dsDNA, lineal	ssDNA, lineal	dsDNA, lineal
Maximum cloning capacity	8 kb	8 kb	36 kb	4.7 kb	150 kb
Production at high titres	Yes	No	Yes (lower titres with third-generation vectors)	Yes	No
Insertion in host genome	Yes, with preference for regulatory elements	Yes, but with no preference for regulatory elements	No	Yes, but randomly and with extremely low frequency, mainly episomal	No
Innate immunity	Yes	Yes	High for first- and second-generation vectors	Very limited	Yes
Target cells	Infects dividing cells	Infects dividing and quiescent cells	Infects dividing and quiescent cells	Infects dividing and quiescent cells	Infects dividing and quiescent cells
Transgene expression	Long-lasting	Long lasting	Short-lived, except for third-generation vectors	Long-lasting	Short-lived, except for late-generation vectors
Main advantages	Long-lasting expression in dividing cells Production at high titres	Long-lasting expression in dividing cells	Episomal Production at high titres (except for third generation) High levels of transduction <i>in vivo</i> Non-pathogenic, low immunogenicity High cloning capacity	Episomal Production at high titres High levels of transduction <i>in vivo</i> Several serotypes with different tissue tropism	Episomal High cloning capacity
Main disadvantages	Infects only dividing cells Limited cloning capacity Risk of insertional mutagenesis	Limited cloning capacity Risk of insertional mutagenesis, but lower than for retroviral vectors	Inflammatory and immune responses to the viral proteins limit persistence of transgene expression. Diminished in third-generation vectors Useful only for short-term studies Unselective tropism	Limited cloning capacity	Transient expression of the transgene Non-characterized neurotoxicity

This strategy prevents recurrence of autoimmunity and allogeneic rejection, resulting in prolongation of graft survival and remission of diabetes in mice [26, 27].

Ectopic production of insulin by non- β cells

Other gene therapy strategies have focused on the use of surrogate cells to produce insulin. In β cells, proinsulin is processed into mature insulin by the proprotein convertases PC1/3 and PC2, which are absent in the majority of other cells. To solve this problem and enable the processing of proinsulin by surrogate cells not expressing PC1/3 and PC2, new proteolytic sites have been engineered in the proinsulin molecule, which are recognized by furin, a protease present in most cells. Several cell types have been used in *ex vivo* gene transfer approaches to achieve ectopic production of insulin [28–44]. However, in most of these studies the therapeutic effect was short-lived due to loss of transplanted cells.

The most noteworthy results in the attempts to achieve ectopic insulin production have been obtained by genetic engineering of hepatocytes *in vivo*. Hepatocytes are attractive target cells because they express the same glucose-sensing molecules as β cells, such as the glucose transporter type 2 (GLUT2), which mediates the

insulin-independent entry of blood glucose into the cell, and the enzyme glucokinase (GK), which phosphorylates the incoming glucose molecule. In addition, hepatocytes are essential regulators of carbohydrate metabolism and several genes expressed in the liver are transcriptionally regulated by glucose or insulin, offering the possibility of engineering glucose/insulin-controlled expression cassettes that mediate the production of insulin as a function of circulating glucose and insulin levels. To this end, naturally occurring promoters such as those from the GLUT2, phosphoenolpyruvate carboxykinase (PEPCK), glucose-6-phosphatase (G-6-Pase), and liver-pyruvate kinase (L-PK) genes as well as engineered hybrid and synthetic promoters have been used to mediate glucose/insulin-responsive insulin expression following *in vivo* delivery of gene transfer vectors [45–53]. Furthermore, lentiviral- and AAV-mediated constitutive expression of insulin by hepatocytes has been reported to be efficacious in diabetic rodents [41, 54–56]. However, none of the aforementioned *in vivo* systems managed to mimic the quick response to glucose of the insulin promoter [34], and the slow glucose-mediated transcriptional control of these promoters may result in an inadequate insulin secretory response, with post-prandial episodes of hyperglycaemia followed by hypoglycaemia several hours later [48, 53, 57].

Enhancement of glucose disposal

As an alternative to ectopic insulin expression in the liver, transfer of the insulin gene can be used to engineer a glucose sensor in skeletal muscle to enhance glucose uptake in a glucose-dependent manner in this tissue to lower hyperglycaemia [58]. Several reasons support the choice of skeletal muscle as a target organ for this strategy. First, muscle can efficiently secrete proteins into the bloodstream and has a metabolism highly based on glucose consumption, accounting for ~70% of glucose disposal after a meal. Second, muscle is easily accessible by non-invasive procedures, and gene transfer by AAV vectors leads to minimal systemic biodistribution, limiting biological effects to this organ even if ubiquitous promoters are used to direct therapeutic transgene expression [59]. Moreover, gene delivery to muscle is not limited by the presence of pre-existing neutralizing antibodies against AAV [60], a key aspect given the relatively high prevalence of anti-AAV antibodies in the general population [61].

Under normal conditions, insulin stimulates glucose uptake in skeletal muscle by promoting the translocation of the glucose transporter type 4 (GLUT4) to the plasma membrane [62]. Once inside the muscle cell, glucose is phosphorylated by hexokinase II (HK-II) [63]. HK-II has a low K_m for glucose and is inhibited by glucose-6-phosphate, which limits glucose uptake. In contrast to HK-II, the hepatic GK has a high K_m for glucose (about 8 mM), is not inhibited by glucose 6-phosphate, and shows kinetic cooperativity with glucose [63]. In diabetes, because of the lack of insulin, the translocation of GLUT4 to the plasma membrane and mRNA levels and activity of HKII are decreased in muscle cells [64, 65], compromising the ability of the skeletal muscle to dispose of glucose after a meal. To counteract the hyperglycaemia, a novel gene therapy approach has been developed based on the co-expression of the insulin and glucokinase genes in muscle cells. The rationale behind this approach is based on the following premises:

- Expression of constant, low levels of insulin ensures translocation of GLUT4 to the plasma membrane without the risk of causing hypoglycaemia.
- Low levels of insulin are also sufficient to inhibit lipolysis and prevent ketoacidosis.
- The expression of GK draws the uptake of glucose into the muscle cell only when blood glucose levels are high.

Hence, the combination of these two genes generates a glucose sensor in the skeletal muscle that uptakes large quantities of glucose only when circulating glucose levels rise, such as in post-prandial conditions, but does not cause hypoglycaemia, because GK activity is shut down at physiological glucose concentrations.

As a proof of concept, this approach was first tested in transgenic animals that overexpressed the insulin and glucokinase genes specifically in skeletal muscle [58]. When rendered diabetic, these mice were normoglycaemic and did not develop secondary complications. Afterwards, AAV1 vectors were used to transfer the insulin and glucokinase (GCK) genes to the skeletal muscle of diabetic mice. In contrast to untreated diabetic mice, in AAV1-Ins- and AAV1-GCK-treated mice, long-term restoration of fed and fasted normoglycaemia was achieved [58]. AAV1-treated mice also showed increased skeletal muscle glucose uptake, normalization of glucose metabolism in the liver (increased glucose uptake and glycogen synthesis and reduced hepatic glucose production), and improved glucose tolerance [38]. Moreover, these mice had normal food and fluid intake, and the weight of the abdominal fat pad and skeletal muscle was normalized [58]. This study established the proof of concept that a gene therapy based on the production of

basal levels of insulin and the increased uptake of glucose by the skeletal muscle allowed for tight regulation of glycaemia [58].

As a next step towards the clinical translation of this approach, a pre-clinical study in diabetic dogs was undertaken to investigate the feasibility, efficacy, and duration of the therapeutic effect as well as safety issues. A single intramuscular administration of AAV1 vectors encoding for insulin and GCK resulted in normalization of fasting glycaemia and accelerated disposal of glucose after an oral challenge for >4 years after gene transfer, with no episodes of hypoglycaemia, not even during exercise [59]. This normalization of glucose metabolism was associated with recovery of body weight, normal levels of glycated plasma proteins, and long-term survival without secondary complications. In contrast, gene transfer of either the insulin or the GCK genes alone failed to achieve complete correction of diabetes, indicating that a synergistic action of insulin and GK is needed for full therapeutic effect [59]. In a follow-up study, successful, multiyear (>8 yr) control of glycaemia without the need of supplementation with exogenous insulin was reported [66]. Metabolic correction was demonstrated through normalization of serum levels of fructosamine, triglycerides, and cholesterol, and remarkable improvement in the response to an oral glucose challenge. The persistence of vector genomes and therapeutic transgene expression years after vector delivery was documented in multiple samples from treated muscles, which showed normal morphology. This study demonstrated the long-term efficacy and safety of insulin and glucokinase gene transfer in large animals, and especially the ability of the system to respond to the changes in metabolic needs as animals grow older [66].

Reprogramming of surrogate cells into β cells

The concept of β -cell reprogramming implies the trans-differentiation of a surrogate cell into a functional β cell capable of sensing glucose and releasing insulin accordingly. This is generally achieved through the use of transcription factors, which are key for the differentiation of progenitor cells into β cells during pancreas development.

Most *in vivo* approaches tested so far have used adenoviral- or AAV-mediated gene transfer of pancreatic duodenal homeobox-1 (Pdx-1), NeuroD, MafA, and neurogenin-3 (Ngn3), individually or in combination, to liver or pancreatic cells [67–78]. Although adenoviral vectors generally mediate short-term expression of transgenes of interest (Table 78.1), their use here is justified because, at least in the liver of mice, adenoviral transduction *per se* is required for efficacy [77]. When the target cells were hepatocytes, oval cells, or ductal cells in the liver, hyperglycaemia partially ameliorated because of the expression of insulin in these cells, but full phenotypic conversion into functional β cells could not be achieved [67, 68, 71–74, 76, 77]. In contrast, when cells from the exocrine pancreas were reprogrammed, the resulting cells did not exhibit a hybrid or mixed phenotype, but closely resembled islet β cells at a biochemical and ultrastructural level [75, 78]. Furthermore, reprogrammed cells formed islet-like structures and mediated long-term (>1 yr) normalization of hyperglycaemia [75].

Promising results have also been obtained on reprogramming of α cells into functional β cells by adenoviral- or AAV-mediated expression of Pdx1 and MafA [70, 79]. The reprogrammed mouse insulin⁺ cells exhibited a gene expression pattern similar to endogenous β cells and mediated normalization of glycaemia for four months in both alloxan-induced diabetic mice and non-obese diabetic (NOD) mice, a model of spontaneous autoimmune diabetes [70, 79]. These gene therapy strategies also induced α - to β -cell

conversion in both streptozotocin-treated human islets and purified human α cells before pseudo-islet reaggregation [70, 79]. When transplanted into immunodeficient NOD mice, reprogrammed cells ameliorated hyperglycaemia and glucose tolerance for at least six months [70, 79]. Pseudo-islets obtained on reaggregation of reprogrammed human α cells displayed a transcriptomic and proteomic signature that was intermediate between α and β cells, which further shifted towards that of β cells after transplantation into mice, and displayed reduced immunogenicity for type 1 diabetes autoreactive T cells [79]. Moreover, adenoviral-mediated expression of Pdx1 and MafA also mediated successful reprogramming of human γ cells, which produced and secreted insulin in response to glucose [79].

It should be borne in mind that *in vivo* and *ex vivo* genetically reprogrammed β cells, like endogenous islet β cells, will be susceptible to autoimmunity [70, 80], hence reprogramming gene therapy approaches may require concomitant immunotherapy to avoid destruction of the β -cell surrogates.

In Vivo β -cell regeneration

Another approach to restore the β -cell mass considers the regeneration of β cells from those cells that have survived the attack of the immune system. The regenerative potential of the endocrine pancreas seems to be quite high immediately after the onset of the disease [81], but it slows down as the disease progresses [82]. To induce replication of the remaining β cells, genes have been transferred *in vivo* to murine and canine β cells, mostly by means of adenoviral and AAV vectors, the latter having a much more efficient transduction, via different routes of delivery including intravenous and intraperitoneal systemic administration and local delivery to the pancreas through the bile-pancreatic duct [83–87]. Moreover, non-viral gene transfer to the pancreas in rats and non-human primates has also been reported using ultrasound targeted microbubble destruction technology (UTMD), although transgene expression was transient [88–90]. *In vivo* gene transfer of mitogenic and anti-apoptotic/pro-survival factors such as HGF, Sirtuin 1, angiopoietin-like protein 8, or downregulation of NADPH oxidase 2 (Nox2) or miR-338-3p reduced apoptosis and induced proliferation of β cells [85, 91–94]. Noticeably, delivery of glucagon-like peptide 1 (GLP-1), β -cellulin, Akt, or Nkx2.2 mediated not only β -cell regeneration but also reversal of diabetes [89, 95–98]. Other genes that promote therapeutic benefit in transgenic animal models and are therefore promising for gene therapy approaches for type 1 diabetes include insulin-like growth factor I (IGF-I), regenerating gene 1 (Reg1), epidermal growth factor (EGF), gastrin, and nerve growth factor (NGF) [99–103]. In this regard, AAV-mediated pancreatic-specific overexpression of IGF-I in NOD mice dramatically reduced diabetes incidence, both when vectors were delivered before pathology onset and once insulitis was established [104]. Treated NOD animals showed decreased β -cell apoptosis, preserved β -cell mass, normal insulinaemia, and lower islet infiltration than controls. Moreover, AAV-IGF-I-treated NOD mice also exhibited decreased islet expression of antigen-presenting molecules, inflammatory cytokines, and chemokines important for tissue-specific homing of effector T cells, suggesting IGF-I modulated islet autoimmunity [104].

Immune modulation

The immune system is a key component of the aetiopathogenesis of type 1 diabetes. The T cell-mediated destruction of β cells arises as a consequence of the breakage of tolerance to β -cell antigens.

Consequently, many gene therapy approaches developed for the treatment of type 1 diabetes aim to increase the number and/or activation of regulatory T cells (Tregs) and/or decrease the frequency of autoreactive T cells. Among all vectors, AAVs have been the most widely used vectors *in vivo* to transfer immunomodulatory genes to prevent or ameliorate type 1 diabetes in mice. AAV-mediated overexpression of the cytokines IL-2, IL-4, IL-10, IL-35, or the chemokine CCL22 have demonstrated therapeutic efficacy in NOD mice [105–111]. IL-2 is the key cytokine supporting the survival and function of Tregs [105]. Treatment with low-dose recombinant IL-2 safely expands and stimulates Tregs and improves the clinical condition in humans with type 1 diabetes, but multiple administrations were needed [112]. In contrast, one-time, AAV-mediated, systemic, muscular, or β cell-specific delivery of the IL-2 gene increased the frequency and activation of Tregs and prevented diabetes in NOD mice [105, 106, 108]. IL-4 induces the expression of the transcription factor forkhead box P3 (Foxp3), the defining marker of Tregs [113], in Treg precursor cells [114]. AAV-mediated expression of IL-4 in β cells prevented islet destruction and onset of diabetes in NOD mice [110].

On the other hand, IL-10 plays an important role in the development of Tregs and secretion of IL-10 by Tregs inhibits effector T-cell responses [113]. Gene transfer of IL-10 to murine muscle increased Tregs in a dose-dependent manner and abrogated diabetes development [107]. IL-35 is secreted by and contributes to the suppressor function of Tregs [115]. Additionally, IL-35 promotes differentiation of CD4 $^{+}$ T cells into induced regulatory Th35 suppressor cells [116]. AAV-mediated β cell-specific expression of IL-35 in NOD mice suppressed β -cell autoimmunity and prevented diabetes onset. Protection was marked by significantly reduced numbers of islet CD4 $^{+}$ and CD8 $^{+}$ T cells and dendritic cells and a phenotypically distinct islet Foxp3 $^{+}$ Treg pool, which in turn was needed to suppress effector CD4 $^{+}$ T differentiation [111]. Finally, CCL22 is the ligand of the chemokine receptor CCR4, highly expressed on Tregs. Overexpression of CCL22 in β cells recruited endogenous Tregs to the islets, limiting the expansion and effector activity of autoreactive T cells and conferring long-term protection from autoimmune diabetes [109].

Another strategy is based on the conversion of cytotoxic T cells, including pathogenic, β cells specific T cells, into Tregs through *ex vivo* lentiviral or retroviral vector-mediated gene transfer of Foxp3 [117, 118]. Tregs have also been genetically engineered with antigen-specific immunoreceptors using lentiviral vectors to generate islet-specific Tregs, which showed antigen-specific suppression *in vitro* and compare favourably to adoptive Treg therapy using *ex vivo* expanded polyclonal Tregs [119]. Polyclonal Tregs therapy is currently in clinical trials for the treatment of type 1 diabetes [120], but antigen-specific Tregs exhibit higher specific potency, furthering the promise of this therapy [119]. In addition, systemic administration of adenoviral vectors encoding a cytotoxic T lymphocyte-associated antigen 4 (CTLA4)-Fas ligand fusion protein stimulated apoptosis, blocked co-stimulation of autoreactive T cells, and greatly reduced the incidence of type 1 diabetes [121]. *Ex vivo* antigen-specific targeting of autoreactive CD8 or CD4 T cells specifically killed diabetogenic T cells *in vitro* as well as reducing the incidence and delaying the onset of diabetes in NOD mice [122, 123]. Similarly, engineered CAR-T cells that specifically target diabetogenic APCs delay the onset of type 1 diabetes in NOD diabetes [124].

Another group of strategies has relied on the active induction of immune tolerance, for example by expression of the pre-proinsulin

II gene in the thymus following intrathymic administration of lentiviral vectors [125]; by non-viral, lentiviral, or AAV-mediated gene transfer of the IGF-I gene, the insulin B chain 9–23 (InsB9–23), or the major histocompatibility complex (MHC) class I molecule H-2K to the liver [126–129]; or by transient, adenoviral-mediated expression of a soluble form of the immunoadhesin intercellular adhesion molecule 1 (ICAM-1) [130] soon after diabetes onset. All these approaches resulted in suppression of autoimmune diabetes in NOD mice or transgenic mice overexpressing human interferon β in β cells [100], both of which are murine models of human type 1 diabetes. Induction of antigen-specific tolerance by retroviral-mediated expression of insulin or glutamic acid decarboxylase 65 (GAD65) in B lymphocytes is also promising for type 1 diabetes [131]. Likewise, the administration of viral vector- or plasmid-based gene transfer vaccines encoding the autoreactive antigens insulin, proinsulin, or GAD65 induces immune tolerance and prevents the development of type 1 diabetes in mice [132–134].

Gene therapy for type 2 diabetes

Although most of the gene therapy strategies developed so far for diabetes have focused on type 1 diabetes, as the scientific understanding of the pathophysiology of type 2 diabetes increases, a growing number of proof-of-concept gene transfer studies are being conducted in rodents to evaluate the therapeutic efficacy of several candidate factors, as well as to gain insight into the molecular mechanisms underlying type 2 diabetes. The results of these studies highlight the tremendous potential of the genetic modification of metabolic tissues for the treatment of type 2 diabetes.

Type 2 diabetes results from a state of insulin resistance in peripheral tissues (mainly skeletal muscle, adipose tissue, and liver), which is not appropriately compensated for by an increased insulin secretory response, likely due to a combination of decreased β -cell mass and function. Development of insulin resistance and type 2 diabetes is strongly associated with obesity. Obesity results from a sustained imbalance between energy intake and expenditure. Indeed, impaired brown adipose tissue (BAT) activity (non-shivering thermogenesis) and/or decreased mass are considered among the main contributors to type 2 diabetes and obesity both in experimental animal models and in humans.

Therefore, the vast majority of gene therapy strategies for type 2 diabetes have focused on ameliorating insulin resistance and glucose tolerance, on enhancing energy expenditure (by increasing BAT activity and/or inducing browning of white adipose tissue [WAT]), and on improving adipose tissue dysfunction and inflammation.

Amelioration of insulin resistance

The systemic administration of adenoviral vectors encoding GLP-1 improved insulin sensitivity through restoration of insulin signalling in peripheral tissues and reduction of hepatic gluconeogenesis in diabetic obese *ob/ob* mice [135]. The attenuation of insulin resistance has also been achieved in type 2 diabetes high-fat diet (HFD)-fed rats through systemic AAV-mediated gene transfer of the serine protease kallikrein [136]. Kallikrein converts kininogen to the peptidic hormone bradykinin, which increases insulin sensitivity and stimulates glucose uptake *in vivo* [137]. Similarly, the AAV-mediated local gene transfer of HK-II to WAT or BAT has managed to increase glucose uptake in adipocytes [138, 139], and may also be a promising strategy for improving insulin sensitivity in type 2 diabetes [140]. Intra-WAT administration of AAV vectors encoding perilipin A reduced blood glucose and free fatty acid

levels and modified the respiratory exchange ratio, indicating a more pronounced use of glucose as an energy source [141].

Individuals with type 2 diabetes overexpress phosphoprotein enriched in diabetes/phosphoprotein enriched in astrocytes (PED/PEA-15) in skeletal muscle and adipose tissue [142], a protein that causes insulin resistance by interacting with the D4 domain of phospholipase D1 (PLD1) [143]. The disruption of the association between PLD1 and PED/PEA-15 at a tissue level through adenoviral-mediated overexpression of a soluble form of D4 in the liver, pancreas, and skeletal muscle restored glucose homeostasis by improving both insulin sensitivity and secretion in diabetic transgenic mice ubiquitously overexpressing PED/PEA-15 and in obese HFD-fed wild-type mice [144].

Cholesterol is involved in the development of obesity, insulin resistance, and hepatic steatosis [145]. The ABCG5 ABCG8 (G5G8) sterol transporter promotes cholesterol excretion into the bile and the intestinal lumen. Following adenovirus-mediated delivery of the G5G8 genes to the liver of *db/db* mice, the levels of biliary cholesterol and faecal sterol increased, the levels of plasma glucose and triglycerides decreased, and glucose tolerance improved [145]. These changes were associated with reduced expression of lipogenic genes, alleviation of endoplasmic reticulum (ER) stress, and restoration of hepatic insulin signalling [145].

Expression and activity of HO-1 are reduced in obesity, resulting in elevation of reactive oxygen species and insulin resistance in both humans and mice [146]. Adipose-specific lentiviral-mediated overexpression of HO-1 in HFD mice increased insulin sensitivity in adipose tissue, and decreased adipocyte hypertrophy and expression of inflammatory cytokines and fibrosis in WAT. Moreover, HO-1-treated mice also showed increased thermogenesis, reduced body weight and fasting blood glucose levels, and increased glucose tolerance [146].

Enhancement of thermogenesis and reduction of adipose tissue dysfunction and inflammation

Given the strong association between type 2 diabetes and obesity, many gene transfer studies have targeted adiposity, adipocyte dysfunction, and/or adipose tissue inflammation as well as energy expenditure, with the aim of ultimately improving insulin sensitivity and glucose tolerance. AAV-mediated gene transfer of bone morphogenic protein 4 (BMP4) to the liver of mice resulted in increased BMP4 circulating levels and enhanced whole-body energy expenditure due to marked browning of WAT. AAV-BMP4-treated mice were protected from obesity and showed improved insulin sensitivity and glucose tolerance [147]. In obese animals, AAV-BMP4 vectors had no effect on body weight, browning of WAT, or energy expenditure, but whole-body insulin sensitivity and glucose tolerance were robustly improved [148]. Insulin signalling and insulin-stimulated glucose uptake were increased in both adipose cells and skeletal muscle. AAV-BMP4 also decreased hepatic glucose production, reduced gluconeogenic enzymes in the liver, and enhanced insulin action [148].

Several studies have shown that cold temperature can activate pro-opiomelanocortin-expressing neurons and increase sympathetic neuronal tone to regulate browning of WAT. AAV-mediated overexpression of connexin 43 in white adipocytes mediated browning of WAT by facilitating the propagation of sympathetic neuronal signals [149]. Likewise, AAV-mediated BAT-specific miR-32 overexpression led to increased BAT thermogenesis and browning of WAT [150]. The intra-cerebroventricular administration of AAV vectors encoding the adipokine leptin prevented

HFD-induced adiposity, reduced blood glucose and insulin levels, and increased thermogenesis [151]. The effect was mediated by transduction of the hypothalamic cells of the brain [152]. Intraperitoneal or intra-WAT administration of AAV-leptin vectors to *ob/ob* obese mice also mediated therapeutic benefit, ranging from partial to total, in ameliorating obesity and glucose homeostasis [153, 154]. The administration to the skeletal muscle of AAV vectors encoding the secreted glycoprotein Wnt10b, a recently described member of the Wnt family reported to inhibit adipogenesis, decreased overall fat mass and improved glucose and energy homeostasis in obese rats [155]. In humans, mutations in Wnt10b are associated with obesity [156], and certain variants of the transcription factor 7-like 2 (*TCF7L2*, formerly *TCF4*) gene, another member of the Wnt signalling pathway, confer increased risk of type 2 diabetes [157].

AAV-mediated delivery to white adipocytes of mitoNEET, a protein residing in the mitochondrial outer membrane and involved in the regulation of mitochondrial iron content, or of BMP7 resulted in benign expansion of WAT, reduced inflammation, and preservation of insulin sensitivity in obese mice [158, 159]. Likewise, the adenoviral-mediated gene transfer of the secreted frizzled-related protein 5 (*Sfrp5*) to the liver reduced adiposity and adipose tissue inflammation in different models of obesity and diabetes, improving glucose tolerance and insulin sensitivity [160]. *Sfrp5* is an anti-inflammatory adipokine linked to the Wnt signalling pathway whose expression is perturbed in models of obesity and type 2 diabetes [160]. Inhibition of macrophage infiltration and inflammation in adipose tissue occurs on intravascular delivery to obese diabetic mice of adenoviral vectors encoding GLP-1 that result in increased circulating levels of the protein [161]. This observation suggested that the anti-inflammatory action of GLP-1 on adipose tissue might be the mechanism underlying the reported improvement in insulin sensitivity.

Interferon regulatory factor (IRF) proteins are a family of nine transcription factors involved in the mammalian regulation of type I interferon expression and innate immunity [162, 163]. These proteins also seem to play an important role in metabolism [164, 165]. For example, hepatic expression of IRF3 decreases in animals with diet-induced and genetic obesity [165], making IRF proteins interesting targets for gene therapy approaches to counteract type 2 diabetes. Adenoviral-mediated liver-specific overexpression of IRF3 or 9 improves glucose and lipid homeostasis and attenuates systemic and hepatic inflammation in diet-induced diabetic and *ob/ob* mice [164, 165].

Another promising therapeutic candidate for type 2 diabetes and obesity is adiponectin, which possesses insulin-sensitizing and anti-inflammatory properties [166]. In humans, adiponectin levels are inversely correlated with the degree of adiposity, insulin resistance, and type 2 diabetes [167, 168]. Muscular or hepatic gene transfer of adiponectin by means of AAV vectors enhanced insulin sensitivity, reduced obesity, and downregulated hepatic gluconeogenesis, *de novo* lipogenesis, and inflammation in HFD-fed diabetic rats [166, 169]. Similar results were obtained on non-viral-mediated overexpression of adiponectin in obese-diabetic rats [170]. Likewise, the adenoviral-mediated expression of C1q/TNF-related protein-12, an adipokine sharing partial homology with adiponectin, improved glucose tolerance and insulin sensitivity, and normalized hyperglycaemia and hyperinsulinemia in obese diabetic mice [171].

Obesity-associated adipose tissue hypoxia that occurs as a result of insufficient blood flow could trigger insulin resistance by

inducing inflammation, altering adipokine expression, and/or affecting adipocyte differentiation [172–174]. Recent studies have demonstrated that AAV-mediated overexpression of VEGF in murine WAT or BAT can not only increase tissue vascularization, but also induce browning of WAT or non-shivering thermogenesis in BAT, respectively [138, 175, 176]. This may be a promising approach for the treatment of type 2 diabetes, as VEGF overexpression in adipose tissue of transgenic mice protects against obesity and insulin resistance in HFD-fed mice [177].

Long-term reversal of insulin resistance and obesity

Although the aforementioned gene transfer approaches for insulin resistance and obesity show promising results in animal models, long-term therapeutic benefit has not been reported for any of them.

Fibroblast growth factor 21 (FGF21) has recently emerged as a promising therapeutic agent for the treatment of type 2 diabetes and metabolic disorders [178, 179]. This peptide hormone is secreted by several organs and can act on multiple tissues to regulate energy homeostasis. FGF21 analogues with improved pharmacokinetic properties have reached the clinical stage, and reports from phase I and phase II clinical trials have shown significant improvement of dyslipidaemia, slight body weight loss, increases in adiponectin, and reductions in fasting insulinaemia in individuals with obesity and type 2 diabetes [180–186]. Nevertheless, engineered FGF21 mimetics or analogues may raise immunological issues associated with the administration of exogenous proteins [180–182, 187, 188]. In contrast, gene therapy allows one to work with the wild-type protein that is recognized as its own by the immune system and signals through the canonical FGF21 signalling pathways, avoiding unspecific biological responses.

Recently, a single administration of AAV vectors encoding native FGF21 was reported to enable efficient genetic engineering of the liver and long-lasting secretion of therapeutically relevant levels of FGF21 to the bloodstream, which mediated sustained (>1 yr) counteraction of obesity, non-alcoholic steatohepatitis (NASH), and insulin resistance in two different models of obesity and type 2 diabetes (HFD-fed mice and *ob/ob* mice) [189]. Specifically, reversal of adipose tissue hypertrophy and inflammation as well as of hepatic steatosis, inflammation, and fibrosis was achieved. Moreover, AAV-FGF21-based gene therapy also mediated improvements in energy expenditure and glucose homeostasis, which were linked to increased non-shivering thermogenesis in BAT, glucose uptake in brown or white adipocytes, normalization of adiponectin and leptin levels, and counteraction of islet hyperplasia, with consequent reduced insulin and glucagon levels. These therapeutic effects were achieved in the absence of side effects despite continuously elevated serum FGF21. Indeed, AAV-FGF21-treated mice were protected from obesity-associated liver neoplasms. Similar therapeutic benefit was reproduced after genetic engineering of adipose tissue or skeletal muscle to mediate sustained FGF21 circulating levels [138, 189]. Furthermore, FGF21 overproduction in healthy animals fed a standard diet expanded health span and prevented age-related weight gain and insulin resistance, confirming that AAV-FGF21 gene therapy is safe [189].

Therefore, AAV-FGF21-based gene therapies recapitulate the previously reported benefits of pharmacological FGF21 analogues and mimetics, while avoiding essential obstacles such as treatment adherence and immunogenic reactions. These findings reinforce the therapeutic efficacy of AAV-mediated FGF21 gene therapy and constitute the basis to support the future clinical translation of FGF21 gene transfer to treat type 2 diabetes, obesity, and related comorbidities.

Conclusion and perspectives

Viral vectors have taken the lead as tools to achieve efficient *ex vivo* and *in vivo* long-term genetic modification of tissues and organs through a single vector delivery. This technological advance has opened the possibility not only of performing gene transfer studies to understand the role of a given gene in disease, but also of the

development of new therapeutic strategies. In the case of diabetes there are several gene transfer approaches with demonstrated efficacy in lowering blood glucose that could offer an advantage over conventional treatments. Future studies are required to demonstrate the efficacy and safety in large animal models of the approaches that have demonstrated promise in small animals before any of these gene therapies are brought to the clinic to treat diabetes in humans.

Clifford J. Bailey

School of Life and Health Sciences, Aston University, Birmingham, UK

Key points

- Despite a variety of differently acting glucose-lowering agents, many people with type 2 diabetes do not achieve or maintain adequate glycaemic targets. Hence there is a continued need for new agents.
- The variable aetiology and pathogenesis of type 2 diabetes require a diversity of therapies that can be used in combination as the disease progresses.
- Fixed-ratio combinations of peptides such as a glucagon-like peptide 1 (GLP-1) receptor agonist with insulin, and potential hybrid peptides of incretins and other gluco-regulatory hormones, offer the opportunity to interact with several target receptors via a single injection.
- Further incretin-based therapies include orally active peptide formulations, small-molecule (non-peptide) receptor agonists, and depot injections.
- Tissue selective insulins and glucose-responsive (smart) insulins are attractive possibilities: the latter release insulin from a circulating chemical complex or implanted depot by direct chemical interaction with glucose, so that rising concentrations of glucose are matched by increasing release of insulin.
- Novel insulinotropic agents have been shown to alter β -cell energetics, reduce β -cell apoptosis, and preserve β -cell mass in pre-clinical studies: these could slow the long-term progression of type 2 diabetes.
- Proof of principle has been demonstrated for small molecules to mimic and potentiate insulin action to counter insulin resistance.
- Glucagon receptor antagonists, selective peroxisome proliferator-activated receptor (PPAR) modulators, cellular glucocorticoid inhibitors, adiponectin receptor agonists, and fibroblast growth factor analogues continue to be at various stages of development.
- Agents that directly enhance glucose metabolism or suppress glucose production have been described, such as activators of adenosine 5'-monophosphate-activated protein kinase.
- New inhibitors of sodium–glucose cotransporters (SGLT-1 and SGLT-2) are becoming available.
- Emerging pharmacogenomics and proteomics could offer novel therapeutic opportunities.

Despite many initiatives to prevent type 2 diabetes, its prevalence continues to rise, accounting for >90% of the global totality of people with diabetes (~465 million in 2019 and projected to be ~700 million by 2045) [1]. Current treatment strategies are reviewed in earlier chapters of this book, and the importance of an early, effective, individualized therapeutic approach to glycaemic management is emphasized to defer the onset and reduce the severity of complications. Although many differently acting classes of glucose-lowering agents are already available (Figure 79.1), a sustained return to normal glucose homeostasis is rarely achieved, and more than one-third of people with type 2 diabetes do not attain or maintain acceptable glycaemic targets [2–4]. This chapter reviews some of the new therapeutic approaches under consideration to improve glycaemic management in type 2 diabetes, from innovative concepts in pre-clinical investigation through to agents advanced in clinical development.

Development of new glucose-lowering agents

The highly variable aetiology and pathogenesis of type 2 diabetes, which typically involves disturbances in multiple tissues and organ systems, open the possibility of many potential approaches to blood

glucose management [5]. Some of these approaches directly target underlying pathophysiological defects such as insulin resistance and pancreatic β -cell dysfunction, but interventions that improve glycaemic indices by any safe means should reduce the risk of complications. Because treatments are often life-long and contemporaneous with comorbidities, frailty, multiple pharmacotherapies, and lifestyle challenges, it is important that new agents offer a commendable safety profile, are well tolerated, and are compatible with a broad selection of other medications. Ideally, they will provide durable and additive glucose-lowering efficacy to existing agents through different but complementary modes of action, while carrying minimal risk of serious hypoglycaemia. Additional capability to reduce adiposity and improve other modifiable cardiovascular risk factors such as dyslipidaemia and hypertension would also be preferred.

Identifying a new chemical entity and progressing it through the pre-clinical and clinical phases of development to marketing approval are likely to take at least 10 years (Table 79.1). The cost is expected to exceed US\$1 billion, with some estimates up to US\$2.8 billion [6]. For glucose-lowering drugs, post-authorization safety studies to monitor cardiovascular outcomes and other events may be required [7]. Further development is often undertaken for additional indications and to produce new formulations, including single-tablet fixed-dose combinations or fixed-ratio injection combinations.

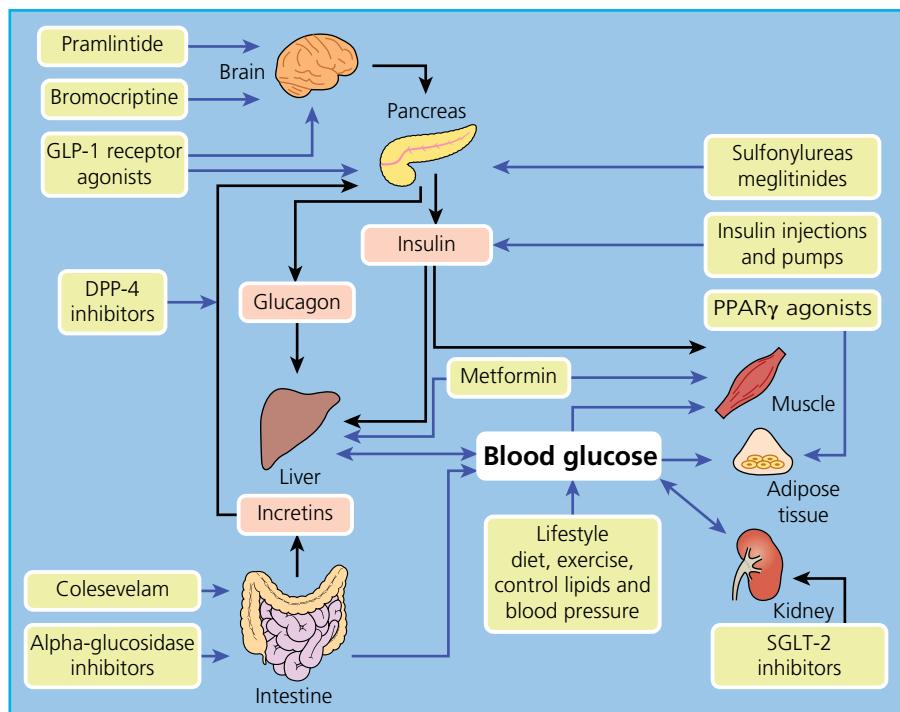

Figure 79.1 Current glucose-lowering therapies showing their main sites of action. Not all classes of therapies are indicated for the treatment of type 2 diabetes in all regions. DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide 1; PPAR, peroxisome proliferator-activated receptor; SGLT-2, sodium–glucose cotransporter 2.

Table 79.1 Stages in the development of a new drug.

Pre-clinical stages
New chemical entity
<ul style="list-style-type: none"> Identification, extraction/synthesis, chemical characterization, and patenting of compounds Genotoxicity testing: screening for biological activity <i>in vitro</i> and <i>in vivo</i> in animals Pre-clinical pharmacology, mode of action, pharmacodynamics (activity, safety, tolerance), pharmacokinetics (bioavailability, distribution, metabolism, elimination), and toxicity in ≥2 mammalian species
Clinical stages
Investigational new drug application: permission to begin clinical studies
Phase I
<ul style="list-style-type: none"> First administration to a small number of healthy human volunteers Dose ranging, vital signs, pharmacodynamics, pharmacokinetics, drug interactions, safety
Phase II
<ul style="list-style-type: none"> First trials in small numbers of people with the condition Dose ranging, efficacy, further pharmacodynamics, pharmacokinetics, and safety
Phase III
<ul style="list-style-type: none"> Trials in larger numbers of people with the condition Multicentre trials, comparative trials with other treatments, efficacy, further pharmacodynamics and safety (including meta-analysis of cardiovascular events)
New drug application: permission to market as a drug
Phase IV
<ul style="list-style-type: none"> Use in medical practice Additional trials (similar to phase III) for long-term efficacy and safety, and use in special subgroups (e.g. older people), post-marketing surveillance, and adverse drug reactions

Dietary supplements and intestinal agents

Of the many dietary supplements promoted as beneficial in type 2 diabetes, there are substantial data confirming that various soluble and insoluble plant polysaccharides can delay the digestion and absorption of carbohydrates, and may exert a prebiotic effect to alter the intestinal microbiome (Table 79.2). Reductions of post-prandial hyperglycaemia and *carry-over* reductions in basal glycaemia are generally modest, but can be useful when taken in conjunction with most classes of glucose-lowering pharmacotherapies [8]. Extended digestion times achieved with fibre supplements can reduce inter-prandial hypoglycaemia in insulin-treated individuals. Various changes in the composition of the intestinal microbiome have been reported in type 2 diabetes, and some probiotic cultures have been associated with modest glucose lowering in some studies, although findings have been inconsistent [9, 10].

The effects of vitamin and mineral supplements as adjunct treatments in type 2 diabetes remain controversial, and it is stressed that potential benefits of correcting deficiencies are very different to massive doses for individuals who already have adequate levels. Deficiencies in vitamin D are associated with insulin resistance and β-cell dysfunction, but supplementation in deficient individuals has shown only nominal (if any) reductions in glycated haemoglobin ($\text{HbA}_{1\text{c}}$) [11]. Low concentrations of antioxidant vitamins, notably vitamins C (ascorbic acid) and E (α-tocopherol) and β-carotene, are not uncommon in type 2 diabetes, but supplements have achieved little improvement in glycaemic indices or cardiovascular risk [12]. Thiamine (vitamin B₁) and biotin (vitamin H) have also been considered as possible supplements to improve glucose metabolism [13].

Reduced levels of magnesium, chromium, and zinc are frequently encountered in type 2 diabetes and supplements have

Table 79.2 Dietary fibre supplements and probiotics.

	Mechanisms of action	Effect on glycaemic indices
Soluble fibre e.g. gums, pectins, hemicelluloses, mucilages, fructans	Includes non-digestible carbohydrate and entrapped digestible carbohydrate causing digestion and absorption to be slowed. Possible prebiotic effect to alter microbiome	Reduce post-prandial hyperglycaemia: modest reductions of fasting plasma glucose and glycated haemoglobin (HbA_{1c})
Insoluble fibre e.g. celluloses, wheat bran		
Probiotics Live cultures of e.g. <i>Lactobacillus species</i> and <i>Bifidobacterium species</i>	Mechanisms unclear: probably decrease gut permeability, immunomodulation, increase short-chain fatty acid production	Small reductions in fasting plasma glucose and HbA_{1c} in some studies (considerable differences in cultures tested and study designs)

improved glycaemia in deficient individuals [14]. Selenium, molybdenum, tungsten, mercury, and cadmium have also been reported to improve glucose metabolism in pre-clinical models, but the mechanisms are unclear, the therapeutic index is generally narrow, and toxicity risks are high. Lithium can improve insulin sensitivity, but may also decrease insulin secretion with unpredictable effects [15].

Inhibitors of α -amylases to slow the hydrolysis of starch continue to generate interest, but have not given sufficiently predictable effects for therapeutic application [16]. Inhibitors of brush-border α -glucosidases such as acarbose, miglitol, and voglibose are well established therapies to slow the last stages of carbohydrate digestion. Although novel α -glucosidase-inhibiting molecules have been identified, these have not proceeded in clinical development [17]. Inhibition of sodium–glucose cotransporter 1 (SGLT-1) in the intestinal brush border provides another option to slow the absorption of glucose, and this is considered in a later section.

Supporting pancreatic β -cell function

Disturbances of pancreatic β -cell function occur early in the pathogenesis of type 2 diabetes and β -cell failure is a prominent feature of advanced stages of type 2 diabetes, making the β cell a key therapeutic target. Agents that initiate insulin secretion (sulphonylureas and meglitinides) or potentiate nutrient-induced insulin secretion (dipeptidyl peptidase 4 [DPP-4] inhibitors and glucagon-like peptide 1 [GLP-1] receptor agonists) are widely used in the treatment of type 2 diabetes (see Chapters 35 and 36). These agents partially compensate for the loss of an adequate first-phase insulin response in type 2 diabetes, enhance the second phase of secretion, and improve the secreted proportion of insulin relative to proinsulin. Limitations to the clinical use of these agents are considered in Chapter 35, but it is emphasized here that preservation or restoration of β -cell mass and function, especially in advanced stages of type 2 diabetes, remains a fundamental challenge [5].

Many compounds with insulin-releasing properties have received pre-clinical and early clinical investigation, but targeting the pancreatic β cells to the exclusion of other cell types has been a particular problem, and few compounds have proceeded further in development [15]. Included here are agents that increase adenosine triphosphate (ATP) production, close K^+ ATP channels, depolarize the β -cell membrane, increase cytosolic calcium, enhance cyclic adenosine monophosphate (cAMP) or protein kinase C (PKC), activate imidazoline receptors, or suppress α_2 -adrenergic receptors.

Glucokinase activators

Agents that activate the glucose phosphorylating enzyme glucokinase (GK) (EC 2.7.1.1) continue to attract interest as a means of initiating insulin secretion by increasing β -cell glucose metabolism (Figure 79.2). However, this approach is prone to precipitate hypoglycaemia and often incurs loss of efficacy after several months of treatment in type 2 diabetes [16, 17]. Glucokinase is also expressed in the liver, where it is regulated differently to pancreatic β cells. Hepato-selective GK activators are being investigated to increase post-prandial hepatic glucose uptake, and although this avoids hypoglycaemia, it presents a risk of excess glycogen deposition and increased lipogenesis in the liver.

Fatty acid receptor agonists

Pancreatic β cells express G protein-coupled receptors for medium-chain and long-chain free fatty acids, notably FFAR1 (GPR40) and GPR119. Small-molecule agonists of these receptors can enhance insulin secretion in different ways: FFAR1 agonists can initiate and potentiate insulin secretion via raised cytosolic Ca^{2+} ; whereas GPR119 signals via adenylate cyclase to potentiate nutrient-induced insulin secretion by raising cAMP [18, 19] (Figure 79.2). Both FFAR1 and GPR119 are expressed by enteroendocrine K cells, L cells, and I cells; this enables agonists for these receptors to increase the incretin effect by increasing secretion of glucose-dependent insulinotropic peptide (GIP), GLP-1, and polypeptide YY (PYY), and further increasing satiety via oxyntomodulin and cholecystokinin. Activation of FFAR1 receptors expressed by pancreatic α cells may also reduce glucagon secretion, whereas GPR119 agonists can raise glucagon levels [20]. Agonists of another fatty acid receptor, FFAR4 (GPR120), which is widely expressed mainly by endocrine, intestinal, and adipose tissues, promote adipogenesis, increase insulin sensitivity, improve glucose tolerance, and reduce ectopic fat. FFAR4 is therefore being considered as a potential therapeutic target [21]. The widespread expression and diverse effects of fatty acid receptors, however, create challenges to confine the effects of agonists to selected tissues.

Imeglimin

Imeglimin is a triazine compound that alters mitochondrial energetics with an increased flux through complex III, and possibly also delays the opening of mitochondrial permeability transition pores. This increases ATP synthesis, reduces the production of reactive oxygen species, and restricts the release of pro-apoptotic proteins from mitochondria [22]. Accordingly, in pancreatic β cells glucose-stimulated insulin secretion is improved and apoptosis is reduced, while hepatic gluconeogenesis is suppressed and insulin-mediated glucose uptake by skeletal muscle is enhanced.

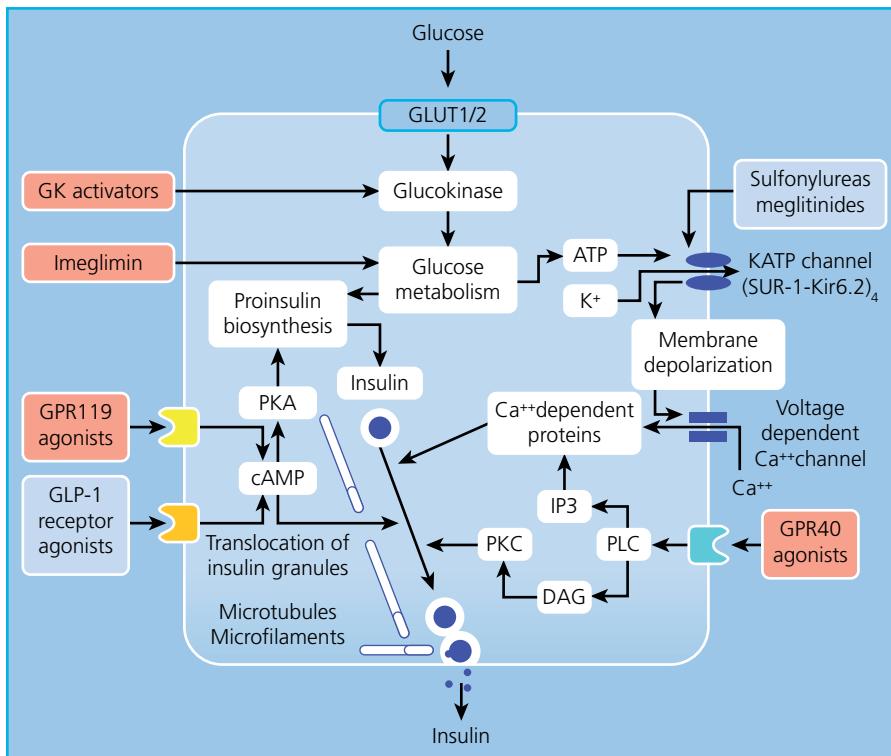

Figure 79.2 Mechanisms of action of insulin-releasing agents on pancreatic β cells. Glucose is taken up by the pancreatic β cells in proportion to the circulating concentration. The glucose is metabolized to produce adenosine triphosphate (ATP), which closes the Kir6.2 pores of ATP-sensitive potassium channels (K_{ATP} channels). This reduces elimination of potassium from the cell, causing localized membrane depolarization that opens voltage-dependent calcium channels. The influx of Ca^{2+} raises the cytosolic Ca^{2+} concentration, which activates calcium-dependent proteins that promote the translocation of insulin granules to the plasma membrane for exocytosis. Sulfonylureas and meglitinides initiate insulin release mainly by binding to sites on the

sulfonylurea receptor 1 (SUR1), which forms part of the Kir6.2 complex. Activated glucagon-like peptide 1 (GLP-1) receptors and GPR119 receptors increase adenylate cyclase activity, which raises cyclic adenosine monophosphate (cAMP) concentrations, while FFAR1 (GPR40) receptor agonists are functionally linked to phospholipase C (PLC), leading to a redistribution of intracellular Ca^{2+} that promotes insulin exocytosis. Glucokinase (GK) activators increase glucose flux into glycolysis and imeglimin acts on mitochondria. DAG, diacylglycerol; GLUT, glucose transporter isoform; GPR, G protein-coupled receptor; IP3, inositol trisphosphate; Kir, inwardly rectifying potassium channel; PKA, protein kinase A; PKC, protein kinase C; SUR, sulfonylurea receptor.

Randomized controlled studies in type 2 diabetes have shown improved glycaemic indices with imeglimin as monotherapy and an add-on to metformin or a DPP-4 inhibitor [23].

Incretins

GLP-1 receptor agonists (exenatide, liraglutide, lixisenatide, dulaglutide, and semaglutide) potentiate insulin secretion and suppress glucagon secretion when glucose concentrations are raised, delay gastric emptying, and exert a satiety effect (Figure 79.3). In addition to their glucose-lowering and weight-reducing effects, these agents have either no detrimental effects or significant beneficial effects in reducing major adverse cardiovascular events and improving kidney outcomes in randomized trials in type 2 diabetes. All current GLP-1 receptor agonists are available as daily or weekly subcutaneous injections and semaglutide is also available as an oral formulation. To enable absorption across the gastric epithelium, semaglutide is combined with an absorption enhancer, sodium hydroxybenzoylamino-caprylate (SNAC), which protects the peptide from proteolytic degradation by raising the pH around the peptide and assists in transcellular absorption [24]. Although bioavailability of the oral formulation is considerably less than the injected formulation, this is compensated for by increased dosage to achieve similar efficacy in regulating blood glucose and body weight [25]. Other approaches being considered for oral delivery of

GLP-1 receptor agonists include various types of nanocapsules and cell-penetration technologies, but these have yet to match the bioavailability achieved with the SNAC system [26].

A subcutaneously implanted miniature (matchstick-sized) osmotic pump (ITCA-650) that delivers exenatide continuously for up to 48 weeks has shown comparable efficacy to once-weekly injections and awaits approval by regulatory authorities. Pre-clinical studies have provided proof of principle for other approaches to continuous GLP-1 delivery, including transdermal patches and various depot formulations. An example of the latter is the subcutaneous injection of a DPP-4-resistant GLP-1 analogue linked with the soluble fusion protein elastin-like-polypeptide (ELP). ELP forms a gel at body temperature and serves as a reservoir for the GLP-1 analogue, which can be released by local proteases [27].

Although the molecular structures of GLP-1 receptor agonists are modified from native GLP-1 to prevent rapid breakdown by DPP-4, the incidence of anti-drug antibody production appears to be low and there is little evidence of a significant loss of drug efficacy. Nevertheless, small-molecule (non-peptide) GLP-1 receptor agonists should enable oral delivery and avoid antibody interference, and several such molecules have recently shown sufficient potency to progress into clinical trials [28]. In addition to GLP-1, several further gastrointestinal and pancreatic hormones, analogues, or small-molecule receptor agonists or antagonists have

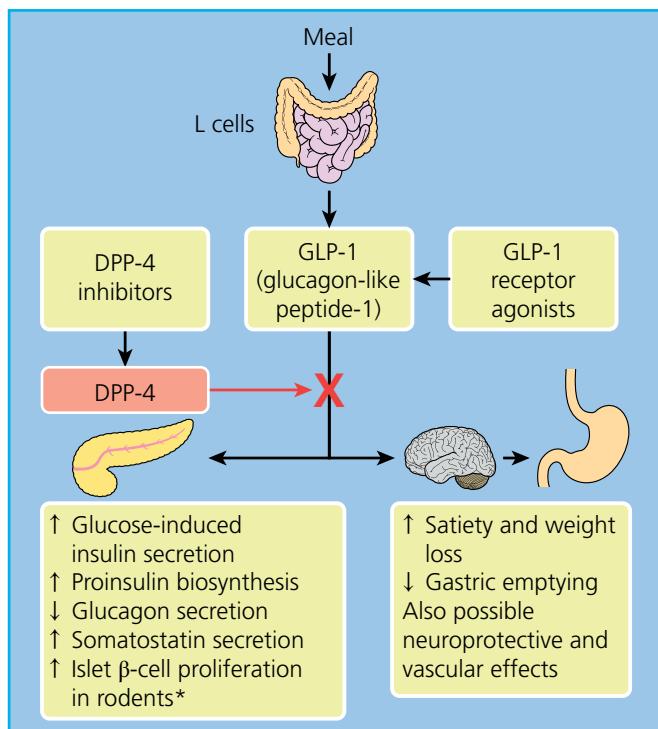

Figure 79.3 Actions of glucagon-like peptide 1 (GLP-1). GLP-1 is a key incretin hormone that enhances the insulin response to enteral glucose. Intestinal glucose stimulates secretion of GLP-1 by L cells. The effects of GLP-1 on glucose homeostasis include pancreatic effects (potentiation of insulin release and reduced glucagon release, each in a glucose-dependent manner), increased satiety, and delayed gastric emptying. GLP-1 is rapidly inactivated by the enzyme dipeptidyl peptidase 4 (DPP-4). DPP-4 inhibitors prolong the activity of endogenous GLP-1. GLP-1 receptor agonists are analogues that are altered from native GLP-1 to protect against degradation by DPP-4. *Effect seen in pre-clinical studies but not confirmed in human type 2 diabetes.

been considered as possible therapies for use in the management of type 2 diabetes. Their actions are summarized in Table 79.3 and several are considered in what follows.

Peptide mixtures

Advances in formulation chemistry have enabled the preparation of mixtures of peptides with different physico-chemical properties to achieve sufficient stability for storage together and administration in a single injection. Simultaneous delivery of two or more peptides with complementary actions offers the opportunity to conveniently expand the range of therapeutic effects and gain additive efficacy while using lower doses of the individual components, thereby reducing side effects. The complementary actions of GLP-1 receptor agonists (mainly targeting post-prandial hyperglycaemia) and basal insulin (mainly targeting basal hyperglycaemia) are now combined in mixtures of the two peptides (*fixed-ratio* combinations) that have been formulated into a single subcutaneous injection. For example, IDegLira contains liraglutide with insulin degludec (3.6 mg: 100 units) and LixiLan contains lixisenatide with glargine (50 µg: 100 units) [29]. The combinations are titrated as for basal insulin, and randomized studies in type 2 diabetes have noted that the combinations can give greater reductions in HbA_{1c} than with either agent alone, while requiring less insulin, avoiding weight gain, and incurring a reduced risk of hypoglycaemia.

Several combinations of gastrointestinal and pancreatic hormones have been tested by co-administration separately and/or in mixtures [30]. For example, in pre-clinical and clinical studies, co-administration of GLP-1 with glucagon reduced hyperglycaemia and increased energy expenditure, while co-administration of GLP-1 with GIP reduced hyperglycaemia and body weight, in each case to a much greater extent than with an individual agent alone. Similarly, hyperglycaemia, food intake, and body weight were decreased with triple co-administration of GLP-1, glucagon, and GIP as well as with triple co-administration of GLP-1, oxynto-

Table 79.3 Glucoregulatory effects of gastrointestinal and pancreatic peptides in clinical use or being investigated as templates to develop therapeutic interventions for type 2 diabetes.

modulin, and peptide YY [30–33]. In pre-clinical studies co-administration of GLP-1 with either gastrin or cholecystokinin-8 (CCK-8) has increased islet β -cell mass and assisted appetite control, while extra glucose-lowering efficacy has been noted when xenin is co-administered with GLP-1 or GIP. Although the amylin analogue pramlintide has long received minority use in insulin-treated individuals in some regions to reduce appetite and weight gain, pre-clinical studies have shown that co-administration of pramlintide with GLP-1 can accentuate appetite regulation and increase weight loss. Similarly, combination of another amylin analogue (cagrelinotide) with a GLP-1 receptor agonist has been reported to produce large reductions body weight together with improved glycaemic levels. Because many of these peptides are not readily mixed together at the concentrations required for a single injection, attention has been given to the development of hybrid peptides that are designed to interact with a specified selection of receptors to create a desired therapeutic profile (single-molecule multi-agonists).

Hybrid peptides

Single-peptide molecules that can interact with several different receptors can be produced by fusion of different molecules or by selection of amino acid sequences that interact with particular receptors, and linking these sequences together to produce a unique chimeric molecule. The latter approach has given rise to clinical studies with several dual receptor agonists (e.g. GLP-1/GIP, GLP-1/glucagon) and triple receptor agonists (e.g. GLP-1/GIP/glucagon) (Figure 79.4). Many of the subtleties in the design of these molecules are concerned with achieving an appropriate balance of effects at the different target receptors while retaining peptide stability and reducing the risk of anti-drug antibody production.

Several dual GLP-1/GIP receptor agonists have been studied in people with type 2 diabetes, the most advanced in development being tirzepatide (LY3298176) [34, 35]. This is a 39 amino acid

peptide based on the biologically active N-terminal GIP(1–14) sequence with an N2 aminoisobutyric acid substitution to prevent degradation by DPP-4 (Figure 79.4). The mid-sequence confers GLP-1 receptor agonism, and a C20 fatty di-acid chain linked via glutamic acid to Lys20 facilitates attachment to albumin to prolong viability in the circulation. The molecule is a stronger agonist at the GIP receptor than the GLP-1 receptor to account for the physiologically higher circulating concentrations of GIP than GLP-1.

A 26-week phase 2 double-blind placebo-controlled study of 316 individuals with type 2 diabetes treated by lifestyle plus metformin (baseline HbA_{1c} 8.2% [66 mmol/mol], body weight 92 kg, and body mass index [BMI] 32 kg/m²) compared once-weekly subcutaneous injection of tirzepatide (1, 5, 10, and 15 mg), dulaglutide (1.5 mg), and placebo [35]. The tirzepatide was associated with dose-related reductions in HbA_{1c} by 1.00%, 1.67%, 1.83%, and 1.89% (~11–20 mmol/mol) for the 1, 5, 10, and 15 mg doses, respectively, compared to placebo. In comparison, dulaglutide reduced HbA_{1c} by 1.21% (13 mmol/mol), suggesting that high doses of tirzepatide exceeded the glucose-lowering efficacy of the highest dose of dulaglutide in current clinical use. Tirzepatide also markedly reduced body weight in a dose-dependent manner (by 0.9 kg at the 1 mg dose to 11.3 kg at the 15 mg dose), compared with reductions of 2.7 kg for dulaglutide and 0.4 kg for placebo. The tirzepatide also slightly lowered circulating triglyceride concentrations and blood pressure and did not cause hypoglycaemia. However, the higher doses of tirzepatide were associated with a high incidence of initial gastrointestinal disturbances and with the development of anti-drug antibodies, although these were generally of low titre and did not appear to compromise efficacy.

GLP-1/glucagon receptor co-agonists studied in individuals with type 2 diabetes have been based mostly on oxyntomodulin, which itself exerts relatively weak agonist effects at both GLP-1 receptors and glucagon receptors, but is amenable to minor

Figure 79.4 Examples of dual and triple co-agonist hybrid peptides. These receptor co-agonists have used glucagon-like peptide 1 (GLP-1), glucagon, glucose-dependent insulinotropic polypeptide (GIP), or oxyntomodulin as their foundation structure, and the structure has then been modified to confer agonism at other peptide receptors. Amino acid residues are indicated by the letter code. The presence of an alanine (A) or serine (S) amino acid residue at the N-terminal position 2

renders these molecules vulnerable to degradation by DPP-4, hence the engineered co-agonists are usually modified in this position. ^A, D-Ala (dextrorotatory alanine); X, aminoisobutyric acid. sequence adjustments to modify efficacy. This co-agonist combination captures the appetite-suppressing, insulin-releasing, and energy-expending effects of each agent to promote weight loss, while the GLP-1 agonist moiety can suppress endogenous glucagon secretion and the insulin-releasing effects can overcome the hyperglycaemic effect of the glucagon moiety to achieve overall glucose lowering. Cotadutide (MEDI0382), for example, is an oxyntomodulin-based GLP-1/glucagon receptor co-agonist studied in a 49-day phase 2 randomized placebo-controlled trial with 65 overweight and obese individuals with type 2 diabetes [36]. Daily subcutaneous injections of cotadutide (50 µg escalated to 300 µg) produced clinically significant reductions in body weight (~3 kg), HbA_{1c} (~0.7%; 8 mmol/mol), and basal and post-prandial glycaemia, and increased meal-stimulated insulin.

Pre-clinical studies in obese and diabetic rodents have assessed various GLP-1/GIP/glucagon receptor tri-agonists and noted improved glucose tolerance, increased insulin secretion, and reduced body weight [31, 32, 37, 38]. Pre-clinical studies of other combinations of triple receptor agonists such as an exendin-4/gastrin/xenin-8 tri-agonist have shown similar efficacy [39]. In addition to the potential benefits of multireceptor agonists for the treatment of type 2 diabetes and obesity, there is emerging evidence that incretin-based multireceptor agonists could assist in the management of hyperlipidaemias, hepatic steatosis, degenerative bone diseases, neurological disorders, and cardio-renal conditions [40]. It is also noted that incretin peptides have been attached to steroid molecules (e.g. oestrogens and glucocorticoids) and thyroid hormones, indicating opportunities to target other therapies [31, 41].

Dipeptidyl peptidase 4 inhibitors and bile acid receptor agonists

Inhibitors of the enzyme DPP-4 (EC 3.4.14.5) are widely used in the treatment of type 2 diabetes to prevent the breakdown of endogenous incretins, particularly raising endogenous GLP-1 concentrations [42]. They include sitagliptin, saxagliptin, linagliptin, and alogliptin taken once daily, and vildagliptin taken twice daily. Other DPP-4 inhibitors are available in some regions including once-weekly agents such as omarigliptin and trelagliptin, and further DPP-4 inhibitors are reported to be in development, offering similar properties to those already available.

Another approach to raise endogenous GLP-1 could involve TGR5 (GP-BAR1) bile acid receptors, which are strongly expressed by intestinal L cells, and activation by bile acids enhances GLP-1 secretion [43]. The bile acid sequestrant colesvelam, which has an indication for the treatment of hyperglycaemia in individuals with type 2 diabetes in some regions, carries bile acids more distally along the intestinal tract and has been associated with a small rise in GLP-1. However, TGR5 receptors are mostly located in the basolateral membranes of L cells, suggesting that activation by agents in the intestinal lumen may require large doses.

Modifiers of glucagon secretion and action

The therapeutic potential for stimulants and inhibitors of glucagon secretion and action continues to be debated. As already noted, the appetite-suppressing, energy-expending, weight-lowering, and insulin-releasing effects of glucagon are used to advantage in glucagon-based and oxyntomodulin-based hybrid peptides, provided that concomitant intervention over-rides the hyperglycaemic

effect of hepatic glucose output induced by glucagon receptor activation. The hyperglycaemic effect of glucagon is part of the normal physiological response to protect against hypoglycaemia, and glucagon administration is used to reverse insulin-induced hypoglycaemia in type 1 diabetes. However, administration of glucagon to treat hypoglycaemia is not encouraged in type 2 diabetes due to the strong insulin-releasing effect of glucagon.

Glucagon concentrations are typically inappropriately raised in type 2 diabetes, and blood glucose can be lowered by suppression of glucagon secretion from pancreatic α cells (e.g. with GLP-1 receptor agonists, somatostatin analogues, or non-peptide inhibitors), or by suppression of glucagon action using peptide glucagon receptor antagonists, anti-glucagon antibodies, or glucagon receptor anti-sense oligonucleotides. A catalogue of small-molecule glucagon receptor antagonists has been examined, but glucagon receptor antagonism is associated with compensatory hyperglucagonaemia, such that rebound hyperglycaemia occurs if continuous therapy is interrupted. Also, unwanted liver effects have further complicated the therapeutic application of glucagon receptor antagonism [44].

Insulin mimetic agents

Insulin resistance is a prominent feature of most forms of type 2 diabetes, typically reflecting the cumulative detrimental impact of multiple pathogenic factors that disrupt the kinase activity of insulin receptors and signalling intermediates along the post-receptor pathways. The resulting diversity of presentations of insulin resistance has complicated the search for agents to override or circumvent the *pinch points* [45]. Normal binding of insulin molecules to extracellular regions of the insulin receptor at spatially separated sites on the α subunits is difficult to replicate using small molecules [46, 47]. However, conformational changes similar to those produced by insulin binding may be achieved in other ways, as indicated by a monoclonal antibody that interacts with the insulin receptor at different sites to insulin, but creates a conformational adjustment to the receptor that initiates some of the metabolic effects of insulin, sufficiently to improve glucose homeostasis in insulin-resistant diabetic animals [48]. There is also proof of principle that conformational changes to the insulin receptor induced by small molecules can elicit some metabolic effects of insulin. This has been shown with several compounds, such as the fungal metabolite chaetochromin that interacts with the extracellular portion of the insulin receptor to initiate some actions of insulin independently of insulin binding to the receptor [49]. Small molecules might also be able to bypass the extracellular domains of the insulin receptor and interact with cytosolic regions of the β subunits of the receptor to activate receptor signalling without insulin binding, as shown for example with another fungal metabolite, demethylasterriquinone [50]. However, although several small molecules have been reported to activate the insulin receptor, these have yet to gain clinical validation [51].

Insulin action potentiators

Many compounds will potentiate insulin action after insulin has initiated a conformational change to the receptor and enabled tyrosine phosphorylation of the β subunits. For example, insulin action is enhanced and prolonged by agents that prevent receptor

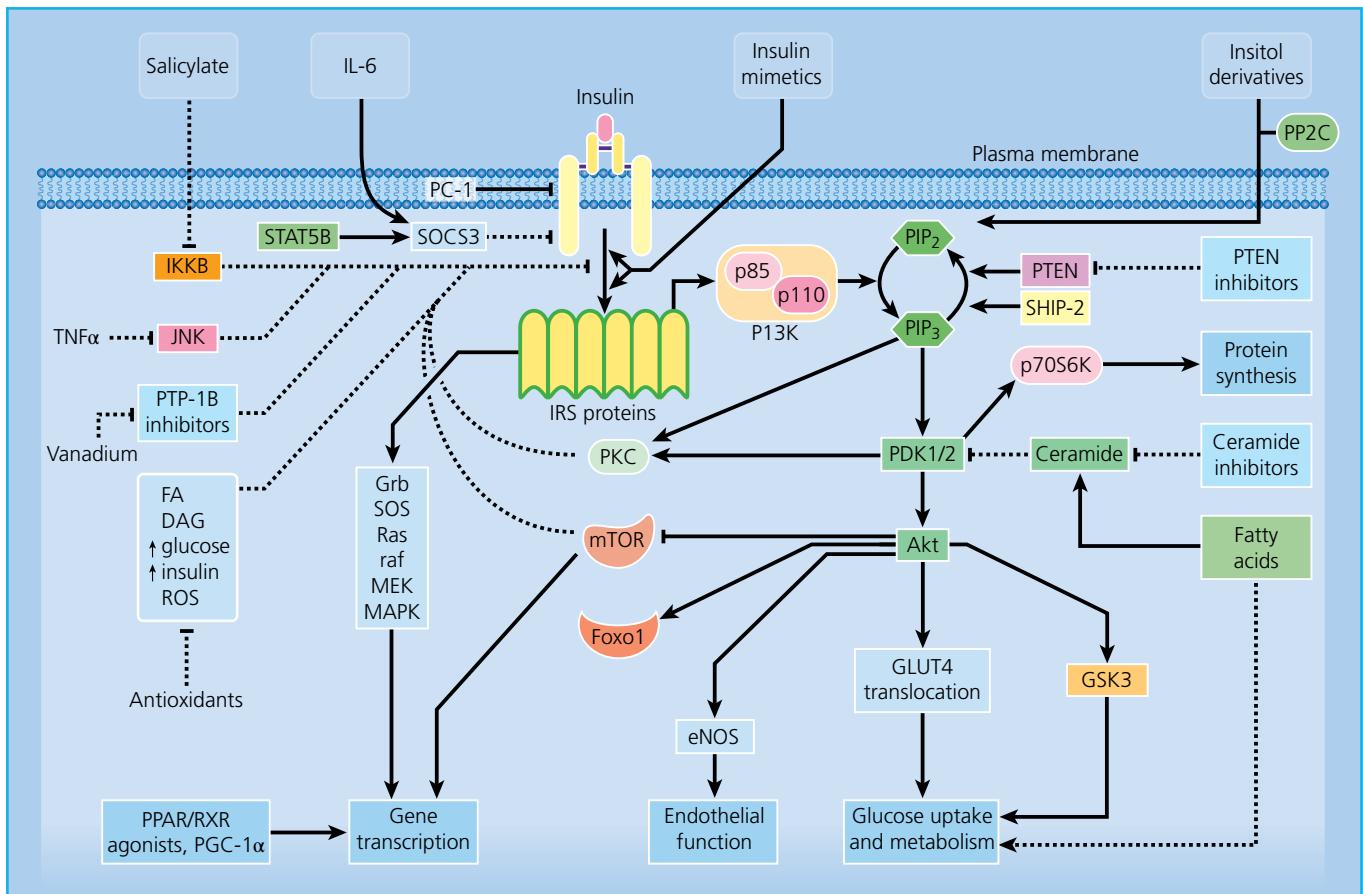

Figure 79.5 Pathways of intracellular insulin signalling illustrating potential sites for therapeutic intervention. Insulin binds to the α subunits of the extracellular region of the insulin receptor, producing conformational changes that extend into the intracellular regions and alter the conformation of the β subunits of the receptor. This allows the β subunits to be phosphorylated on tyrosine residues, which enables the β subunits to act as tyrosine kinase enzymes to phosphorylate a collection of insulin receptor substrate (IRS) proteins. The phosphorylated IRS proteins initiate signalling along the intracellular pathways that control the diverse biological effects of insulin. Many of the signalling steps are restricted (*pinch-points*) by factors contributing to insulin resistance, and these steps are potential targets for therapeutic interventions. dephosphorylation by suppressing phosphatase enzyme activity. Included here are inhibitors of protein tyrosine phosphatase 1B (PTP1B) and less specific phosphatase inhibitors, notably vanadium compounds (Figure 79.5). Although some of these compounds have shown efficacy during initial clinical studies, off-target effects and/or a narrow therapeutic window have so far precluded further development [52, 53].

Another approach to extend the signalling time of activated insulin receptors and insulin receptor substrate (IRS) proteins has been to interrupt the negative feedback effects of more distal intermediates within the insulin action pathways. Certain isoforms of PKC mediate the negative effects of excess fatty acids, diacylglycerol, and products of glucotoxicity, in part by phosphorylation of the receptor and IRS proteins at serine or threonine sites [54]. Although some PKC inhibitors have increased insulin action and shown promise in the treatment of diabetic retinopa-

thy and neuropathy, this approach has yet to prove sufficiently effective for the management of hyperglycaemia in type 2 diabetes. Other signalling intermediates that inhibit the activity of insulin receptors or IRS proteins by serine phosphorylation have also been considered as potential therapeutic targets. These include inhibitor κ B kinase- β (IKK β) and c-Jun N-terminal kinase (JNK), which mediate the insulin resistance produced by certain cytokines such as tumour necrosis factor α (TNF- α) and the mammalian target of rapamycin (mTOR), which mediates a negative feedback from AKT (protein kinase B) [45]. Supplementing the availability of substrates for post-receptor steps is a further intervention to enhance insulin action, as illustrated by the administration of methylchiroinositol (pinitol), which facilitates signalling through phosphatidylinositol 3-kinase and has improved glycaemic indices in animal models of insulin resistance and insulin deficiency [45].

Adipokines

Several peptides and other substances produced by adipose tissue can affect the endocrine pancreas, insulin action, food intake, and/or energy expenditure, and some have been explored as potential therapeutic leads [55] (Figure 79.6). For example, leptin exerts centrally mediated satiety and thermogenic effects, acts directly on tissues to improve insulin action and suppress glucagon, and facilitates weight loss. However, therapeutic doses of leptin and leptin analogues generate leptin resistance, which severely compromises long-term efficacy, although a leptin analogue is used in some regions to treat lipodystrophy and congenital leptin deficiency [56].

Adiponectin offers a range of potentially advantageous effects, including increased insulin sensitivity, improved endothelial function, and reduced inflammation, but the amounts of adiponectin released by adipose tissue are reduced in people with overweight or obesity with type 2 diabetes. Supplementary adiponectin itself may not be a realistic intervention, but small-molecule agonists of the adiponectin receptors could provide a suitable alternative, and initial pre-clinical studies have indicated that this approach can reduce insulin resistance and improve glycaemic management [57]. Several other adipocyte hormones have been implicated in the pathogenesis of type 2 diabetes, but their therapeutic potential remains to be determined [55]. For example, resistin and retinol-binding protein 4 reduce insulin sensitivity, whereas omentin and visfatin appear to improve insulin sensitivity. Many of the adipocyte peptides influence inflammatory processes, and the major proinflammatory adipokines, TNF- α , and interleukin 6 (IL-6) have been implicated in insulin resistance, but it is unclear whether these are appropriate targets for glucose-lowering purposes [58].

Fibroblast growth factor 21 (FGF21) is secreted by adipose tissue, liver, and muscle, and in pre-clinical studies has improved insulin sensitivity and β -cell survival, in addition to promoting fatty acid oxidation and hepatic gluconeogenesis during fasting. However, type 2 diabetes in individuals with obesity appears to be associated with resistance to FGF21, and plasma concentrations of FGF21 are often raised. Nevertheless, clinical studies with FGF21 analogues have shown improvements in insulin sensitivity, glycaemic indices, and the blood lipid profile, possibly due in part to increased production of adiponectin [59, 60].

Peroxisome proliferator-activated receptor γ agonists

The insulin-sensitizing effects of thiazolidinediones (e.g. pioglitazone) are mostly mediated by activation of the nuclear transcription factor peroxisome proliferator-activated receptor γ (PPAR γ). Redesigned PPAR γ agonists have not been able to eliminate unwanted side effects such as fluid retention, increased adiposity, and bone resorption, which have limited suitability for routine clinical use. Dual agonists of PPAR γ and PPAR α (known as glitazars) incorporate the advantage of the lipid-lowering and anti-inflammatory effects of PPAR α , but also have encountered problematic side effects [61, 62]. Triple PPAR $\gamma/\alpha/\delta$ agonists (pan-PPARs) have the additional properties of increased energy expenditure and weight loss conferred by PPAR δ agonism, but these agents have yet to receive clinical sanction (Figure 79.7). Nevertheless, selective manipulation of PPAR-mediated activities continues to be explored, and PPAR agonist molecules are being considered for the treatment of hepatic steatosis.

Hydroxysteroid dehydrogenase 1 inhibitors

Raised glucocorticoid concentrations can precipitate and aggravate truncal obesity, insulin resistance, and hyperglycaemia, whereas interventions to reduce glucocorticoid action can prevent and reverse these effects. The enzyme 11 β -hydroxysteroid dehydrogenase 1 (11 β HSD1) converts cortisone to active cortisol mostly within liver and adipose tissue and without substantially affecting circulating cortisol. Inhibitors of 11 β HSD1 have reduced cortisol production within these tissues, associated with improvements in insulin sensitivity, glycaemic indices, and the lipid profile of people with type 2 diabetes while enabling weight loss [63, 64]. However, it has proved difficult to avoid some reduction of circulating cortisol, which gives rise to a compensatory increase in adrenocorticotrophic hormone (ACTH), and the outcome of long-term trials is awaited.

Sodium–glucose cotransporter inhibitors

Intestinal absorption of glucose is mediated via SGLT-1 in the brush border of enterocytes, while reabsorption of glucose that is filtered by the kidney is mediated mostly (~90%) via SGLT-2 in the initial part of the proximal tubules, and the remainder is reabsorbed via SGLT-1 in more distal parts of the proximal tubules (Figure 79.8). SGLT inhibitors in current clinical use (e.g. canagliflozin, dapagliflozin, empagliflozin, ertugliflozin) predominantly inhibit SGLT-2, lowering the renal threshold for glucose and eliminating excess glucose in the urine (glucosuria) [65]. This provides an insulin-independent mechanism to lower blood glucose and dispose of calories, thereby assisting in weight loss (Chapter 35). The osmotic diuresis that accompanies the glucosuria may contribute in part to a lowering of blood pressure, and there is considerable evidence that these agents confer cardio-renal protection by reducing the onset and progression of heart failure and slowing the age-related decline in glomerular filtration rate [66]. Additional SGLT-2 inhibitors have been developed and are available in some regions. There are also variants that exert a significant inhibitory effect against both SGLT-2 and SGLT-1, such as sotagliflozin [67]. This latter type of agent can

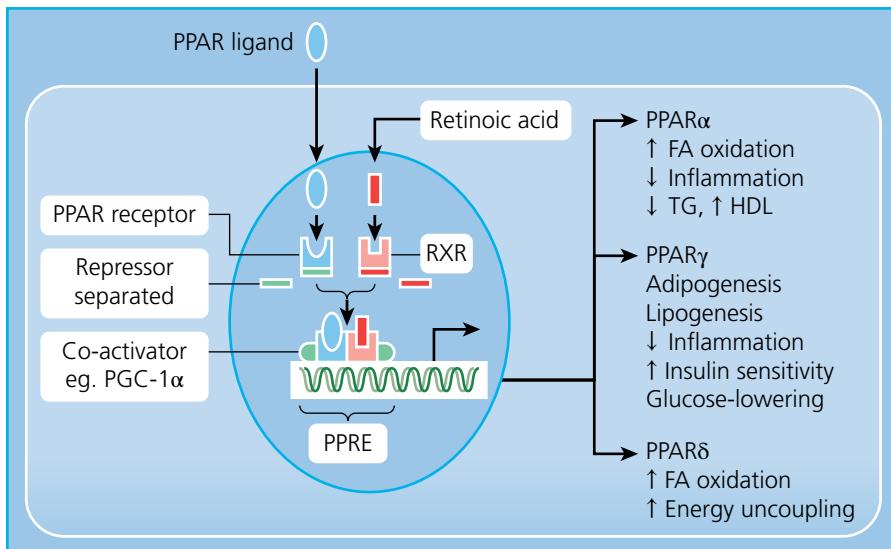

Figure 79.7 Cellular mechanism of action of a peroxisome proliferator-activated receptor (PPAR) ligand. The PPAR ligand binds to its nuclear PPAR receptor, which forms a heterodimer with the retinoid X receptor (RXR). Ligand binding releases repressors, attracts co-activators, and exposes the active site of the receptor that binds with its specific DNA nucleotide sequence – peroxisome proliferator response element (PPRE). RNA polymerase is recruited for transcription of mRNA from genes that carry the PPRE sequence in a promoter region. The mRNA is translated into the enzymes and transporters responsible

for the biological effects. There are three types of PPAR agonists: PPAR γ , PPAR α , and PPAR δ . Each type of agonist offers a range of effects. PPAR γ agonists enhance lipogenesis, adipogenesis, insulin sensitivity, and glucose lowering, PPAR α agonists have lipid-lowering and anti-inflammatory effects, and PPAR δ agonists promote energy expenditure. Selective structural modifications to agonist molecules provide an opportunity to retain and accentuate desired effects while reducing unwanted effects. FA, fatty acids; HDL, high-density lipoprotein; PGC-1 α , PPAR co-activator 1 α ; TG, triglyceride.

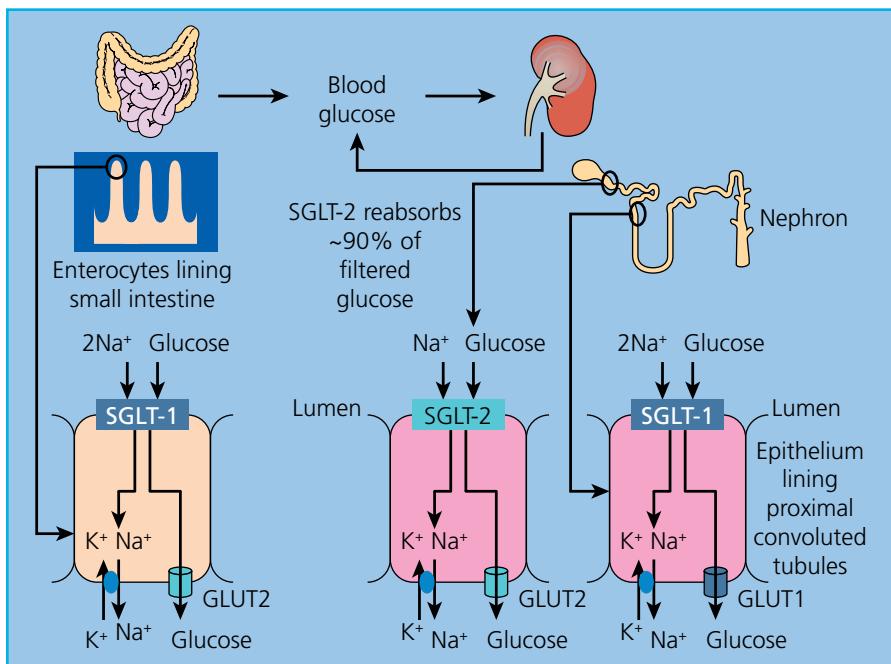

Figure 79.8 Sites of action of sodium–glucose co-transporters SGLT-1 and SGLT-2. SGLT-1 is responsible for intestinal glucose absorption and SGLT-2 is the main transporter responsible for glucose reabsorption from renal proximal convoluted tubules. GLUT, glucose transporter.

defer glucose absorption more distally along the intestinal tract, slow the appearance of glucose in the portal circulation, and increase the secretion of GLP-1 from ileal L cells. However, to avoid unabsorbed glucose passing into the large bowel, these agents must be absorbed or denatured along the intestinal tract. Because the inhibition of SGLT-2 increases the passage of extra glucose along

the proximal tubules, it appears to upregulate SGLT-1 that is expressed in more distal parts of the proximal tubules; thus, it is possible that an agent capable of inhibiting SGLT-1 could also increase glucosuric efficacy.

Evidence that SGLT-2 inhibition can reduce the onset and severity of heart failure with reduced or preserved ejection fraction and

preserve renal function in people without diabetes as well as with diabetes has provided a new impetus to research with this class of agents. Accordingly, established and new inhibitors of SGLT-2 are being investigated to capitalize on these properties.

Modifiers of nutrient metabolism

Suppression of hepatic gluconeogenesis and/or glycogenolysis can reduce blood glucose, but such effects must only be partial and promptly limited by counter-regulatory mechanisms to prevent significant hypoglycaemia [68]. Reduced mobilization of glycogen stores by inhibitors of glycogen phosphorylase has lowered blood glucose in pre-clinical studies, but clinical efficacy has been modest or unsustained. Glucose 6-phosphatase inhibitors prevent the last step in glucose output from both glycogenolysis and gluconeogenesis, but their activity is not easily terminated and the risk of hypoglycaemia is increased. Inhibitors of fructose 1,6-bisphosphatase prevent the dephosphorylation of fructose 1,6-bisphosphate to fructose 6-phosphate, which is the penultimate step in gluconeogenesis before glucose 6-phosphate. These inhibitors can maintain a partial reduction of hepatic glucose output due to increased compensatory glycogenolysis, and clinical studies are ongoing [69].

Many substances directly stimulate glucose uptake and utilization by muscle and adipose tissue, but few have been advanced for a therapeutic application in type 2 diabetes, as their effects are difficult to control and side effect profiles are not suitable. Examples include dichloroacetate, spermine, diamides, various peroxides, vitamin K₅, deoxyfrenolicin, okadaic acid, and several phorbol esters [15]. Inhibitors of glycogen synthase kinase have increased glycogenesis and lowered blood glucose in insulin-resistant diabetic animals, but potential adverse effects on the control of cellular division have deterred development for type 2 diabetes.

Agents that activate adenosine 5'-monophosphate-activated protein kinase (AMPK) have improved glycaemic indices in pre-clinical studies and attracted interest as therapies for type 2 diabetes. AMPK is a key energy-regulating enzyme that appears to be one of several targets for metformin, some PPAR γ agonists, and adiponectin receptor agonists. It is activated when cellular energy status declines and AMP concentrations rise, promoting the uptake and oxidation of glucose and fatty acids to restore ATP production. AMPK also reduces gluconeogenesis and lipogenesis, and may have a tumour-suppressor effect [70]. Analogues of AMP, α -lipoic acid, various polyphenols, salicylates, and other small molecules have been identified as activators of AMPK, and more extensive clinical evidence is awaited to assess efficacy and off-target effects such as effects on other AMP-sensitive enzymes [70].

Tissue selective and smart insulins

The drainage of endogenous insulin from the pancreas into the portal circulation normally delivers a much higher concentration of insulin to the liver than to the periphery, but this difference in tissue exposure is not achieved by subcutaneous injection of exogenous insulin. To deliver more exogenous insulin to liver cells than muscle cells, insulin analogues have been attached to large carrier molecules such as polyethylene glycol, albumin, or thyroid-binding protein that move freely through the fenestrated hepatic sinusoids, but provide limited access through the tighter peripheral capillary

endothelia [71]. Further exploration of these and other approaches to improve hepto-selectivity of insulins continue in development.

To adjust the supply of insulin in concert with the prevailing glucose concentration, proof of principle has been established for glucose-responsive *smart* insulins, which are released from a circulating chemical complex or an implanted depot by direct chemical interaction with glucose. For example, glucose will displace insulin that is inactive when linked to a boronic acid derivative, so as the glucose concentration increases, more insulin is released [72]. Also, polymers containing boronic acid derivatives can be cross-linked by glucose. If these polymers are included in hydrogels containing insulin, the cross-links formed by an increased concentration of glucose will deform the polymer and squeeze out insulin [73]. Further glucose-responsive approaches include insulin patches that incorporate glucose oxidase to register changes in the glucose concentration and release insulin accordingly.

Anti-obesity agents

Losing weight by reducing food intake or increasing energy dissipation, and the long-term reduction of adiposity, improve insulin sensitivity and improve glycaemic indices in individuals with overweight or obesity and type 2 diabetes. Indeed, very low-calorie diets and bariatric surgery have produced laudable results in this respect [74, 75]. However, there has been a reluctance to manage hyperglycaemia through pharmacological interventions primarily designed for weight loss. The intestinal lipase inhibitor orlistat is a widely used weight-reducing therapy, and several centrally acting satiety-inducing agents are available in some regions. These agents include the amphetamine-like sympathomimetic phentermine, a phentermine-topiramate combination, and a bupropion–naltrexone combination. A 5HT2c serotonin receptor agonist (lorcaserin) has been withdrawn. Each of these agents improves glycaemic indices in individuals with overweight and obesity with type 2 diabetes, but it is uncertain whether these agents exert significant glucose-lowering effects independently of reduced adiposity [76]. Although GLP-1 receptor agonists and SGLT-2 inhibitors already combine glucose-lowering and weight-reducing properties, it would be highly advantageous if future attention could strongly target the coexisting problems of obesity and diabetes.

Epigenetic and pharmacogenomic factors

Epigenetic opportunities for glucose lowering have come to attention through the effects of sirtuin enzymes. Sirtuins are nicotinamide adenine dinucleotide (NAD)-dependent histone deacetylases and adenosine diphosphate (ADP) ribosyltransferases that alter histone structure and chromatin stability. This in turn alters the transcription of genes that influence mitochondrial biogenesis and energetics. These effects plus the actions of sirtuins on non-histone proteins modulate insulin secretion and nutrient metabolism to mimic caloric restriction, and protect against weight gain, diabetes, and cardiovascular disease in animal models [77]. Several small-molecule sirtuin activators have delivered initially encouraging effects in animal models of diabetes, but inconsistencies in these studies suggest that pharmacological interventions will need to discriminate between the activation of specific sirtuins to create the desired profile of effects.

The recognition of certain gene variants can help to predict the likely efficacy, tolerability, and risk of adverse effects with a particular glucose-lowering agent (e.g. metformin, sulfonylurea, thiazolidinedione) for an individual. Gene variants for transporter proteins that affect the absorption, cellular distribution, and elimination of drugs, and also variants encoding the enzymes involved in their metabolism, influence responses to these drugs within the genetic constraints of the disease process itself [78]. However, the predictive capacity of pharmacogenomics is complicated by the vast numbers of genes that can have impacts on the pharmacokinetics and pharmacodynamics of drug therapies in type 2 diabetes, but as pharmacogenomic testing is refined it will offer valuable clinical utility to improve drug–patient compatibility and reduce the risk of ineffective or harmful interventions.

Using pharmacogenomics to design new drug therapies presents a particular challenge for the treatment of type 2 diabetes owing to the multivariable genetic components that contribute to the aetiology, pathogenesis, and progressive natural history of the disease [78, 79]. There is seldom a single rate-limiting protein that can be pharmacologically manipulated to reset normal glucose homeostasis, but continued mapping of genetic variants and disturbances to the diabetes proteome should identify prime contenders for future pharmacological interventions, especially to address the defects of β -cell function and survival as type 2 diabetes advances [80].

Safety

The long-term use of diabetes medications requires particular attention to long-term safety, and regulatory processes for the approval and subsequent pharmacovigilance for new glucose-lowering agents take thorough account of this requirement [81]. As noted at the start of this chapter, individuals with type 2 diabetes are

prone to develop comorbidities that contraindicate some medicines, lead to drug interactions, or introduce other safety concerns. Some safety issues can take many years to emerge and necessitate revision to the label in accordance with the change in risk–benefit balance. If new medicines are to become available in a timely manner, such revisions will need to be accepted without prejudice as part of the lifespan of a medicine [82].

Conclusion

This chapter has considered glucose-lowering medications in development and potential novel therapeutic targets for type 2 diabetes. Therapeutic developments directed against type 1 diabetes are reviewed in Chapters 76 and 77. It is noted that type 2 diabetes involves such a variable mix of defects that effective management usually needs to exploit a selection of differently acting agents that can be used in combination as the disease progresses. For the future, attention to adiposity, hunger–satiety discord, energy expenditure, and inflammation may acquire greater precedence alongside more conventional approaches directed towards the secretion and actions of insulin, glucagon, and incretins. There will also be the expectation that new agents can benefit cardio–renal disturbances in diabetes as well as provide long-term metabolic management. Futuristic mechanisms might incorporate very different forms of intervention such as antisense oligonucleotides and short-interference RNA to modify the proteome, or prebiotics and probiotics to modify the microbiome. Cell-based therapies, especially glucose-sensing surrogate endocrine cells, could deliver more than insulin, and so-called smart drugs that are activated in accordance with the prevailing glucose concentration could more closely align pharmacotherapy with physiological control and obviate problems of dose titration and hypoglycaemia.

Index

Notes: Page numbers for figures are in *italics*, tables are in **bold**.

Conditions prefixed by the word “diabetic,” e.g. diabetic autonomic neuropathy, diabetic retinopathy, are indexed under the name of the condition, i.e. autonomic neuropathy, retinopathy.

mediobasal hypothalamus glial cell activation
128, 132–133
Mediterranean diet 56, 63, 374, 716, 832, 1065
meglitinides 492, 496–498, 505–506,
535, 537–538
Melanesian populations 65
melanin 325, 530
melanocortin-signalling 131–132, 147,
199–200
MELAS syndrome 158, 287
melatonin 192–193
melatonin receptor gene (MTNR1B) 228
meliodiosis 882, 885
membrane attack complex (MAC) 622–625
membrane depolarization 90–92
memory
cognitive function 922–929
glycaemic memory 616–618, 683–684
metabolic 192, 646–648, 664, 683–684
Mendelian disorders 197–198
menopause hormone therapy (MHT) 295, 298
mental health 933–955
acute metabolic complications 933,
943–946, 949
adolescents 1022, 1026–1028
anxiety disorders 933–934, 938–942,
945–947
bipolar affective disorder 933–934, 947–948
body weight 933–952
care aims 343, 347, 351–352
comorbidity 933–938, 941–947
complications 933, 936–937, 943–945, 949
depression 907–918, 933–942, 945, 947–949
eating disorders 907, 910–915, 942–947,
1029–1030
environmental factors 933–936,
941, 948–949
genetic factors 933, 937–938, 949
global burden of diabetes 34–35
healthcare teams 933, 938–939, 946–947
morbidity 933–938, 941–947
obesity 933–937, 944–946, 949–952
patient education 362
primary care 933–939, 942
psychotic illnesses 933–934, 947–953
schizophrenia 933–934, 940, 947–952
screening 933–934, 938–939, 942–946,
950–952
transition to adulthood 1022, 1026–1028
Menzel, Ruth 18
MERCI device 750
Mering, Josef von 7
mesenchymal stem cells (MSC)
1138–1139, 1142
mesenteric arteries 478, 761–762
