

Sixth Edition

Textbook of **Diabetes**

Edited by **Richard I.G. Holt • Allan Flyvbjerg**

WILEY Blackwell

Textbook of Diabetes

We dedicate this book to all people living with diabetes and the healthcare professionals who look after them. We would also like to dedicate this book to our families, without whose support and encouragement the book would never have been finished.

Textbook of Diabetes

EDITED BY

RICHARD I.G. HOLT MA, MB BChir, PhD, FRCP, FHEA

Professor in Diabetes & Endocrinology
Human Development and Health
Faculty of Medicine, University of Southampton
Southampton, UK
Honorary Consultant Physician
Southampton National Institute for Health Research Biomedical Research Centre
University Hospital Southampton NHS Foundation Trust
Southampton, UK

ALLAN FLYVBJERG MD, DMSc

Former CEO at Steno Diabetes Center Copenhagen (SDCC)
The Capital Region of Denmark
Professor of Clinical Endocrinology
Faculty of Health and Medical Sciences
University of Copenhagen
Copenhagen, Denmark

SIXTH EDITION

WILEY Blackwell

Limit of Liability/Disclaimer of Warranty

The contents of this work are intended to further general scientific research, understanding, and discussion only and are not intended and should not be relied upon as recommending or promoting scientific method, diagnosis, or treatment by physicians for any particular patient. In view of ongoing research, equipment modifications, changes in governmental regulations, and the constant flow of information relating to the use of medicines, equipment, and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each medicine, equipment, or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. While the publisher and authors have used their best efforts in preparing this work, they make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation any implied warranties of merchantability or fitness for a particular purpose. No warranty may be created or extended by sales representatives, written sales materials or promotional statements for this work. The fact that an organization, website, or product is referred to in this work as a citation and/or potential source of further information does not mean that the publisher and authors endorse the information or services the organization, website, or product may provide or recommendations it may make. This work is sold with the understanding that the publisher is not engaged in rendering professional services. The advice and strategies contained herein may not be suitable for your situation. You should consult with a specialist where appropriate. Further, readers should be aware that websites listed in this work may have changed or disappeared between when this work was written and when it is read. Neither the publisher nor authors shall be liable for any loss of profit or any other commercial damages, including but not limited to special, incidental, consequential, or other damages.

Contents

List of Contributors, viii

Preface, xv

List of Abbreviations, xvi

Part 1 Diabetes in its Historical and Social Context

- 1 The History of Diabetes Mellitus, 3
Robert B. Tattersall and David R. Matthews

- 2 Classification and Diagnosis of Diabetes, 22
Ambady Ramachandran, Chamukuttan Snehalatha, Arun Raghavan, and Arun Nanditha

- 3 The Global Burden of Diabetes, 28
Jessica L. Harding, Mary Beth Weber, and Jonathan E. Shaw
- 4 Epidemiology of Type 1 Diabetes, 41
Lars C. Stene and Jaakko Tuomilehto
- 5 Epidemiology of Type 2 Diabetes, 55
Ronald C.W. Ma and Peter C.Y. Tong

Part 2 Normal Physiology

- 6 Overview of Glucose Metabolism, 77
Richard I.G. Holt
- 7 Islet Function and Insulin Secretion, 84
Peter M. Jones and Shanta J. Persaud
- 8 Glucagon in Islet and Metabolic Regulation, 99
Jonathan E. Campbell and David A. D'Alessio
- 9 Mechanism of Insulin Action, 111
Morris F. White
- 10 Central Control of Glucose Homeostasis, 128
Kimberly M. Alonge, Kendra L. Francis, Nicole E. Richardson, and Michael W. Schwartz
- 11 Control of Body Weight: How and Why Do We Gain Weight Easier Than We Lose It?, 142
Janine Makarondis and Rachel L. Batterham

Part 3 Pathogenesis of Diabetes

- 12 The Genetics of Diabetes, 157
Rashmi B. Prasad
- 13 Genetics of Obesity, 197
I. Sadaf Farooqi
- 14 Autoimmune Type 1 Diabetes, 203
Omar Akel and Åke Lernmark
- 15 Other Disorders with Type 1 Diabetes and Atypical Phenotypes, 216
Alice P.S. Kong, Elaine Y.K. Chow, Andrea O.Y. Luk, and Juliana C.N. Chan
- 16 Abnormalities of Insulin Secretion and β -Cell Defects in Type 2 Diabetes, 225
Stefano Del Prato, Cristina Bianchi, and Giuseppe Daniele
- 17 Insulin Resistance in Type 2 Diabetes, 238
Michael Roden, Kitt Falk Petersen, and Gerald I. Shulman
- 18 Obesity and Diabetes, 250
Nick Finer
- 19 The Microbiome and Diabetes, 261
Amanda J. Cox, Nicholas P. West, and Allan W. Cripps

Part 4 Other Types of Diabetes

- 20 Monogenic Causes of Diabetes, 275
Brittany L. Resnick, Maggie H. Shepherd, and Andrew T. Hattersley
- 21 Drug-Induced Diabetes, 295
Charles D. Ponte and Devra K. Dang
- 22 Diabetes in Hypersecreting Endocrine Disorders, 304
Allan A. Vaag, Neil A. Hanley, and Caroline M. Kistorp
- 23 Pancreatic Disease and Diabetes, 319
Ranjit Unnikrishnan and Viswanathan Mohan
- 24 Clinical Presentations of Diabetes, 330
Ee Lin Lim and Roy Taylor

Contents

Part 5 Managing the Person with Diabetes

- 25 The Aims of Diabetes Care, 343
Katharine D. Barnard-Kelly and Richard I.G. Holt
- 26 Education to Empower the Person with Diabetes, 354
Ingrid Willaing and Michael Vallis
- 27 Dietary Management of Diabetes, 368
Nicola Guess
- 28 Physical Activities and Diabetes, 382
Emma J. Cockcroft and Robert C. Andrews
- 29 Monitoring Diabetes, 404
Emma English
- 30 Biomarkers and Precision Medicine in Diabetes, 414
Sok Cin Tye, Michele Provenzano, and Hiddo J.L. Heerspink

Part 6 Treatment of Diabetes

- 31 Insulin and Insulin Treatment, 431
Roman Vangoitsenhoven, Parth Narendran, and Chantal Mathieu
- 32 New Technologies for Glucose Monitoring, 444
Thomas Danne and Olga Kordonouri
- 33 New Technologies for Insulin Administration, 459
Hannah Forde and Pratik Choudhary
- 34 Whole Pancreas and Islet Cell Transplantation, 473
Braulio A. Marfil-Garza, Peter A. Senior, and A.M. James Shapiro
- 35 Oral Glucose-Lowering Agents, 492
Clifford J. Bailey and Andrew J. Krentz
- 36 Non-insulin Parenteral Therapies, 520
Tina Vilsbøll, Mikkel Christensen, Andreas Andersen, and Filip K. Knop
- 37 How to Use Type 2 Diabetes Treatments in Clinical Practice, 534
Thomas Karagiannis, Aris Liakos, and Apostolos Tsapas
- 38 Weight Management and Metabolic Surgery, 551
Alexis Sudlow, Dimitri J. Pournaras, and Carel W. le Roux
- 39 In-Hospital Treatment and Surgery in People with Diabetes, 559
Ketan Dhatriya, Philip Newland-Jones, and Mayank Patel
- 40 Hypoglycaemia in Diabetes, 579
Ahmed Iqbal, Elaine Y.K. Chow, Timothy W. Jones, and Simon R. Heller
- 41 Acute Metabolic Complications of Diabetes: Diabetic Ketoacidosis and the Hyperosmolar Hyperglycaemic State in Adults, 602
Philip Newland-Jones, Mayank Patel, and Ketan Dhatriya

Part 7 Microvascular Complications in Diabetes

- 42 Pathogenesis of Microvascular Complications, 615
Allan Flyvbjerg
- 43 Diabetic Retinopathy, 629
Toke Bek

- 44 Diabetic Nephropathy, 640
Peter Rossing and Allan Flyvbjerg
- 45 Diabetic Neuropathy, 655
Shazli Azmi, Uazman Alam, and Rayaz A. Malik

Part 8 Macrovascular Complications in Diabetes

- 46 Pathogenesis of Macrovascular Complications in Diabetes, 681
Jakob A. Østergaard, Tomasz J. Block, Sophia Dahm, Waheed Khan, and Karin A.M. Jandeleit-Dahm
- 47 Hypertension and Diabetes, 700
Peter M. Nilsson
- 48 Dyslipidaemia and Diabetes, 713
Adie Viljoen, Ahmed Handhle, and Anthony S. Wierzbicki
- 49 Ischaemic Heart Disease in Diabetes, 724
Michael Lehrke and Nikolaus Marx
- 50 Heart Failure and Diabetes, 732
Ambarish Pandey, Kershaw V. Patel, and Subodh Verma
- 51 Cerebrovascular Disease and Diabetes, 745
Colum F. Amory, Jesse Weinberger, and Travis S. Smith
- 52 Peripheral Vascular Disease, 755
Henrik H. Sillesen

Part 9 Other Complications of Diabetes

- 53 Foot Problems in People with Diabetes, 771
Frank L. Bowling, Keeley J. Foley, and Andrew J.M. Boulton
- 54 Sexual Function in Men and Women with Diabetes, 780
Kirsty Winkley, Camilla Kristensen, Jackie Fosbury, and David Price
- 55 Gastrointestinal Manifestations of Diabetes, 796
Michael Camilleri and Adil E. Bharucha
- 56 Diabetes and Oral Health, 810
Palle Holmstrup, Christian Damgaard, and Allan Flyvbjerg
- 57 Diabetes and Non-alcoholic Fatty Liver Disease, 820
Alessandro Mantovani, Giovanni Targher, and Christopher D. Byrne
- 58 The Skin in Diabetes, 838
Paul Devakar Yesudian
- 59 Bone and Rheumatic Disorders in Diabetes, 853
Andrew Grey and Nicola Dalbeth
- 60 Diabetes and Cancer: Risk, Outcomes, and Clinical Implications, 867
Ellena Badrick, Emily J. Gallagher, and Andrew G. Renahan
- 61 Diabetes and Infections, 878
Andrea O.Y. Luk and Clive S. Cockram
- 62 Sleep and Diabetes, 897
Sonya Deschênes, Amy McInerney, and Norbert Schmitz

Part 10 Psychosocial Aspects of Diabetes

- 63 Psychosocial and Behavioural Aspects of Diabetes, 907
Frans Pouwer and Jane Speight
- 64 Role of Cognitive Function in Managing People with Diabetes, 922
Tamsin Santos, Chelsea Baird, Sally Eastwood, Kerrie Shiell, and Joseph E. Ibrahim
- 65 Mental Disorders and Diabetes, 933
Najma Siddiqi, Marietta Stadler, and Richard I.G. Holt
- 66 Social Aspects of Diabetes, 956
Brian M. Frier and Mark W.J. Strachan
- 67 Social Determinants of Diabetes, 973
Keri F. Kirk, Gerald McKinley, Briana Mezuk, and Erica Spears

Part 11 Diabetes in Special Groups

- 68 Ethnic, Cultural, and Religious Aspects to the Management of Diabetes, 987
Wasim Hanif, Sarah N. Ali, and Vinod Patel
- 69 Diabetes in Childhood, 999
Jennifer M. Ikle, Ananta Addala, and David M. Maahs
- 70 Adolescence and Emerging Adulthood: Diabetes in Transition, 1019
Charlotte W. Chen and Lori M.B. Laffel
- 71 Diabetes in Pregnancy, 1034
David R. McCance and Laura Cassidy

- 72 Diabetes in Old Age, 1072
Ahmed H. Abdelhafiz and Alan J. Sinclair
- 73 Diabetes at the End of Life, 1085
Trisha Dunning and June James

Part 12 Delivery and Organization of Diabetes Care

- 74 The Role of the Multidisciplinary Team across Primary and Secondary Care, 1097
Samuel Seidu and Kamlesh Khunti
- 75 Models of Diabetes Care in Low- and Middle-Income Countries, 1107
David Beran, Sigiriya Aebischer Perone, and Maria Lazo-Porras

Part 13 Future Directions

- 76 Immunotherapies for Type 1 Diabetes, 1125
Jesper Johannessen and Flemming Pociot
- 77 Stem Cell Therapy in Diabetes, 1137
Angelo Avogaro and Gian Paolo Fadini
- 78 Gene Therapy for Diabetes, 1144
Veronica Jimenez and Fatima Bosch
- 79 Future Drug Treatments for Type 2 Diabetes, 1154
Clifford J. Bailey

Index, 1167

List of Contributors

Ahmed H. Abdelhafiz

Department of Elderly Medicine
Rotherham General Hospital
Rotherham, UK

Ananta Addala

Division of Endocrinology, Department of Pediatrics
Stanford University
Stanford, CA, USA

Omar Akel

Department of Clinical Sciences, Lund University CRC
Skåne University Hospital
Malmö, Sweden

Uazman Alam

Department of Cardiovascular and Metabolic
Medicine, Institute of Life Course and Medical
Sciences, University of Liverpool, Liverpool, UK

Sarah N. Ali

Department of Diabetes and Endocrinology
Royal Free London NHS Foundation Trust
London, UK

Kimberly M. Alonge

UW Medicine Diabetes Institute, Department of
Medicine
University of Washington
Seattle, WA, USA

Colum F. Amory

Albany Medical College
Albany, NY, USA

Andreas Andersen

University of Copenhagen
Copenhagen, Denmark

Robert C. Andrews

Faculty of Health & Life Science, Clinical and
Biomedical Sciences, University of Exeter, Exeter, UK
Department of Diabetes, Taunton and Somerset
NHS Foundation Trust, Taunton, UK

Angelo Avogaro

Department of Medicine
University of Padova
Padua, Italy

Shazli Azmi

Faculty of Biology, Medicine and Health
University of Manchester
Manchester, UK

Ellena Badrick

Division of Cancer Sciences
University of Manchester
Manchester, UK

Clifford J. Bailey

School of Life and Health Sciences
Aston University
Birmingham, UK

Chelsea Baird

Queen Elizabeth Centre, Ballarat Health Service and
Department of Forensic Medicine, Monash
University
Melbourne, Australia

Katharine D. Barnard-Kelly

Southern Health NHS Foundation Trust
Southampton, UK

Rachel L. Batterham

Centre for Obesity Research, Rayne Institute
Department of Medicine, University College London
University College London Hospital (UCLH)
Bariatric Centre for Weight Management and
Metabolic Surgery
National Institute of Health Research, UCLH
Biomedical Research Centre
London, UK

Toke Bek

Department of Ophthalmology
Aarhus University Hospital
Department of Clinical Medicine, Faculty of Health
Aarhus University
Aarhus, Denmark

David Beran

Division of Tropical and Humanitarian Medicine
University of Geneva and Geneva University
Hospitals
Faculty Diabetes Centre, Faculty of Medicine
University of Geneva
Geneva, Switzerland

Adil E. Bharucha

Clinical Enteric Neuroscience Translational and
Epidemiological Research (CENTER)
Division of Gastroenterology and Hepatology, Mayo
Clinic
Rochester, MN, USA

Cristina Bianchi

Department of Clinical and Experimental Medicine
University of Pisa
Pisa, Italy

Tomasz J. Block

Department of Diabetes, Central Clinical School
Monash University
Melbourne, Australia

Fatima Bosch

Center of Animal Biotechnology and Gene Therapy,
Department of Biochemistry and Molecular
Biology

Preface

It is nearly seven years since the last edition of the *Textbook of Diabetes* was published, during which time there have been many exciting developments in our understanding of diabetes and novel treatments that have improved the lives of those living with diabetes. Despite our ability to alleviate the risk of its long-term complications, the global burden of diabetes continues to rise as the prevalence inexorably increases. According to the International Diabetes Federation, diabetes now affects 537 million adults, compared with 415 million when the last edition was published. Over three-quarters of people with diabetes live in low- and middle-income countries and diabetes causes 6.7 million deaths a year, approximately one every five seconds. The cost of treating diabetes has reached almost US\$1 trillion per annum, a threefold increase over the last 15 years. The need for accurate and up-to-date information to help healthcare professionals support people with diabetes has never been greater.

Ironically, as the volume of information and diversity of digital resources have increased, many are finding it overwhelming to keep abreast of the new advances. It is particularly challenging to determine the validity of many source materials. In this textbook we aim to bring together a series of chapters from internationally leading diabetes experts who provide accurate and clinically relevant information to both academic and practising diabetes healthcare professionals.

We have retained the structure from the previous edition, with a similar length and number of chapters. The centenary of the discovery of insulin has just passed and the book begins with a history of diabetes that provides many valuable insights from the past. We then move through the epidemiology of diabetes, the physiology of glucose metabolism, and the pathogenesis of diabetes, before sections on clinical management. A discussion of the microvascular and macrovascular complications then follows, after which there are sections on the psychosocial aspects of diabetes, the management of diabetes in special groups, and models of care, before a final section to glimpse into the future. New chapters include an overview of glucose homeostasis and the central control of glucose metabolism, as well as chapters on the genetics and management of obesity to recognize the close relationship between obesity and type 2 diabetes. There is a new chapter on the emerging topic of biomarkers and precision medicine, while the rapid advance in

diabetes technology has necessitated a split into separate chapters on glucose monitoring and insulin delivery. Transplantation has moved from future treatments to current management to acknowledge its current place in clinical care. In the macrovascular section, we have added a new chapter on heart failure, which has come to the fore as a result of the sodium–glucose cotransporter 2 (SGLT-2) inhibitor cardiovascular outcome trials. Oral health and sleep are added to the list of other areas of diabetes complications, while the importance of social determinants of health and ethnicity, culture, and religion is now included in the psychosocial aspects of diabetes section. The final new chapter describes managing diabetes in low- to middle-income countries, where the majority of people with diabetes live.

As editors, we are only too aware of the hard work that goes into the production of a comprehensive and up-to-date book such as this. For this edition the pressures of the Covid-19 pandemic added to the challenges of bringing the book to fruition. Our thanks go to each and every chapter author who, despite busy academic, clinical, and professional lives, was prepared to devote the time, energy, and expertise to provide their essential contributions to the text. Thank you for your forbearance of our nagging e-mails!

We are also grateful for the support we have received from our publisher, Wiley-Blackwell. Our commissioning editor Jennifer Seward, who took over from Priyanka Gibbons during the book's development, has provided guidance and encouragement. Our thanks also go to Rajalaxmi Rajendrasingh, Sally Osborn, and the rest of the Wiley-Blackwell team. The book looks even better than the last edition! We would like to pay tribute to Clive Cockram and Barry Goldstein, our editing colleagues for the fourth and fifth editions. You were missed this time round.

We hope you enjoy reading the book, whether it be dipping in or reading from cover to cover, as much as we did editing it. We have taken away useful, novel information that will aid in our daily professional lives and hope that this book will help you to support the people with diabetes you know in the widest sense of this meaning.

1 Diabetes in its Historical and Social Context

1

The History of Diabetes Mellitus

Robert B. Tattersall¹ and David R. Matthews²

¹University of Nottingham, Nottingham, UK

²University of Oxford, Oxford, UK

Key points

- Polyuric diseases have been described for over 3500 years. The name *diabetes* comes from the Greek word for a syphon; the sweet taste of diabetic urine was recognized at the beginning of the first millennium, but the adjective *mellitus* (honeyed) was added by Rollo only in the late eighteenth century.
- The sugar in diabetic urine was identified as glucose by Chevreul in 1815. In the 1840s, Bernard showed that glucose was normally present in blood, and that it was stored in the liver (as glycogen) for secretion into the bloodstream during fasting.
- In 1889, Minkowski and von Mering reported that pancreatectomy caused severe diabetes in the dog. In 1893, Lagesse suggested that the pancreatic *islets* described by Langerhans in 1869 produced an internal secretion that regulated glucose metabolism.
- Insulin was discovered in 1921 by Banting, Best, Macleod, and Collip in acid-ethanol extracts of pancreas. It was first used for treatment in January 1922.
- Diabetes was subdivided on clinical grounds into *diabète maigre* (lean people) and *diabète gras* (obese people) by Lancereaux in 1880, and during the 1930s by Falta and Himsworth into insulin-sensitive and insulin-insensitive types. These classifications were the forerunners of the aetiological classification into type 1 (insulin-dependent) diabetes and type 2 (non-insulin-dependent) diabetes.
- Insulin resistance and β -cell failure, the fundamental characteristics of type 2 diabetes, have been investigated by many researchers. The *insulin clamp* method devised by Andres and DeFronzo was the first accurate technique for measuring insulin action.
- Maturity-onset diabetes of the young was described as a distinct variant of type 2 diabetes by Tattersall in 1974.
- Lymphocytic infiltration of the islets (*insulitis*) was described as early as 1901 and highlighted in 1965 by Gepts, who suggested that it might be a marker of autoimmunity. Islet cell antibodies were discovered by Doniach and Bottazzo in 1979.
- The primary sequence of insulin was reported in 1955 by Sanger and the three-dimensional structure by Hodgkin in 1969. Proinsulin was discovered by Steiner in 1967, and the sequence of the human insulin gene by Bell in 1980. Yalow and Berson invented the radioimmunoassay for

insulin in 1956. The presence of insulin receptors was deduced in 1971 by Freychet, and the receptor protein was isolated in 1972 by Cuatrecasas.

- The various types of diabetic retinopathy were described in the second half of the nineteenth century, as were the symptoms of neuropathy. Albuminuria was noted as a common abnormality in people with diabetes in the nineteenth century and a unique type of kidney disease was described in 1936 by Kimmelstiel and Wilson. The concept of a specific diabetic angiopathy was developed by Lundbaek in the early 1950s.
- Milestones in insulin pharmacology have included the invention of delayed-action preparations in the 1930s and 1940s, synthetic human insulin in 1979, and in the 1990s novel insulin analogues by recombinant DNA technology.
- The first sulfonylurea carbutamide was introduced in 1955, followed by tolbutamide in 1957 and chlorpropamide in 1960. The biguanide phenformin became available in 1959 and metformin in 1960.
- That improved glucose management in both type 1 diabetes and type 2 diabetes was beneficial was proved by the Diabetes Control and Complications Trial (DCCT) in 1993 and the UK Prospective Diabetes Study (UKPDS) in 1998.
- Landmarks in the treatment of complications include photocoagulation for retinopathy, first described by Meyer-Schwickerath; the importance of blood pressure management to slow the progression of nephropathy, demonstrated by Mogensen and Parving; the introduction of low-dose insulin in the treatment of diabetic ketoacidosis in the 1970s; improvements in the care of pregnant women with diabetes pioneered by White and Pedersen; and the emergence of heart failure as a common and treatable pathology.
- The understanding of the complex physiology of type 2 diabetes improved at the beginning of the twenty-first century with clarification of the roles of fat metabolism and signalling; the gut as an endocrine organ; the signals of satiety to the brain; and the role of glucagon as an important homeostatic signal.
- The many therapeutic breakthroughs of the twenty-first century include the discovery of peroxisome proliferator-activated receptor γ (PPAR- γ) activation as a therapy for insulin resistance; the activation of the incretin axis by glucagon-like peptide 1 (GLP-1) receptor agonists and the dipeptidyl peptidase 4 (DPP-4) inhibitors; and the blocking of the renal glucose transporter channels by sodium-glucose cotransporter 2 (SGLT-2) inhibitors.

Professor Robert Tattersall died on 23 November 2020. This historical text is largely his work. Professor David R. Matthews has updated and revised the chapter.

Ancient times

Diseases with the cardinal features of diabetes mellitus were recognized in antiquity (Table 1.1). A polyuric state was described in an Egyptian papyrus dating from c. 1550 BCE, discovered by Georg Ebers (Figure 1.1), and a clearly recognizable description of what would now be called type 1 diabetes was given by Aretaeus of Cappadocia in the second century CE (Figure 1.2a). Aretaeus was the first to use the term *diabetes*, from the Greek word for a syphon, ‘because the fluid does not remain in the body, but uses the man’s body as a channel whereby to leave it’. His graphic account of the disease highlighted the incessant flow of urine, unquenchable thirst, the ‘melting down of the flesh and limbs into urine’, and short survival.

The Hindu physicians Charak and Sushrut, who wrote between 400 and 500 BCE, were probably the first to recognize the sweetness of diabetic urine (Figure 1.2b). Indeed, the diagnosis was made by tasting the urine or seeing that ants congregated round it. Charak and Sushrut noted that the disease was most prevalent in those who

Table 1.1 Milestones in the clinical descriptions of diabetes and its complications.

Clinical features of diabetes	
Ebers papyrus (Egypt, 1500 BCE)	Polyuric state
Sushrut and Charak (India, fifth century BCE)	Sugary urine; thin individuals and those with obesity distinguished
Aretaeus (Cappadocia, second century CE)	Polyuric state named <i>diabetes</i>
Chen Chuan (China, seventh century CE)	Sugary urine
Avicenna (Arabia, tenth century CE)	Sugary urine; gangrene and impotence as complications
Diabetic ketoacidosis

were indolent, overweight, and gluttonous, and who indulged in sweet and fatty foods. Physical exercise and liberal quantities of vegetables were the mainstays of treatment in people with obesity, while lean people, in whom the disease was regarded as more serious, were given a nourishing diet. The crucial fact that diabetic urine tasted sweet was also emphasized by Arabic medical texts from the ninth to eleventh centuries CE, notably in the medical encyclopaedia written by Avicenna (980–1037).

Seventeenth and eighteenth centuries

In Europe, diabetes was neglected until Thomas Willis (1621–1675) wrote *Diabetes, or the Pissing Evil* [1]. According to him, ‘diabetes was a disease so rare among the ancients that many famous physicians made no mention of it . . . but in our age, given to good fellowship and guzzling down of unallayed wine, we meet with examples and instances enough, I may say daily, of this disease’. He described the urine as being ‘wonderfully sweet like sugar or honey’, but did not consider that this might be because it contained sugar.

The first description of hyperglycaemia was in a paper published in 1776 by Matthew Dobson (1735–1784) of Liverpool (Figure 1.3 and Table 1.2) [2]. He found that the serum as well as the urine of his patient Peter Dickonson (who passed 28 pints of urine a day) tasted sweet. Moreover, he evaporated the urine to ‘a white cake [which] smelled sweet like brown sugar, neither could it by the taste be distinguished from sugar’. Dobson concluded that the kidneys excreted sugar and that it was not ‘formed in the secretory organ but previously existed in the serum of the blood’.

The Edinburgh-trained surgeon, John Rollo (*d.* 1809) was the first to apply the adjective *mellitus* (from the Latin word meaning *honey*). He also achieved fame with his *animal diet*, which became the standard treatment for most of the nineteenth century.

(a)

Diabetes is a dreadful affliction, not very frequent among men, being a melting down of the flesh and limbs into urine. The patients never stop making water and the flow is incessant, like the opening of aqueducts. Life is short, unpleasant and painful, thirst unquenchable, drinking excessive, and disproportionate to the large quantity of urine, for yet more urine is passed. One cannot stop them either from drinking or making water. If for a while they abstain from drinking, their mouths become parched and their bodies dry; the viscera seem scorched up, the patients are affected by nausea, restlessness and a burning thirst, and within a short time, they expire.

(b)

298 *Medical Observations and Inquiries.*

XXVII. Experiments and Observations on the Urine in a Diabetes, by Matthew Dobson, M.D. of Liverpool; communicated by Dr. Fothergill.

SOME authors, especially the English, have remarked, that the urine in the diabetes is sweet. Others, on the contrary, deny the existence of this quality, and consequently exclude it from being a characteristic of the disease. So far as my own experience has extended, and I have met with nine persons who were afflicted with the diabetes, the urine has always been sweet in a greater or less degree, and particularly so in the case of the following patient.

Peter Dickonfon, thirty-three years of age, was admitted into the public hospital in Liverpool, October 22, 1772. His disease was a confirmed diabetes; and he passed twenty-eight pints of urine every 24 hours. He had formerly enjoyed a good state of health; nor did it appear what had been the remote causes of this indispo-

Figure 1.3 Frontispiece and opening page of the paper by Matthew Dobson (1776) in which he described the sweet taste of both urine and serum from a person with diabetes [2].

Rollo thought that sugar was formed in the stomach from vegetables and concluded that the obvious solution was a diet of animal food. Thus, the regimen described in his 1797 book, *An Account of Two Cases of the Diabetes Mellitus* [3], allowed his patient Captain Meredith to have for dinner 'Game or old meats which have been long kept; and as far as the stomach may bear, fat and rancid old meats, as pork'. Rollo was probably the first to note the difficulty that some people with diabetes find in following a treatment regimen, a difficulty he blamed for the death of his second patient (Figure 1.4).

Nineteenth century

In 1815, the French chemist Michel Chevreul (1786–1889) proved that the sugar in diabetic urine was glucose [4]. In the middle of the century, tasting the urine to make the diagnosis was superseded by chemical tests for reducing agents such as glucose, as introduced by Trommer in 1841, Moore in 1844, and – the best known – Fehling in 1848. Measurement of blood glucose could only be done by

* My urine as yesterday. Eat animal food only; took an emetic of ipecacuan in the evening, which made me very sick, and I brought up all I had eaten in the course of the day; and in the last puke the matter was very sour.

* Urine since last night not exceeding a pint and a quarter, high coloured, very urinous in smell, and depositing a reddish sand. Continued my bitter, alkali in milk, and the hepatised ammonia.

Remarks.

The patient was strongly remonstrated with, and told the consequence of repeated deviations, in probably fixing the disposition to the disease so firmly as not only to increase the difficulty, but to establish the impracticability of removing it. Fair promises were therefore renewed, and absolute confinement to the house, entire animal food, and the hepatised ammonia as before, with the quaffia infusion, were prescribed and agreed upon. The urine continued pale, though salt, and of an urinous smell; but on Sunday the 4th December, the urine had a doubtful smell, and some of it being evaporated, yielded a residuum evidently saccharine, though much less so than in the first experiment, the urinous salts being now more predominant.

skilled chemists, but needed so much blood that it was rarely used in either clinical care or research. It only became practicable with the introduction in 1913 of a micromethod by the Norwegian-born physician Ivar Christian Bang (1869–1918), and it was the ability to measure glucose repeatedly that led to development of the glucose tolerance test between 1913 and 1915.

Glucose metabolism was clarified by the work of Claude Bernard (1813–1878) [5], the Frenchman whose numerous discoveries have given him a special place in the history of physiology (Figure 1.5). When Bernard began work in 1843, the prevailing theory was that sugar could only be synthesized by plants, and that animal metabolism broke down substances originally made in plants. It was also thought that the blood only contained sugar after meals, or in pathological states such as diabetes. Between 1846 and 1848, Bernard reported that glucose was present in the blood of normal animals, even when starved. He also found higher concentrations of glucose in the hepatic than in the portal vein, and 'enormous quantities' of a starch-like substance in the liver that could be readily converted into sugar. He called this *glycogen* (i.e. sugar-forming) and regarded it as analogous to starch in plants. His hypothesis – the *glycogenic* theory – was that sugar absorbed from the intestine was

Figure 1.6 Oskar Minkowski (1858–1931).

converted in the liver into glycogen and then constantly released into the blood during fasting.

Another discovery by Bernard made a great impression in an era when the nervous control of bodily functions was a scientifically fashionable concept. He found that a lesion in the floor of the fourth ventricle produced temporary hyperglycaemia (*pique diabetes*) [6]. This finding spawned a long period in which nervous influences were thought to be important causes of diabetes; indeed, one piece of ‘evidence’ – cited by J.J.R. Macleod as late as 1914 – was that diabetes was more common among engine drivers than other railway workers because of the mental strain involved [7].

In the first part of the nineteenth century the cause of diabetes was a mystery, because autopsy usually did not show any specific lesions. A breakthrough came in 1889 when Oskar Minkowski (Figure 1.6) and Josef von Mering (1849–1908) reported that pancreatectomy in the dog caused severe diabetes [8]. This was serendipitous, because they were investigating fat metabolism; it is said that the laboratory technician mentioned to Minkowski that the dog, previously house-trained, was now incontinent of urine. Minkowski realized the significance of the polyuria, and tested the dog’s urine (Table 1.3).

Possible explanations for the role of the pancreas were that it removed a diabetogenic toxin, or produced an internal secretion that regulated carbohydrate metabolism. The concept of *internal*

secretions had been publicized in June 1889 by the well-known physiologist Charles-Édouard Brown-Séquard (1817–1894), who claimed to have rejuvenated himself by injections of testicular extract [9]. It was given further credence in 1891, when Murray reported that myxoedema could be cured by sheep thyroid extract by injection or orally.

In 1893, Gustave Laguesse suggested that the putative internal secretion of the pancreas was produced by the *islands* of cells scattered through the gland's parenchyma [10], which had been discovered in 1869 by the 22-year-old Paul Langerhans (1847–1888) (Figure 1.7). Langerhans had described these clusters of cells, having teased them out from the general pancreatic tissue, but had not speculated about their possible function [11]; it was Laguesse who named them the *islets of Langerhans*. At this time the glucose-lowering internal secretion of the islets was still hypothetical, but in 1909 the Belgian Jean de Meyer named it *insuline* (from the Latin for *island*) [12].

It would be wrong to give the impression that Minkowski's experiments immediately established the pancreatic origin of diabetes. In fact, during the next two decades it was widely agreed that diabetes was a heterogeneous disorder with various subtypes, and that its pathogenesis involved at least three organs: brain, pancreas, and liver [13]. The discovery by Blum in 1901 that injection of an adrenal extract caused glycosuria implicated other glands, and led to the *polyglandular theory* of Carl von Noorden (Vienna), who proposed that the thyroid, pancreas, adrenals, and parathyroids controlled carbohydrate metabolism.

Clinical diabetes in the nineteenth century

Doctors in the nineteenth century were therapeutically impotent; their main role was as taxonomists who described symptom complexes and the natural history of disease. As a result, most of the major complications of diabetes were well described before 1900. Eduard von Jaeger (1818–1884) is credited with the first description

of diabetic retinopathy, in his beautiful *Atlas of Diseases of the Ocular Fundus*, published in 1869 [14]. In fact, the features illustrated (Figure 1.8), from a 22-year-old man, look more like hypertensive retinopathy. In 1879, Stephen Mackenzie (1844–1909) and Sir Edward Nettleship (1845–1913) found microaneurysms in flat preparations of the retina and, in 1888, Nettleship described new vessels and the beaded appearance of retinal veins [15]. The full picture of diabetic retinopathy was described in 1890 by Julius Hirschberg (1843–1925), who was the first to claim that it was specific to diabetes [16].

Neuropathic symptoms in people with diabetes had been mentioned by Rollo at the end of the eighteenth century, and in 1864 Charles Marchal de Calvi (1815–1873) concluded that nerve damage was a specific complication of diabetes. In 1885, the Guy's Hospital physician Frederick Pavy (1829–1911) gave a description of neuropathic symptoms that could grace any modern textbook [17]:

The usual account given by these patients of their condition is that they cannot feel properly in their legs, that their feet are numb, that their legs seem too heavy – as one patient expressed it, 'as if he had 20 lb weights on his legs and a feeling as if his boots were great deal too large for his feet.' Darting or 'lightning' pains are often complained of. Or there may be hyperaesthesia, so that a mere pinching of the skin gives rise to great pain; or it may be the patient is unable to bear the contact of the seam of the dress against the skin on account of the suffering it causes. Not infrequently there is deep-seated pain located, as the patient describes it, in the marrow of the bones which are tender on being grasped, and I have noticed that these pains are generally worse at night.

Pavy also recorded unusual presentations, including a 67-year-old who complained of 'lightning pains on the right side of the waist' and cases in which the third nerve was affected with 'dropped lid and external squint' [18].

Kidney disease was known to be relatively common in diabetes. In 1859, Wilhelm Griesinger (1817–1868) reported 64 autopsies in adults, half of whom had renal changes that he attributed to hypertension and atherosclerosis [19]; however, the histological features of diabetic kidney disease and the importance of renal complications were not reported until the 1930s.

In the latter part of the nineteenth century it was becoming apparent that there were at least two clinically distinct forms of diabetes. In 1880, the French physician Etienne Lancereaux (1829–1910) identified individuals who were lean and those with obesity as having *diabète maigre* and *diabète gras*, respectively [20], and this observation laid the foundations for subsequent aetiological classifications of the disease.

Twentieth century

Murray's cure of myxoedema in 1891 led to a belief that pancreatic extract would soon result in a cure for diabetes, but, in the face of repeated failures over the next 30 years, even believers in an anti-diabetes internal secretion were depressed about the likelihood of isolating it, and diverted their attention to diet as a treatment for the disease.

Best known was the starvation regimen of Frederick Madison Allen (1876–1964), which Joslin (Figure 1.9) described in 1915 as the greatest advance since Rollo's time [22]. This approach was an

extreme application of one that had been proposed as early as 1875 by Apollinaire Bouchardat (1806–1886), who advocated intensive exercise and '*manger le moins possible*'. Starvation treatment did work in a limited sense, in that some people could survive for many months or even years, instead of a few weeks or months with untreated type 1 diabetes. The quality of life, however, was very poor, and some died of malnutrition rather than diabetes. In 1921, Carl von Noorden (1858–1944), proponent of the *oatmeal cure*, turned away in disapproval when he saw Joslin's prize patient, 17-year-old Ruth A, who at just over 1.52 m in height weighed only 24.5 kg (a body mass index of 10.6 kg/m²).

Discovery of insulin

Many attempts were made between 1889 and 1921 to isolate the elusive internal secretion of the pancreas. These largely failed because the extracts were inactive or had unacceptable side effects; some preparations may have had limited biological activity, but this

was not recognized, either because hypoglycaemia was misinterpreted as a toxic reaction or because blood glucose was not measured. Those who came closest were the Berlin physician Georg Zuelzer (1840–1949) in 1907 [23], Ernest Scott (1877–1966) in Chicago in 1911 [24], and Nicolas Paulesco (1869–1931) in Romania in 1920–1921 [25] (Figure 1.10).

The story of how insulin was discovered in Toronto in 1921 is well known, at least superficially (Figure 1.11). A young orthopaedic surgeon, Frederick Banting, inspired after reading an article by the pathologist Moses Barron (1884–1975), wondered whether the anti-diabetes pancreatic principle was digested by trypsin during extraction, and decided to prevent this loss by ligating the pancreatic duct, thus causing the exocrine tissue to degenerate. He approached the professor of physiology in Toronto, J.J.R. Macleod, an authority on carbohydrate metabolism, who poured scorn on the idea and suggested that the only likely outcome would be a negative result of great physiological importance'.

Eventually, Macleod relented and installed Banting in a rundown laboratory, later leaving for Scotland and a fishing holiday. A student, Charles Best, was chosen by the toss of a coin to help Banting. Within six months of this unpromising start, Banting and Best (referred to in Toronto academic circles as B²) had discovered the most important new therapy since the anti-syphilitic agent salvarsan. These events are described in detail in the excellent book by Michael Bliss [26].

Their approach began with the injection of extracts of atrophied pancreas (prepared according to Macleod's suggestions) into dogs rendered diabetic by pancreatectomy. Subsequently, they discovered that active extracts could be obtained from beef pancreas, which Best obtained from the abattoir. The extraction procedure (using ice-cold acid-ethanol) was greatly refined by James B. (Bert) Collip, a biochemist who was visiting Toronto on sabbatical leave.

The first clinical trial of insulin (using an extract made by Best) took place on 11 January 1922, on 14-year-old Leonard Thompson, who had been on the Allen starvation regimen since 1919 and weighed only 30 kg (Figure 1.12). After the first injection, his blood glucose level fell slightly, but his symptoms were unchanged and he developed a sterile abscess. On 23 January, he was given another extract prepared by Collip, and this normalized his blood glucose by the next morning; further injections over the next 10 days led to

marked clinical improvement and complete elimination of glycosuria and ketonuria. Initial clinical results in seven cases were published in the March 1922 issue of the *Canadian Medical Association Journal* [27], which had the following dramatic conclusions:

- Blood sugar can be markedly reduced, even to normal values.
- Glycosuria can be abolished.
- The acetone bodies can be made to disappear from the urine.
- The respiratory quotient shows evidence of increased utilization of carbohydrates.
- A definite improvement is observed in the general condition of these patients and, in addition, the patients themselves report a subjective sense of well-being and increased vigour for a period following the administration of these preparations.

The term *insulin* was coined by Macleod, who was unaware of de Meyer's earlier suggestion of *insuline*. News of its miraculous effects spread astonishingly rapidly [28]. In 1922, there were only 19 references in the world literature to *insulin* or equivalent terms such as *pancreatic extract*; by the end of 1923, there were 320 new reports, and a further 317 were published during the first six months of 1924.

By October 1923, insulin was available widely throughout North America and Europe. International recognition followed rapidly for its discoverers, and the 1923 Nobel Prize for Physiology or Medicine was awarded jointly to Banting and Macleod. Banting

Experimentelle Untersuchungen über den Diabetes.¹⁾

Kurze Mitteilung.²⁾

Von
G. Zuelzer.

F. Blum hat vor einigen Jahren gezeigt, dass subkutane oder intravenöse Injektion von Nebennierensaft bei den verschiedensten Tieren Glykosurie hervorruft, die 48 bis 74 Stunden anhalten kann. Ich, und kurze Zeit darauf Metzger wiesen nach, dass gleichzeitig eine Hyperglykämie besteht, dass es sich beim Nebennierendiabetes also nicht etwa um ein Analogon des Phloridzindiabetes, um einen sogenannten Nierendiabetes handeln könne. Während ich mich dahin aussprach, dass dieser Diabetes seiner ganzen Natur nach dem richtigen Diabetes ähnele, nur durch die Dauer seines Bestehens von ihm unterschieden sei und naturgemäß auch keine Tendenz zum Fortschreiten zeige, i. e. niemals das Endstadium des gewöhnlichen schweren menschlichen Diabetes darbieten könne, wurde die in Frage stehende Glykosurie von den meisten anderen Autoren als eine ziemlich belanglose-toxische Glykosurie aufgefasst.

Es schien mir nicht sehr wahrscheinlich, dass ein Körper, der anscheinend unverändert, wie er normalerweise produziert und dauernd³⁾ dem Säftestrom des Organismus zugeführt wird, dass ein solcher, quasi physiologischer Körper eine vollkommen unphysiologische Wirkung sollte hervorbringen können. Ich habe also versucht, den Ort des Angriffs des Nebennierensaftes⁴⁾, sowie die Ursachen seiner toxischen Wirkung näher zu erforschen. Ich folgte dabei, wie gesagt, stets dem Gedanken, in dem Nebennierendiabetes ein, wenn auch nur flüchtiges Bild gewisser menschlicher Diabetesformen zu finden.

So untersuchte ich zuerst, welchen Einfluss hat der Nebennierensaft auf die Leber als dasjenige Organ, welches, allgemein angesichtigt, mit der Zuckerregulierung im Körper in erster

1) Die Untersuchungen wurden zum Teil mit Unterstützung der Gräfin Bose-Stiftung im physiologischen Institut der Berliner Universität, und zwar noch unter Mithilfe der verstorbenen Prof. I. Munk und Paul Schultz ausgeführt.

2) Diese kurze Mitteilung wurde der Redaktion bereits vor ca. 3 Jahren eingereicht. Die Drucklegung unterblieb auf Wunsch des Verf. in der bisher nicht erfüllten Erwartung, dass es gelingen würde, aus den theoretischen Untersuchungen praktisch-therapeutische Resultate zu erzielen.

3) Durch Versuche von Ehrmann, Archiv f. experim. Pathol. u. Pharmakol., Bd. 55, ist inzwischen der Nachweis erbracht worden, dass die Adrenalinsekretion konstant vor sich geht.

4) In meinen ersten Versuchen bediente ich mich des von mir selbst hergestellten Nebennierensaftes. In den zahlreichen späteren Versuchen habe ich inzwischen genau die gleichen Wirkungen mit den verschiedenartig hergestellten käuflichen Adrenalinpräparaten feststellen können.

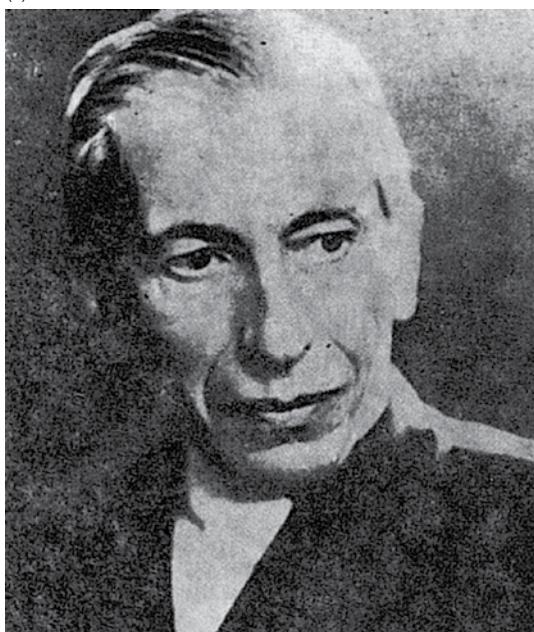

Figure 1.10 (a) Georg Zuelzer (1840–1949) and (b) the title page from his paper (1907) reporting that a pancreatic extract reduced glycosuria in pancreatectomized dogs [23]. (c) Nicolas Paulesco (1869–1931).

was angered by the decision, and announced publicly that he would share his prize with Best, whereupon Macleod decided to do the same with Collip.

The post-insulin era

It was confidently anticipated that insulin would do for diabetes in the young what thyroid extract had done for myxoedema, but it soon became obvious that insulin was a very different type of treatment. Thyroid was given once a day by mouth and at a fixed dosage.

Insulin had to be injected in measured amounts that varied from day to day, and carried the ever-present danger of hypoglycaemia. One often reads that insulin ‘revolutionized’ the treatment of diabetes; it did so in the sense that it saved the lives of many who would otherwise have died, but its unforeseen effect was to transform an acute, rapidly fatal illness into a chronic disease with serious long-term complications. For example, only 2% of deaths among Joslin’s young patients with diabetes before 1937 were caused by kidney disease, while over 50% dying between 1944 and

1950 had advanced renal failure. Strategies to avoid and prevent the chronic complications of diabetes remain important scientific and clinical priorities today.

The rest of this chapter highlights some developments that can be regarded as landmarks in the understanding and management of the disease; to some extent this is a personal choice, and it is obvious from the other chapters in this book that the *history* of diabetes is being rewritten all the time.

Causes and natural history of diabetes

The recognition that diabetes was not a single disease was important in initiating research that has helped to unravel the causes of hyperglycaemia.

The broad aetiological subdivision into type 1 (juvenile-onset, or insulin-dependent) diabetes and type 2 diabetes (maturity-onset, or non-insulin-dependent) stemmed ultimately from Lancereaux's *diabète maigre* and *diabète gras* distinction, as well as observations soon after the discovery of insulin that some individuals did not react *normally* to insulin. In the 1930s, Wilhelm Falta (1875–1950) in Vienna [29] and Harold Himsworth (1905–1993) in London [30] proposed that some individuals with diabetes were more sensitive to the glucose-lowering effects of insulin, whereas others were

insulin insensitive, or insulin resistant. The former were usually thin and required insulin to prevent ketoacidosis, while the latter were older, had obesity, and were ketosis resistant.

The *insulin clamp* technique developed in the 1970s by Ralph DeFronzo and colleagues [31] in the USA was the first to measure rigorously the hypoglycaemic action of insulin, and has led to countless studies of insulin resistance and its relationship to type 2 diabetes and vascular disease. Various groups, including DeFronzo's, have helped to clarify the role of β -cell failure in type 2 diabetes, and how it relates to insulin resistance. Maturity-onset diabetes of the young (MODY) was recognized in 1974 by Robert Tattersall (1943–2020) as a distinct, dominantly inherited subset of type 2 diabetes [32]; since 1993 many different molecular defects have been identified in this condition.

The causes of the profound β -cell loss that led to the severe insulin deficiency of type 1 diabetes remained a mystery for a long time. *Insulitis*, predominantly lymphocytic infiltration of the islets, was noted as early as 1901 by Eugene L. Opie (1873–1971) and colleagues [33], but because it was apparently very rare, found in only 6 of 189 cases studied by Anton Weichselbaum (1845–1920) in 1910, its importance was not appreciated. The possible role of insulitis in β -cell destruction was not suggested until 1965, by the Belgian Willy Gepts (1922–1991) [34]. The theory that type 1 diabetes results from autoimmune destruction of the β cells was first made in 1979 by Deborah Doniach (1912–2004) and GianFranco Bottazzo (1946–2017) [35]. Unlike other autoimmune endocrine diseases where the autoantibody persists, islet cell antibodies turned out to be transient and disappeared within a year of the onset of diabetes. An unexpected finding from the Barts–Windsor prospective study of the epidemiology of diabetes in childhood started by Andrew Cudworth (1939–1982) was that islet cell antibodies could be detected in siblings of young people with diabetes up to 10 years before they developed apparently acute-onset diabetes. This long lead-in period raised the possibility of an intervention to prevent continuing β -cell destruction. Cyclosporine in people with newly diagnosed type 1 diabetes prolonged the honeymoon period, but without permanent benefit once the drug was stopped [36]. Nicotinamide and small doses of insulin (together with many other interventions) prevented diabetes in the non-obese diabetic (NOD) mouse, but were without effect in relatives of people with type 1 diabetes with high titres of islet cell antibodies [37, 38].

From 1967, when Paul Lacy (1924–2005) showed that it was possible to cure diabetes in inbred rats with an islet cell transplant, it always seemed that the problem of islet cell transplantation in humans was about to be solved. Hope was rekindled in 2000 by a team in Edmonton, Canada. After five years 80% of those who had received a transplant were producing some endogenous insulin, but only 10% could manage without any injected insulin [39].

Chronic diabetic complications

It had been assumed that arteriosclerosis caused chronic diabetic complications, but this notion was challenged by two papers published in the mid-1930s, which pointed to specific associations of diabetes with retinal and renal disease (Table 1.2). In 1934, Henry Wagener (1890–1961) and Russell Wilder (1885–1959) from the Mayo Clinic reported people who had retinal haemorrhages but no other clinical evidence of vascular disease [40], and concluded that ‘The very existence of retinitis in cases in which patients have no

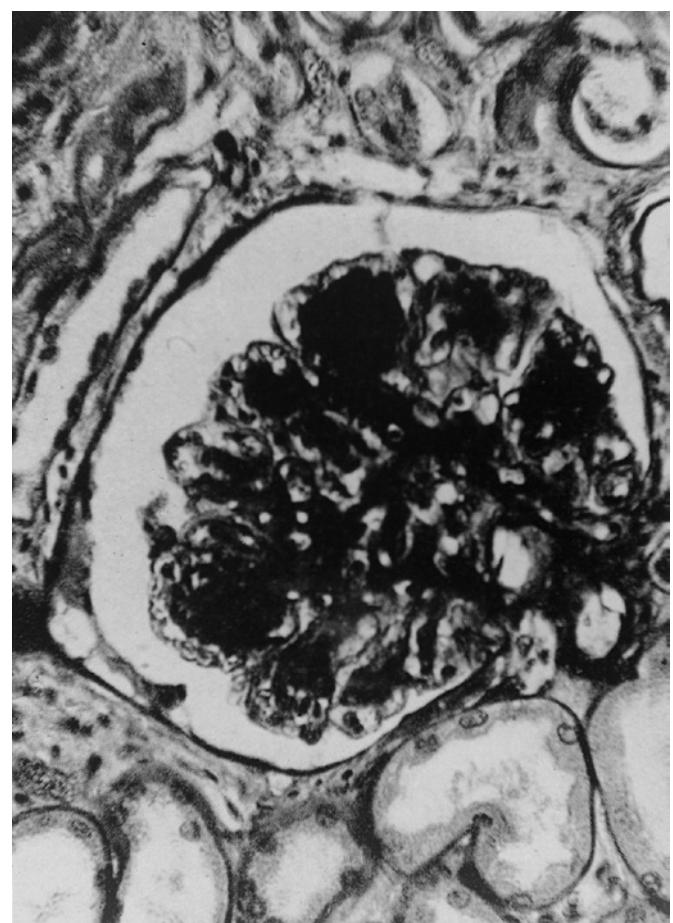

Figure 1.13 Nodular glomerulosclerosis. Figure from the paper by Kimmelstiel and Wilson, 1936 [41]. Source: Courtesy of the British Medical Association Library.

other signs of vascular disease must mean that diabetes alone does something to injure the finer arterioles or venules of the retina, probably the latter’.

In 1936, Paul Kimmelstiel (1900–1970) and Clifford Wilson (1906–1997) described the striking histological finding of *intercapillary glomerulosclerosis*, large hyaline nodules in the glomeruli in the kidneys of eight people at autopsy (Figure 1.13) [41]. Seven of the eight individuals had a known history of diabetes, and Kimmelstiel and Wilson noted the common features of hypertension, heavy albuminuria with ‘oedema of the nephrotic type’, and renal failure. In fact, this paper led to considerable confusion during the next 15 years: according to one writer, the *Kimmelstiel–Wilson syndrome* came to mean all things to all people [42]. Nonetheless, it was significant because it drew attention to a specific diabetic renal disease.

Acceptance of the concept that diabetic angiopathy was specific to the disease owed much to the work of Knud Lundbæk from Aarhus, Denmark (Figure 1.14), who published his findings in a book in 1953–1954 and a paper in the *Lancet* in 1954 [43, 44]. His key arguments were that long-standing diabetic vascular disease differed fundamentally from atherosclerosis, in that both sexes were equally affected, and that microaneurysms, ocular phlebopathy, and Kimmelstiel–Wilson nodules were unique to diabetes and usually occurred together.

The molecular and cellular mechanisms underlying diabetic tissue damage remain controversial after decades of intensive research.

Figure 1.14 Knud Lundbæk (1912–1995). Source: Courtesy of Dr Carl Erik Mogensen.

One of the early landmarks in this field was the work of J.H. Kinoshita (*b.* 1922) during the early 1970s, which pointed to the involvement of the polyol pathway in the formation of diabetic cataracts [45].

Physiology

In 1907, M.A. Lane, a student of Robert Bensley (1867–1956), professor of anatomy in Chicago, used conventional histological techniques to distinguish two different cell types in the islet of Langerhans, which he termed A and B [46]. The hormones secreted by these respective cell types were not identified until much later (Table 1.2). Frank Young (1908–1988) and colleagues reported in 1938 that injections of anterior pituitary extract could induce permanent diabetes in the dog, and that this was accompanied by selective degranulation and loss of the β cells [47]; it was surmised that these cells produced insulin, and this was finally confirmed using immuno-histochemistry by Paul Lacy in 1959 [48]. Glucagon was similarly localized to the α cells in 1962 by John Baum and colleagues [49].

The amino acid sequence of insulin was reported in 1955 by Frederick Sanger in Cambridge, UK [50], and the three-dimensional structure of the molecule in 1969 by Dorothy Hodgkin in Oxford [51]; both discoveries were recognized by the award of Nobel Prizes (Figure 1.15). The complete insulin molecule was synthesized from amino acids by Wang Ying-lai (1908–2001) and colleagues in Shanghai in 1965 [52]. The insulin precursor, proinsulin, was described in 1967 by Donald Steiner (1930–2014) in Chicago [53]. The first bioassay for insulin, based on the hormone's ability to lower blood glucose in the alloxan-diabetic rat, was reported in 1950 by the Australian Joseph Bornstein (1918–1994), working in London with Robin D. Lawrence [54]. This method was superseded in 1956 by Rosalyn Yalow and Solomon Berson in the

USA, who discovered that insulin was antigenic; they exploited the binding of the hormone to anti-insulin antibodies to develop the first radioimmunoassay [55]. This assay method revolutionized endocrinology – and, indeed, many areas of physiology and medicine – and was also rewarded with a Nobel Prize (Figure 1.16).

The sequence of rat insulin genes was described in 1977 by Axel Ullrich (*b.* 1945) and colleagues [56], and the human sequence by Graham Bell (*b.* 1948) and his group in 1980 [57]. The existence of insulin receptors was inferred from the insulin-binding characteristics of liver-cell membranes by Pierre Freychet (*b.* 1935) and colleagues in 1971 [58], and the receptor protein was isolated by Pedro Cuatrecasas (*b.* 1936) in the following year [59]. The gene encoding the insulin receptor was cloned and sequenced in 1985 by two groups [60, 61]. In recent years, numerous advances have helped to clarify how insulin exerts its biological actions. Among these was the discovery in 1985 of the first of the glucose transporter (GLUT) proteins by Mueckler and colleagues in the USA [62].

Management of diabetes

An objective observer surveying clinical diabetes during the half-century after the discovery of insulin and the ‘resurrection’ (a word used by Joslin) of young people with diabetes would have been dismayed by what they saw (Table 1.4). In particular, young people were dying of complications that had previously been assumed to be the preserve of older people. Two particularly depressing papers were published in 1947 and 1950. First, Henry Dolger (1909–1997) in New York described 20 people who fulfilled the then-accepted criteria for excellent *diabetic control*, but who all developed severe retinopathy after 6–22 years [72]; among these was the first person ever to receive insulin at Mount Sinai Hospital, New York, who also had heavy albuminuria and hypertension by the age of 32. Second, Ruth Reuting reported a cohort of 50 young individuals with diabetes originally identified in 1929 [73]. By 1949, one-third had died (mostly from cardiovascular and renal disease) at an average age of 25 years, after only 18 years of diabetes, and the survivors showed ‘ominous signs of hypertension, azotemia, and proteinuria in significant numbers’. This had occurred despite the introduction of more versatile insulin preparations; the situation was so hopeless that it inaugurated 20 years of treatment with ‘heroic’ measures such as adrenalectomy and hypophysectomy.

Table 1.4 Selected milestones in the management of diabetes.

Lifestyle modification	
Li Hsuan (China, seventh century)	Avoid wine, sex, and salty cereals
Thomas Willis (England, seventeenth century)	Food restriction
John Rollo (England, 1797)	Animal diet
Apollinaire Bouchardat (France, 1875)	Food restriction and increased exercise
Carl von Noorden (Germany, 1903)	Oatmeal cure
Frederick Allen (USA, 1913)	Starvation diet for early-onset diabetes
Karl Petrin (Sweden, 1915)	High-fat, low-carbohydrate diet
Roy Taylor (England, 2015) [63]	Very low-calorie diet – remission of diabetes
Insulin treatment	
Georg Zuelzer (Germany, 1907) and Nicolas Paulesco (Romania, 1921)	Isolated pancreatic extracts with hypoglycaemic activity
Frederick Banting, Charles Best, J.J.R. Macleod, and James Collip (Canada, 1922–1923)	Isolation and first clinical use of insulin
Hans Christian Hagedorn (Denmark, 1936)	Protamine insulin, the first long-acting insulin
David Goeddel (USA, 1979)	Synthetic human-sequence insulin produced by recombinant DNA technology
John Pickup (London, 1978)	Described continuous subcutaneous insulin infusion
John Ireland (Scotland, 1981)	Invented pen-injection device
Oral anti-diabetes agents	
Avicenna (Arabia, tenth century)	Recommended lupin, fenugreek, and zedoary seeds
Willhelm Ebstein (Germany, 1876)	Recommended sodium salicylate
E. Frank (Germany, 1926)	Biguanide derivative (Synthalin) introduced, but withdrawn because of toxicity
Celestino Ruiz (Argentina, 1930)	Noted hypoglycaemic action of some sulfonylureas
Auguste Loubatières (France, 1942)	Discovered hypoglycaemic action of prototype sulfonylurea Carbutamide introduced
H. Franke and J. Fuchs (Germany, 1955)	Phenformin introduced
G. Ungar (USA, 1957)	Troglitazone, first thiazolidinedione introduced
Parke-Davis (1997)	Exenatide, first GLP-1 receptor agonist introduced
Eli Lilly (2005)	Sitagliptin, first DPP-4 inhibitor introduced
MSD (2007)	Canagliflozin, first SGLT2 inhibitors
Janssen (2013)	
Diabetic monitoring and treatment targets	
University Group Diabetes Program (USA, 1969)	First randomized trial in diabetes
Peter Sönksen and Robert Tattersall (1978)	Introduction of self-blood glucose monitoring
R. Flückiger and K.H. Winterhalter (Germany, 1975)	Showed that HbA _{1c} was glycated haemoglobin
World Health Organization (1991)	St. Vincent Declaration identified targets for diabetes care
James Scott; Exactech (England, 1991)	First direct electronic glucose testing [64]

(continued)

Table 1.4 (Continued)

Diabetes Control and Complications Trial (USA, 1993)	Proved that improved glycaemic management prevents and slows progression of microvascular complication in type 1 diabetes
UK Prospective Diabetes Study (UK, 1998)	Proved that improved glycaemic and blood pressure management improve microvascular and macrovascular outcomes in type 2 diabetes
Steno-2 study (Denmark, 1999)	Multiple risk factor interventions improve outcomes [65]
UK Prospective study 10-year follow-up (UK, 2008)	Early treatment legacy effects [66]
Complications	
Wilhelm Manz (Germany, 1876)	Described <i>Retinitis proliferans</i>
Gerd Meyer-Schwickerath (Germany, 1964)	First use of Xenon photoocoagulation
University of Minnesota Team (USA, 1966)	First combined kidney–pancreas transplants
John A. Hartford Foundation (USA, 1968)	Argon laser therapy [67]
Carl Erik Mogensen and Hans-Henrik Parving (Denmark, 1980s)	Strict blood pressure controls slows progression of diabetic neuropathy
EMPA-REG trial (2015)	SGLT-2 inhibitors ameliorate heart failure and cardiovascular disease [68]
LEADER trial	GLP-1 receptor agonists ameliorate cardiovascular disease [69]
CREDENCE trial	SGLT-2 inhibitors ameliorate chronic kidney disease [70]
Surgical approaches	
SOS study (Sweden, 2013)	Demonstrated resolution of diabetes with gastric by-pass surgery [71]

DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide-1; SGLT, sodium-dependent glucose cotransporters.

These and other studies raised questions about whether lowering blood glucose levels to normal could prevent diabetes-related complications or reverse them once they had appeared. The hypothesis remained untestable for four more decades, until the means to achieve optimal glycaemic levels and measure them had been devised.

Insulin

For the first decade after its discovery, insulin was available only in its soluble (regular) formulation, whose short-action profile required multiple daily injections. The first delayed-action preparation, protamine insulin, was introduced in 1936 by Hans Christian Hagedorn at Steno Diabetes Center in Denmark (Figure 1.17) [74]. This was followed by protamine zinc insulin later the same year, then globin insulin in 1939, NPH (neutral protamine Hagedorn, or isophane) in 1946, and the lente series in 1952. Long-acting insulins were welcomed by diabetes specialists and people with diabetes, but their use as a single daily injection probably produced worse glycaemic levels than three or four

Figure 1.17 Hans Christian Hagedorn (1888–1971) from the Hagedorn Medal.
Source: Courtesy of C. Binder, Steno Diabetes Center Copenhagen, Denmark.

injections of soluble insulin. Indeed, delayed-action preparations were initially condemned by some diabetes specialists, such as Russell Wilder of the Mayo Clinic, because the person with diabetes could slip without apparent warning into hypoglycaemia.

The number and variety of insulin preparations proliferated, but the main advances were in methods to produce highly purified preparations from porcine or bovine pancreas, which remained the source for therapeutic insulin until the early 1980s. Insulin was the first therapeutic protein to be produced by recombinant DNA technology, initially by David Goeddel (*b.* 1951), who expressed synthetic genes encoding the A and B chains separately in *Escherichia coli* and then combined these chemically to produce human-sequence insulin [75]. From there, genetic engineering has been used to produce *designer* insulins such as the fast-acting insulin analogues lispro and aspart and the *peakless* basal insulins such as glargine, detemir, and degludec. These insulins are more expensive than NPH but the evidence suggests that there is less clinical hypoglycaemia with their use [76].

Most people with diabetes still inject insulin subcutaneously. Major milestones in its administration were the replacement of glass and steel syringes by disposable plastic syringes with fine-gauge needles, and then by pen-injection devices invented by John Ireland (1933–1988) in Glasgow in 1981 [77]. Portable insulin infusion pumps were developed by John Pickup (*b.* 1947) and colleagues in London during the late 1970s [78], and have become progressively smaller and more sophisticated. Both people with diabetes and manufacturers hope that there will eventually be an insulin that can be given without injection. The first inhaled insulin was marketed in 2006, although withdrawn a year later because of lack of demand and concerns about safety [79], but other products have reached the market more recently.

Other anti-diabetes agents

The first orally active glucose-lowering drug, synthalitin, a guanidine derivative, was developed by Frank and colleagues in Breslau in 1926 [80], but had to be withdrawn because of toxicity (a recurrent problem for oral anti-diabetes drugs). The sulfonylureas originated from the work of Auguste Loubatières (1912–1977) in France

Figure 1.18 Dan Drucker, Joel Habener, and Jens Juel Holst – recipients of the Warren Alpert Prize (2020) and Canada Gairdiner Award (2021).

during the early 1940s on the glucose-lowering action of a sulfonamide derivative, 2254RP. Loubatières made the crucial observations that proved that these drugs act as insulin secretagogues and that they were effective in intact, but not in pancreatectomized, animals [81]. In 1955 carbutamide was the first sulfonylurea to enter clinical practice and tolbutamide followed in 1957. Phenformin, the first biguanide, was introduced in 1959 following research into the metabolic effects of guanidine derivatives that had built on Frank's initial studies [82]. Metformin appeared on the European market in 1960, but was not marketed in the USA until 1994. Troglitazone, the first of a class of anti-diabetes drugs – the glitazones or thiazolidinediones – was marketed in 1997 but withdrawn because of liver damage. It was followed by rosiglitazone and pioglitazone.

Another class of drugs, acting on the incretin system, was introduced in 2005. In 1986, Joel Habener (*b.* 1937) and Jens Juel Holst (*b.* 1945) simultaneously identified the amino acid sequence of biologically active, truncated glucagon-like peptide 1 (GLP-1), while Dan Drucker (*b.* 1956) described the first direct actions of GLP-1 on the β cell, specifically the glucose-dependent stimulation of insulin secretion and biosynthesis (Figure 1.18) [83]. Holst discovered the glucagon-suppressing and appetite-regulating effect of GLP-1 in humans. Importantly, the islet actions of GLP-1 are glucose dependent, making GLP-1 a safer treatment than sulfonylureas or insulin.

Today, long-acting GLP-1 receptor agonists are very effective treatments for hyperglycaemia in type 2 diabetes and highly efficacious for inducing weight loss. Inhibitors of the enzyme dipeptidylpeptidase-4 (DPP-4), which breaks down GLP-1 (gliptins), are also widely used. Oral versions of GLP-1 receptor agonists are now on the market.

In the 2010s another class of agents, the sodium-glucose cotransporter 2 (SGLT-2) inhibitors – the gliflozins – became widely available with action blocking the renal sodium-glucose cotransporters and thereby causing glycosuria; their effects were to lower plasma glucose, reduce blood pressure, and cause weight loss. A landmark trial using empagliflozin in high-risk people with existing cardiovascular disease showed a marked reduction in mortality [68].

Tolbutamide, phenformin, and insulin were compared in the treatment of *maturity-onset* diabetes in the first randomized controlled trial, the University Group Diabetes Program (UGDP) [84–86]. This much-criticized study concluded that the death rate was higher for both oral agents than for placebo, and that insulin (whether given in a fixed or variable dose) was no better than placebo [85]. The UGDP study, however, did not have correct randomization for pre-existing conditions such as myocardial infarction and its conclusions were uninterpretable and unsafe. Nevertheless, these findings were considered by some as suggesting that treatment

of maturity-onset diabetes was a waste of time, a myth that was only laid finally to rest by the UK Prospective Diabetes Study (UKPDS) [87]. Beyond the UKPDS, there have been many cardiovascular outcome trials addressing separate issues relating to individual pharmacological agents.

Glucose management and treatment targets

During the 1920s, opinion leaders advocated normalizing blood glucose in young people with diabetes, the rationale being to *rest* the pancreas, in the hope that it might regenerate. The only way of monitoring the diabetes was by testing the urine for glucose, and attempts to keep the urine free from sugar inevitably resulted in severe hypoglycaemia and often psychological damage. This led to the so-called *free diet* movement – linked particularly with Adolf Lichtenstein (Stockholm) and Edward Tolstoi (New York) – which encouraged people with diabetes to eat whatever they liked and not to worry about glycosuria, however heavy. Tolstoi's view [88] was that a life saved by insulin should be worth living, and that people with diabetes should be able to forget that they had diabetes after each morning's injection; it seems likely that many physicians followed this policy for the next 40 years.

Adult physicians were similarly ambivalent about the importance of optimal glycaemic management. Only one-third of diabetes physicians questioned in England in 1953 thought that normoglycaemia would prevent diabetes-related complications, and only one-half advised urine testing at home [89].

Practical monitoring of diabetes management became feasible in the late 1970s with the introduction into clinical practice of test strips for measuring blood glucose in a fingerprick sample and the demonstration that most people with diabetes could use them at home [90, 91]. The discovery of haemoglobin A_{1c} by Samuel Rahbar (1929–2012) paved the way for glycated haemoglobin (HbA_{1c}) assays that gave an objective measure of overall glucose levels [92]. These methods in turn made possible the North American Diabetes Control and Complications Trial (DCCT), which in 1993 finally established that optimal glycaemic management prevents and delays the progression of microvascular complications in type 1 diabetes [93]. For type 2 diabetes, the importance of optimal glycaemic management was definitively proved by another landmark study, the UKPDS, masterminded in Oxford by Robert Turner (Figure 1.19). The UKPDS, which reported in 1998, not only showed a beneficial effect of improved glycaemic levels on microvascular complications [87], but also established the importance of treating hypertension [94]. By the late 1990s it was clear that lowering glucose levels, high blood pressure, or cholesterol separately would reduce the frequency of heart disease and death, and it was

Figure 1.19 Robert Turner (1939–1999), instigator of the UK Prospective Diabetes Study, the first study to show that optimal management of blood glucose and blood pressure was beneficial in type 2 diabetes. Source: Courtesy of the British Diabetic Association.

natural to wonder whether tackling them simultaneously (multiple risk factor intervention) would be even better. The Steno-2 study, which began at the Steno Diabetes Center in Copenhagen in 1992, enrolled people with type 2 diabetes with microalbuminuria, and after 13 years of follow-up showed that multiple risk factor intervention reduced the risk of death by 20% and the risk of developing nephropathy, retinopathy, and neuropathy by 50% [95].

Diabetes-related complications

Apart from the general benefits of improving blood glucose, some specific treatments have emerged for certain chronic complications. Well-conducted clinical trials during the late 1970s showed the effectiveness of laser photocoagulation in preventing visual loss from both maculopathy and proliferative retinopathy [96]. This technique was derived from the xenon arc lamp originally described in the late 1950s by Gerd Meyer-Schwickerath (1921–1992) of Essen, Germany [97].

The importance of blood pressure management in preventing the progression of nephropathy is now fully recognized, and

blockade of the renin-angiotensin system may be particularly beneficial; Carl Erik Mogensen (*b.* 1938) and Hans-Henrik Parving (*b.* 1943) published studies in the early 1980s demonstrating that lowering blood pressure slowed the progression of nephropathy [98]. The detection of very low albumin concentrations in urine (microalbuminuria), now used throughout the world to screen for and monitor the course of diabetic nephropathy, is derived from a radioimmunoassay developed in 1969 by Harry Keen (1925–2013) and Costas Chlouverakis, at Guy's Hospital in London [99].

Diabetic ketoacidosis

The introduction of insulin was only one aspect of the management of this acute and previously fatal complication of diabetes. Of the first 33 cases treated by Joslin and his colleagues between 1 January 1923 and 1 April 1925, 31 survived – an excellent outcome, even by modern standards, which Joslin [100] attributed to ‘Promptly applied medical care, rest in bed, special nursing attendance, warmth, evacuation of the bowels by enema, the introduction of liquids into the body, lavage of the stomach, cardiac stimulants, and above all the exclusion of alkalis’.

Sadly, other centres did not pay so much attention to detail. In 1933, the death rate from ketoacidosis in Boston was only 5%, but elsewhere in North America and Europe it averaged 30% and could be as high as 75%. An important advance in management was the acceptance of relatively low-dose insulin replacement, following the example of Ruth Menzel and colleagues in Karlsruhe, Germany [101]. This broke with the tradition of high-dose regimens such as that proposed by Howard Root in the USA, which had recommended an average of 1200 units of insulin during the first 24 hours of treatment [102]. Another step forward was the recognition by Jacob Holler in 1946 of the danger of hypokalaemia [103]. Holler’s observation helped to establish the need for monitoring plasma potassium levels, which became feasible with the introduction of the flame photometer and replacing potassium accordingly.

Diabetes in pregnancy

As late as 1950, the outcome of pregnancy in women with diabetes was still very poor in most units, with perinatal fetal losses of 45–65%, some 10 times higher than in the general population. Exceptions to this depressing rule were the units run by Priscilla White at the Joslin Clinic in Boston, who had published excellent results as early as 1935 [104], and by Jørgen Pedersen in Copenhagen (Figure 1.20). Pedersen identified the common features underpinning success as optimal glucose management and care provided by an experienced and dedicated team comprising a physician, obstetrician, and paediatrician [105]. Pedersen’s target of a fetal mortality rate of 6% was not achieved in most European or US units until the 1980s.

Delivery of care for people with diabetes

From the earliest days of insulin injection and urine testing, it was apparent that people with diabetes needed knowledge and practical skills to manage their disease effectively. Lip service

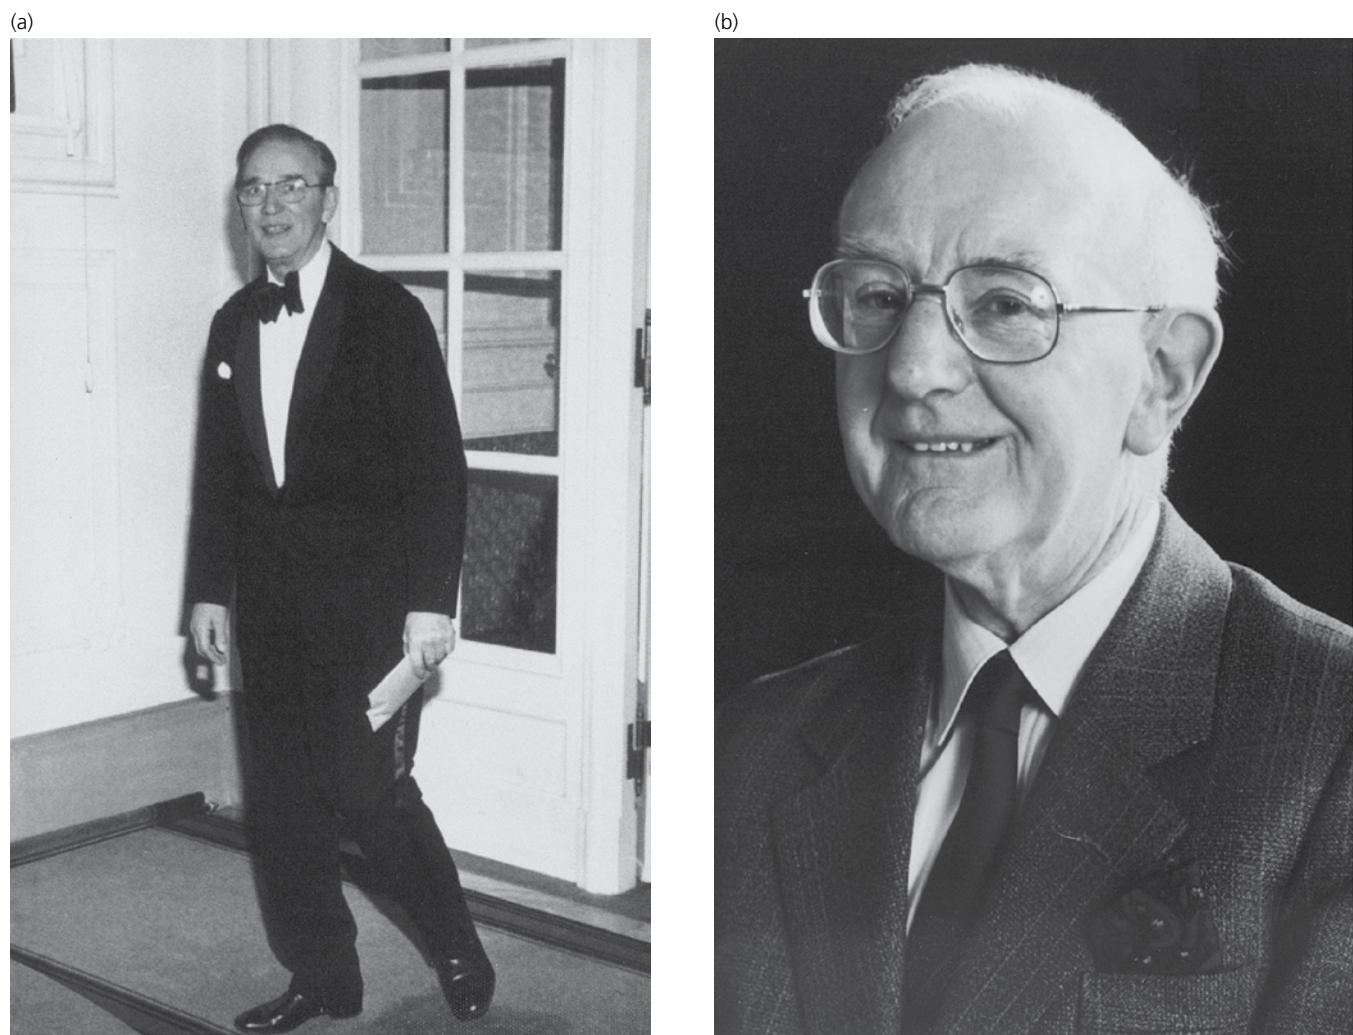

Figure 1.20 (a) Jørgen Pedersen (1914–1978) and (b) Ivo Drury (1905–1988), pioneers, with Priscilla White (1900–1989), in the management of pregnancy in women with type 1 diabetes. Source: Courtesy of Dr Carl Erik Mogensen and the Royal College of Physicians of Ireland.

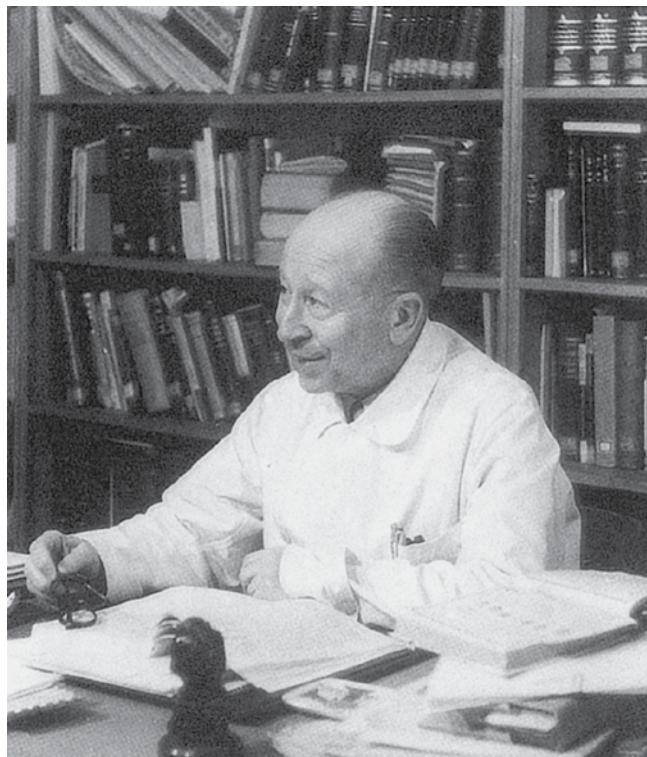

was often paid to the importance of diabetes education, but most individuals with diabetes were badly informed. In 1952, Samuel Beaser (1910–2005) questioned 128 people with diabetes attending the Boston Diabetes Fair, and found that ‘all were distinctly deficient in knowledge of their disease’ [106]; he felt that responsibility lay with both doctors and administrators. Further studies during the 1960s by Donnell Etzwiler (1927–2003) in Minneapolis showed that many doctors and nurses were also ignorant about managing diabetes. Since the 1980s, diabetes specialist nurses and nurse educators have been appointed in increasingly large numbers, thus fulfilling a suggestion originally made by Joslin in 1916.

National and international diabetes associations have also played an important part by supporting scientific and clinical research, providing practical and moral help for people with diabetes, and lobbying governments on their behalf. The first of these organizations was the Portuguese Association for the Protection of Poor Diabetics, founded in 1926 by Ernesto Roma of Lisbon after an

inspiring visit to Joslin’s clinic in Boston (Figure 1.21). The Association’s aim was to provide free insulin and education for people with diabetes and their families. In the UK, the Diabetic Association (later the British Diabetic Association, and now Diabetes UK) was established in 1934 by Robin Lawrence of King’s College Hospital, London, helped by the novelist H.G. Wells (Figure 1.21). Similar organizations were later founded in France (1938), the USA (1940), and Belgium (1942), and now exist in most countries.

On a wider scale, the American Diabetes Association (ADA) was founded in 1939, the International Diabetes Federation was established in 1950, and the European Association for the Study of Diabetes (EASD) in 1964. These organizations are devoted to the practice of diabetes care as well as the basic and clinical science of the disease, and have been valuable in coordinating treatment targets and strategies at international level; an important example was the St. Vincent Declaration, issued jointly in 1990 by the EASD and the World Health Organization [107].

Classification and Diagnosis of Diabetes

**Ambady Ramachandran, Chamukuttan Snehalatha, Arun Raghavan,
and Arun Nanditha**

Dr. A. Ramachandran's Diabetes Hospitals and India Diabetes Research Foundation, Chennai, India

Key points

- Diabetes is a complex metabolic disease characterized by high levels of blood glucose and/or glycated haemoglobin (HbA_{1c}) resulting from defects in insulin secretion, insulin action, or both.
- There are three main types of diabetes and other less common specific types of diabetes with varied and overlapping aetiology.
- Although blood glucose remains the mainstay for the diagnosis of diabetes, HbA_{1c} is approved as an alternative diagnostic test for hyperglycaemia and in many countries is being increasingly used in place of glucose.
- Recent suggestions to classify diabetes according to β -cell defects may facilitate personalized, optimal therapy, but the diagnostic tests are too costly or unavailable in most laboratories.
- Varied diagnostic criteria for gestational diabetes are still being used.
- Impaired glucose tolerance (IGT) is a predictor of future type 2 diabetes and is also a cardiovascular risk factor.

Diabetes is one of the most common metabolic diseases with a complex, multifactorial aetiology and has varied clinical and biochemical manifestations. Multiple and varied therapeutic approaches are required for the glycaemic management of the different types of diabetes. The main pathological abnormalities of diabetes are an inadequate secretion and/or impaired action of insulin on target tissues. The severity of the resultant hyperglycaemia and the symptoms and signs vary widely. The development of diabetes-related microvascular complications depends largely on the degree and duration of hyperglycaemia.

Diabetes mellitus has been known since ancient times. The term *diabetes* was probably first used by Apollonius of Memphis around 250 BCE. The Latin word *mellitus* was added later, as the urine of people with diabetes was sweet and was used to distinguish diabetes mellitus from diabetes insipidus caused by defects in vasopressin [1].

Diabetes was described as early as 1500 BCE by Hindu scholars and Egyptian and Greek physicians as a mysterious disease causing emaciation and excess urination. If the urine tasted sweet, diabetes was diagnosed [2]. It was only in the 1800s that chemical tests were developed to detect the presence of sugar in the urine. The early descriptions were probably related to severe forms of the disease, either type 1 diabetes or overt type 2 diabetes.

In the late nineteenth century two categories were recognized: one category was described as occurring in young people with a short time course before ketoacidosis occurred, and the second one was described as common in older people and those with obesity. In 1936, Himsworth showed that diabetes could be divided into insulin-resistant and insulin-sensitive types, with the former being more common among older people [3].

Definition

Diabetes is a group of metabolic diseases characterized by hyperglycaemia resulting from defects in insulin secretion, insulin action, or both. Diabetes is distinguished by disturbances in carbohydrate, fat, and protein metabolism. The clinical symptoms include polyuria, polydipsia, polyphagia, weight loss, tiredness, and blurring of vision. With severe metabolic dysregulation, ketoacidosis or hyperosmolar non-ketotic coma may occur. However, symptoms may be mild or absent among people with type 2 diabetes for many years, especially when hyperglycaemia is minimal. Although the disease may remain undetected, tissue damage may develop and therefore diabetes-related complications may be present at the time of diagnosis [4,5]. Chronic hyperglycaemia may impair growth in children and increase the susceptibility to certain infections. In addition to the classic symptoms, people with diabetes may present with vague symptoms such as unexplained weight loss, fatigue, restlessness, and body pain.

Diabetes is associated with the development of long-term complications that can be divided into two main types. Microvascular complications include retinopathy (with potential loss of vision), nephropathy (leading to renal impairment), peripheral neuropathy (with risk of foot ulcers, amputations, or Charcot joints), and autonomic neuropathy (causing gastrointestinal, genitourinary, and cardiovascular symptoms, and sexual dysfunction) [4,5]. Macrovascular complications include cardiovascular diseases with increased incidence of atherosclerotic cardiovascular, peripheral arterial, and cerebrovascular diseases as well as heart failure. Hypertension and dyslipidaemia often coexist in people with diabetes.

Diagnosis and classification of diabetes

Although variations in the presentation and course of diabetes have been known for many centuries, a clear distinction between two types of diabetes emerged only in the twentieth century. The first real attempt to classify diabetes was by the World Health Organization (WHO) Expert Committee on Diabetes Mellitus, which classified diabetes based on the age of onset of the disease into juvenile-onset diabetes and maturity-onset diabetes [6]. Although other phenotypes such as the brittle, gestational, pancreatic, endocrine, insulin-resistant, and iatrogenic varieties were described at that time, there was no clear understanding of the aetiology.

Blood glucose measurements became common, but no standard criteria for diagnosis were used. The diagnosis was usually made if there were clinical symptoms with high blood glucose levels and glycosuria. In juvenile-onset diabetes, ketonuria was noted to be common. Later on, with the availability of insulin measurement using radioimmunoassay, insulin deficiency or lack of insulin secretion in juvenile-onset diabetes and apparently normal or raised levels in maturity-onset diabetes could be demonstrated.

The WHO has published several guidelines for the diagnosis of diabetes since 1965 [5–7]. Its second report, published in 1980 [7], marked the beginning of the modern classification, which was a revision of the criteria published by the National Diabetes Data Group (NDDG) [8]. For the first time, four major groups were defined: insulin-dependent diabetes mellitus (IDDM, type 1); non-insulin-dependent diabetes mellitus (NIDDM, type 2); the ‘other types’; and gestational diabetes mellitus. Two risk classes, previous abnormality of glucose intolerance and potential abnormality of glucose tolerance, were also suggested in place of the terms *pre-diabetes* or *potential diabetes*.

Both diagnosis and classification were reviewed in 1985 [9] and 1999 [5]. At the same time the American Diabetes Association (ADA) published a report of an expert committee on the diagnosis and classification of diabetes [10]. Both WHO and ADA classifications attempted to encompass both aetiology and clinical stages of the disease based on the suggestions of Kuzuya and Matsuda [11].

It was known that diabetes could progress through several clinical stages from normoglycaemia to ketoacidosis. With the discovery of human leucocyte antigen (HLA) and islet cell antibodies, it became clear that juvenile-onset diabetes or insulin-independent diabetes had an autoimmune aetiology. Although maturity-onset diabetes was thought to be a *milder* form of the disease, it was recognized that people with type 2 diabetes could progress through varying levels of hyperglycaemia to a stage where insulin was required. By contrast, it was also possible to revert from a stage of requiring insulin to a point where normoglycaemia could be maintained through non-pharmacological intervention with modification of health behaviours, which is now termed *remission of diabetes*.

Methods and criteria for diagnosing diabetes

The criteria for the diagnosis of diabetes recommended by the ADA in 2021 [12] and approved by the WHO [13] and the International Diabetes Federation (IDF) are shown in Table 2.1.

Table 2.1 Criteria for the diagnosis of diabetes.

FPG ≥ 126 mg/dl (7.0 mmol/l). Fasting is defined as no caloric intake for at least 8 h.

OR

2 h PG ≥ 200 mg/dl (11.1 mmol/l) during OGTT. The test should be performed, as described by the WHO, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

OR

HbA_{1C} $\geq 6.5\%$ (48 mmol/mol). The test should be performed in a laboratory using a method that is NGSP-certified and standardized to the DCCT assay.

OR

In a person with classic symptoms of hyperglycaemia or hyperglycaemic crisis, a random plasma glucose ≥ 200 mg/dl (11.1 mmol/l).

In the absence of unequivocal hyperglycaemia, the diagnosis requires two abnormal test results from the same sample or in two separate test samples.

DCCT, Diabetes Control and Complications Trial; FPG, fasting plasma glucose; NGSP, National Glycohemoglobin Standardization Program; OGTT, oral glucose tolerance test; PG, plasma glucose; WHO, World Health Organization.

Diagnostic thresholds

The thresholds for the diagnosis of diabetes are currently based on the glycaemic levels above which diabetes-related microvascular complications mostly occur. However, these thresholds have changed over time. The oral glucose tolerance test (OGTT) was first introduced by Hofmeister in 1889, but this was not standardized and various amounts of glucose with different two-hour thresholds were used throughout the 1960s and 1970s. The second WHO report published in 1980 [7] marked a breakthrough in harmonizing the diagnosis of diabetes. The report established that diabetes could be diagnosed with a casual plasma glucose of >11.0 mmol/l (200 mg/dl) or with a 75 g OGTT using fasting and two-hour thresholds of ≥ 8.0 mmol/l (145 mg/dl) and >11.0 mmol/l (200 mg/dl), respectively. The two-hour threshold was based on the observed risk of developing retinopathy in several populations, but there were less robust data for the fasting glucose threshold, which was later revised to the current value of 7.0 mmol/l (126 mg/dl).

In the development of diabetes, there is a stage when the blood glucose values are above normal, but below the thresholds used for defining diabetes, which is termed *pre-diabetes* or *intermediate hyperglycaemia*. Pre-diabetes encompasses abnormalities in fasting glucose (impaired fasting glycaemia) and two-hour post-glucose challenge glucose (impaired glucose tolerance, IGT). Both impaired fasting glycaemia and IGT increase the risk of developing diabetes, with approximately one-third of people with IGT developing type 2 diabetes; the annual incidence rate ranges between 2% and 10% depending on the population and the presence of risk factors [13]. Use of the term ‘pre-diabetes’ has been criticized on the basis that not all people with this condition progress to type 2 diabetes, and the term ‘intermediate hyperglycaemia’ is preferred by many. The diagnostic thresholds for pre-diabetes have also changed over time. The category of IGT was introduced by the WHO in 1965 and after a few iterations it was defined as a fasting glucose value of <7 mmol/l (126 mg/dl) and post-glucose value between ≥ 7.8 mmol/l (140 mg/dl) and

<11.1 mmol/l (200 mg/dl) [14]. The 1997 ADA and 1999 WHO criteria defined impaired fasting glucose (IFG) as a fasting glucose value between ≥ 6.1 mmol/l (110 mg/dl) and <7.0 mmol/l (126 mg/dl). In 2003, the ADA revised the lower cut-off value to ≥ 100 mg/dl (5.7 mmol/l). The reduction of normal fasting value to ≤ 100 mg/dl was partly to ensure that the prevalence of IFG was similar to that of IGT. Furthermore, many studies have shown that 5.6 mmol/mol (100 mg/dl) provides the best cut-point for predicting future diabetes and the level at which insulin secretion becomes abnormal. However, lowering this threshold significantly increases the prevalence of pre-diabetes, which has important personal and public health implications [15, 16]. As such, the WHO and other organizations did not adopt this change [15].

In 2011, glycated haemoglobin (HbA_{1c}) was also introduced as a further diagnostic criterion for diabetes, with a threshold of 6.5% (48 mmol/mol) [4, 17]. The HbA_{1c} test should be performed using the method certified by the National Glycohemoglobin Standardization Program or International Federation of Clinical Chemistry. A value of $<6.5\%$ (<48 mmol/mol) does not exclude diabetes diagnosed using glucose tests. The ADA report recognizes that individuals with an HbA_{1c} between 5.7% and 6.5% are at risk of diabetes and includes HbA_{1c} as a means of diagnosing pre-diabetes [17]. It should be noted that the risk of diabetes is continuous, can extend below the lower limit of the range, and is disproportionately greater at the higher end of the range [4].

Number of abnormal tests required

In an individual with classic symptoms of hyperglycaemia, only one measurement of glucose or HbA_{1c} above the diagnostic threshold is required to make the diagnosis. In the absence of a clear history of diabetes symptoms, however, the diagnosis of diabetes requires two abnormal test results from the same sample or in two separate test samples. Where there is uncertainty, the WHO and ADA recommend that a standard 75 g OGTT is used if possible in conjunction with HbA_{1c} measurement. However, clinical practice is changing and in many high-income countries, where procedures for the accurate measurement of HbA_{1c} are readily available, the OGTT is being used less and less frequently. In these settings, a single blood sample with measure of either fasting or random glucose and HbA_{1c} is more commonly used for the diagnosis.

Further considerations of method of diagnosis

When used on a population basis, fasting glucose, two-hour glucose, and HbA_{1c} identify slightly different groups of people as having diabetes. Thus, an individual may test positive for diabetes with one test but not another. As the OGTT combines both fasting and two-hour glucose, using fasting glucose alone will identify fewer people with diabetes than an OGTT. Studies in Asian populations [18] and the Diabetes Epidemiology: Collaborative analysis of Diagnostic criteria in Europe (DECODE) study [19] showed that if only fasting blood glucose was used, nearly one-third of cases with diabetes might be missed at diagnosis. There are similar concerns about HbA_{1c} , but with time the groups coalesce to the point where all three tests become positive.

Analytical considerations

Blood glucose measurement has been the mainstay of diagnosis and monitoring glycaemic levels in diabetes for many decades. The OGTT is a comparatively inexpensive, sensitive index of hyperglycaemia including impaired glucose homeostasis. Standard enzymatic methods of glucose estimation are in widespread use.

Table 2.2 Advantages and limitations of using HbA_{1c} .

Advantages	Limitations
<ul style="list-style-type: none"> • Random sampling • Fasting not required • High sample stability • Negligible biological variability • Highly reproducible • Indicator of long-term glycaemic status • Single whole blood sample • Minimal assay variability and accuracy are assured when standard methods are used • Standardized across instruments • Guides physicians on the appropriate treatment • Predictive of development of vascular complications • Point-of-care tests are available in high-income countries 	<ul style="list-style-type: none"> • Depends on changes in lifespan of erythrocytes • Genetic and ethnic variations • Affected by haemoglobinopathies • Affected by severe anaemia, hence may not be valid in people with chronic renal and liver diseases • May be unreliable in individuals with human immunodeficiency virus (HIV) • May not be valid in children, in older people, and in pregnancy • Assays are not standardized in many middle- and low-income countries • High cost • Lack of awareness among citizens and physicians in developing countries

However, high biological variability, poor reproducibility, and influence by acute factors such as stress, food, exercise, and some medications are the main disadvantages of using blood glucose. Moreover, precautions must be taken to reduce the lowering of sample glucose by glycolysis by adding anti-glycolytic agents, such as sodium fluoride. Despite this, the rate of decline in glucose concentration continues for up to four hours in small quantities. In addition, there are differences in glucose concentrations in whole blood, plasma and serum and between capillary and venous blood. The availability of point-of-care testing with glucometers has helped to reduce the disadvantages of blood glucose measurement to some extent. Moreover, rapid bedside measurements have also become possible with these meters.

HbA_{1c} , initially identified as an index of chronic hyperglycaemia, has now evolved into a valuable tool to monitor glycaemic management, for screening and diagnosis of diabetes and pre-diabetes, and as a predictor of micro- and macrovascular complications [20, 21]. Presently the results are traceable to the Diabetes Control and Complications Trial (DCCT) assay values (measured as %) [22] and can also be compared to the highly accurate International Federation of Clinical Chemistry (IFCC) standardized values (mmol/mol) [20]. Measuring HbA_{1c} has multiple advantages over blood glucose, but also has a few limitations, particularly in middle- and low-income developing countries (Table 2.2). Healthcare professionals using the test should be aware of these limitations and employ their discretion in interpreting the results [20, 23].

Classification of diabetes types

The aetiological classification of diabetes was described by the WHO [5] and also approved by the ADA [12]. The classification of type 2 diabetes is largely characterized by exclusion. The most recent WHO classification published in 2019 is shown in Table 2.3 [13].

As new causes are discovered they are included as 'other specific types', such as maturity-onset diabetes of the young (MODY).

Table 2.3 Classification of diabetes.

Type of diabetes	Brief description
Type 1 diabetes	β -cell destruction (mostly immune mediated) and absolute insulin deficiency; onset most common in childhood and early adulthood
Type 2 diabetes	Most common type, various degrees of β -cell dysfunction and insulin resistance; commonly associated with overweight and obesity
Hybrid forms of diabetes	
Slowly evolving, immune-mediated diabetes of adults	Similar to slowly evolving type 1 diabetes in adults, but more often has features of the metabolic syndrome, has a single glutamic acid decarboxylase (GAD) autoantibody, and retains greater β -cell function
Ketosis-prone type 2 diabetes	Presents with ketosis and insulin deficiency but later does not require insulin; common episodes of ketosis, not immune mediated
Other specific types	
Monogenic diabetes	Caused by specific gene mutations; has several clinical manifestations requiring different treatment, some occurring in the neonatal period, others by early adulthood
Monogenic defects of β -cell function	Caused by specific gene mutations; has features of severe insulin resistance without obesity; diabetes develops when β cells do not compensate for insulin resistance
Monogenic defects in insulin action	Various conditions that affect the pancreas can result in hyperglycaemia (trauma, tumour, inflammation, etc.)
Diseases of the exocrine pancreas	Occur in diseases with excess secretion of hormones that are insulin antagonists
Endocrine disorders	Some medicines and chemicals impair insulin secretion or action, some can destroy β cells
Drug or chemical induced	Some viruses have been associated with direct β -cell destruction
Infection-related diabetes	Associated with rare immune-mediated diseases
Uncommon specific forms of immune-mediated diabetes	Many genetic disorders and chromosomal abnormalities increase the risk of diabetes
Other genetic syndromes sometimes associated with diabetes	
Unclassified diabetes	Used to describe diabetes that does not clearly fit into other categories. This category should be used temporarily when there is not a clear diagnostic category, especially close to the time of diagnosis
Hyperglycaemia first detected during pregnancy	
Diabetes in pregnancy	Type 1 diabetes or type 2 diabetes first diagnosed during pregnancy
Gestational diabetes	Hyperglycaemia below diagnostic thresholds for diabetes in pregnancy

Source: Adapted from the World Health Organization Report, 2019 [13].

The WHO has revisited the classification several times with no major modifications. IGT was removed from the formal classification of type 2 diabetes, but was retained as a risk state. A new category of risk status, IFG, was introduced.

Type 1 diabetes

In most cases, type 1 diabetes occurs as a result of cellular-mediated autoimmune destruction of pancreatic β cells, causing an absolute deficiency of endogenous insulin. People with type 1 diabetes are dependent on exogenous insulin for survival and are ketosis prone. Markers of the immune destruction of the β cell include islet cell autoantibodies, autoantibodies to insulin, glutamic acid decarboxylase (GAD), and autoantibodies to the tyrosine phosphatases IA-2 and IA-2 β . One or more of these autoantibodies are present in 85–90% of individuals when fasting hyperglycaemia is initially detected. The disease also has strong HLA associations, with linkage to the DQA and DQB genes, and is influenced by the DRB genes.

The rate of destruction of β cells is usually rapid in infants, young children, and adolescents and they often have ketoacidosis at the time of first presentation. Some people with type 1 diabetes, mostly adults, have a slower deterioration of β -cell function and show detectable levels of plasma C-peptide for many years. Type 1 diabetes is associated with other autoimmune disorders such as Graves' disease,

Hashimoto's thyroiditis, Addison's disease, vitiligo, coeliac-sprue, autoimmune hepatitis, myasthenia gravis, and pernicious anaemia.

About 2–12% of people diagnosed with type 1 diabetes show phenotypic characteristics of type 2 diabetes at diagnosis and initially have glucose levels within target on oral anti-diabetes agents, before rapidly progressing to requiring insulin. They also show the presence of autoimmune markers of β -cell destruction, such as GAD autoantibodies. This subgroup was termed *latent autoimmune diabetes of adults* (LADA), but in the recent WHO classification the term LADA was removed because there was considerable controversy as to whether this was a separate condition to type 1 diabetes. It now comes under hybrid forms of diabetes with slowly evolving immune-mediated diabetes of adults [13].

A few people with type 1 diabetes may have no evidence of autoimmunity, but are prone to episodic ketoacidosis and may exhibit varying degrees of insulin deficiency and insulin dependency during those periods. This form, termed *idiopathic diabetes*, is commonly seen in people of African and Asian ethnicity and is strongly familial [4].

Type 2 diabetes

Type 2 diabetes constitutes more than 95% of the total population with diabetes. Its prevalence is increasing globally, but the most striking changes are now seen in low- and middle-income

countries. Type 2 diabetes may remain asymptomatic for many years and is undetected in nearly 50% of people affected by the disease [4, 5]. It is commonly diagnosed incidentally when a medical check-up is done for other reasons. Type 2 diabetes is characterized by a relative insulin deficiency; although there is insulin secretion, this is insufficient to overcome insulin resistance. Though many people with type 2 diabetes manage their diabetes with lifestyle changes alone, with time oral anti-diabetes agents are needed to maintain normoglycaemia, with many people eventually requiring insulin. Chronic exhaustion of β -cell function is a major cause of this.

Although research studies have focused on the molecular mechanisms underlying type 2 diabetes, only modest success has been achieved in unravelling the genetic abnormalities. In the past two decades, type 2 diabetes in children and adolescents has become common in Asian populations and could be partly attributed to the rising rates of obesity and changing lifestyle patterns [24]. A minority of people with type 2 diabetes are prone to episodes of ketosis. They have insulin deficiency but no immune markers. This hybrid form is termed ketosis-prone type 2 diabetes [13].

There has been a proposal to modify the classification of type 2 diabetes to identify people at increased risk of complications and support precision treatment by tailoring the type of therapy with greatest benefit for the individual with diabetes. Recently, a sub-stratification in 8980 individuals with newly diagnosed diabetes was undertaken in Sweden using clusters based on six variables: GAD antibodies, age at diagnosis, body mass index (BMI), HbA_{1c}, and estimates of β -cell function and insulin resistance. The analysis was based on prospective data from medical prescriptions and development of complications from electronic records of the examined individuals [25]. Five clusters of phenotypes with distinct characteristics were identified. Individuals in cluster 1 (severe autoimmune diabetes) had early-onset disease, low BMI, relatively higher HbA_{1c}, insulin deficiency, and presence of GAD antibodies. Cluster 2 (severe insulin-deficient diabetes) was GAD antibody negative, with low age at onset, low BMI, low insulin secretion, and relatively higher HbA_{1c}. Cluster 3 (severe insulin-resistant diabetes) had high insulin resistance and high BMI, while cluster 4 (mild obesity-related diabetes) had obesity but not insulin resistance. Cluster 5 (mild age-related diabetes) was older but was similar to cluster 4 with modest metabolic derangements. Among these the highest percentage (39.1%) was cluster 5 and the lowest cluster 1 (6.4%).

The clusters had varied dispositions to specific complications of diabetes such as kidney disease, coronary events, and stroke. Clusters 1 and 2 had a higher HbA_{1c} at diagnosis than the other clusters and a higher frequency of ketoacidosis. Cluster 2 had the highest risk of retinopathy, and cluster 3 had the highest prevalence of non-alcoholic fatty liver disease and chronic kidney disease. Cluster 4 had an increased risk of diabetes kidney disease and cluster 5 appeared to have a lower risk of renal disease.

The authors suggested that further improvement in the stratification may be possible through the inclusion of additional variables such as biomarkers, genotypes, or genetic risk scores. Therefore, the study suggested the superiority of identifying the new clusters during classification, which will possibly provide better guidance for appropriate treatment regimens. However, the tests required for identifying the clusters are costly and are available only in a limited number of advanced research institutions and hospitals. More detailed clinical trials are required to confirm the utility of this classification.

Other specific types

These forms of diabetes are relatively less common. The underlying defects of the disease processes can be identified in these forms, such as those listed in Table 2.3. Some of these defects are remediable and the diabetes can be cured [4, 5].

Gestational diabetes

For many years, gestational diabetes was defined a state of carbohydrate intolerance resulting in hyperglycaemia of variable severity, with onset or first recognition during pregnancy. It does not exclude the possibility that the glucose intolerance may antedate pregnancy but has previously gone unrecognized. The definition applies irrespective of whether or not insulin is used for treatment or whether the condition persists after pregnancy [12, 13]. According to this definition, gestational diabetes may develop at any stage of pregnancy, but many now consider diabetes detected during the first trimester of pregnancy to be previously undiagnosed pre-existing diabetes. The term gestational diabetes is then reserved for diagnoses made in the second or third trimester of pregnancy. Women who have diabetes and subsequently become pregnant are termed as having *diabetes mellitus and pregnancy* and should be treated accordingly during and after the pregnancy. This is discussed in greater detail in Chapter 71. The International Association of Diabetes and Pregnancy Study Groups' (IADPSG) criteria for diagnosis of gestational diabetes are shown in Table 2.4 [27]. These criteria have been adopted by main national guidelines, including

Table 2.4 Screening for and diagnosis of gestational diabetes.

One-step strategy

Perform a 75 g OGTT, with plasma glucose measurement when the individual is fasting and at 1 h and 2 h, at 24–28 weeks of gestation in women not previously diagnosed with diabetes. The OGTT should be performed in the morning after an overnight fast of at least 8 h. The diagnosis of gestational diabetes is made when any of the following plasma glucose values are met or exceeded:

- Fasting: 92 mg/dl (5.1 mmol/l)
- 1 h: 180 mg/dl (10.0 mmol/l)
- 2 h: 153 mg/dl (8.5 mmol/l)

Two-step strategy

Step 1: Perform a 50 g GLT (non-fasting), with plasma glucose measurement at 1 h, at 24–28 weeks of gestation in women not previously diagnosed with diabetes. If the plasma glucose level measured 1 h after the load is ≥ 130 , 135, or 140 mg/dl (7.2, 7.5, or 7.8 mmol/l, respectively), proceed to a 100 g OGTT.

Step 2: The 100 g OGTT should be performed when the individual is fasting. The diagnosis of gestational diabetes is made when at least two^a of the following four plasma glucose levels (measured fasting and at 1, 2, and 3 h during OGTT) are met or exceeded:

- Fasting: 95 mg/dl (5.3 mmol/l)
- 1 h: 180 mg/dl (10.0 mmol/l)
- 2 h: 155 mg/dl (8.6 mmol/l)
- 3 h: 140 mg/dl (7.8 mmol/l)

GLT, glucose load test; OGTT, oral glucose tolerance test.

^aAmerican College of Obstetricians and Gynaecologists notes that one elevated value can be used for diagnosis [26].

Source: Adapted from American Diabetes Association, 2021 [12].

those of the ADA, but not by all countries [12]. Establishing a uniform approach to diagnosis will have extensive benefits for women, caregivers, and policy makers.

Women with any of the following risk factors should be screened with an appropriate blood test as shown in Table 2.4, during the first prenatal visit; if the result is found to be normal, they should be tested again between 24 and 28 weeks of pregnancy [12, 13]. The risk factors for gestational diabetes include older age, obesity ($BMI > 30 \text{ kg/m}^2$), history of elevated blood glucose levels or gestational diabetes during previous pregnancy, women who have large-for-gestational age babies, a strong family history of diabetes, and women from high-risk ethnic groups such as Asians [28].

Hyperglycaemia may resolve after the delivery, but 5–10% of women may continue to have diabetes, most often type 2 diabetes. These women require treatment with lifestyle changes and appropriate anti-diabetes agents. Women with gestational diabetes should be screened for diabetes immediately postpartum and again at 6–12 weeks postpartum using non-pregnant OGTT criteria [29]. HbA_{1c} cannot be used in the immediate postpartum period, but is an effective alternative way of screening for persistent glucose abnormalities from 12 weeks postpartum where the facilities for accurate measurement are available. Women with gestational diabetes are at risk of future diabetes outside pregnancy and should be offered screening on an annual basis. Women who show impaired glucose regulation at this

stage should be treated with lifestyle interventions and in some circumstances metformin.

Conclusion

The advances made in the past two decades in diagnostic and research methodologies for identifying pathophysiological components of various types of diabetes have provided significant clarity in the classification and diagnosis of diabetes [26]. This has helped to establish some uniformity in data collection and has also allowed comparison of the international profile of the disease. Consensus in establishing diagnostic criteria for gestational diabetes is lacking. Emphasis should be given to identifying the pre-diabetes states that are the strongest predictors of incident type 2 diabetes.

The classification of diabetes should facilitate optimal personalized diabetes care. There are many diabetes subtypes, especially among type 2 diabetes, type 1 diabetes, and the autoimmune type of diabetes. The current state of knowledge suggests that the classification should be based on β -cell pathology contributing to β -cell dysfunction [30]. At present, the facilities for specialized analysis required for such a classification, such as genotyping and advanced immune pathology, are available only in a few advanced specialized research laboratories and are too costly [31, 32]. Nevertheless, the classification of diabetes continues to evolve as underlying genetic and other factors become identified with increasing precision.

Key points

- Diabetes results in a range of distressing symptoms, altered daily functioning (requiring attentive self-care, health monitoring, and treatments), changed family roles, higher healthcare costs, lost productivity, disability, and premature mortality, which are felt by individuals, households, communities, and national economies.
- The prevalence of diabetes has grown worldwide, with no country or region spared. Concerningly, estimates of prevalence and absolute numbers of people living with diabetes have consistently outpaced each previous projection. Projections for 2045 suggest that the greatest increases will be seen in low- and middle-income countries.
- In contrast, evidence from predominantly high-income countries suggests that diabetes incidence may have started to decline in more recent years.
- Diabetes is a leading cause of death in the world with 4.2 million deaths annually, equivalent to one death every eight seconds. Diabetes-related mortality disproportionately affects low- and middle-income countries, the young, and economically active populations.
- Declining mortality among people with diabetes will increase the total years of life spent living with diabetes and may drive the emergence of new diabetes-related complications such as cancer, mental health disorders, cognitive impairment, and disability. A longer life lived with diabetes may also exacerbate the risk of established diabetes macrovascular and microvascular complications, as well as infections, including the newly emerged Covid-19.
- In 2019, the global direct health expenditure of diabetes was estimated to be US \$760 billion and is expected to grow substantially in the coming decades. The majority of this spending (~90%) is in high-income countries, despite a greater absolute diabetes burden in low- and middle-income countries, exacerbating existing disparities between high-income countries and low- and middle-income countries.
- Diabetes impairs one's ability to perform domestic and occupational activities. Decreased workplace productivity, impaired interpersonal relationships, and perceived discrimination can impede diabetes self-management and affect an individual's ability to integrate fully into society.
- Preparation for the increasing diabetes burden requires progress in the wider collection of reliable data in a standardized manner across various countries. In particular, there is a current scarcity of data from low- and middle-income countries regarding diabetes-related mortality, complications, disability, and costs.
- Confronting the increasing burden of diabetes, particularly in vulnerable subpopulations, will require addressing the underlying political, social, cultural, behavioural, and economic factors that impede the translation of known effective strategies to reduce diabetes risk in the population.

Diabetes is one of the fastest-growing health challenges of the twenty-first century. The number of adults living with diabetes has more than tripled over the past 20 years, with serious health-related and socioeconomic impacts on individuals and populations alike. Pandemic growth of diabetes is spurred on by transitioning demographic (e.g. population ageing), nutritional, and lifestyle patterns, and an affiliated proliferation of overweight and obesity in adults and children [1–3]. The International Diabetes Federation (IDF) estimated that there were 463 million people with diabetes worldwide in 2019 and projects that the absolute number will reach 700 million by 2045 if current trends persist [1]. The overwhelming

majority of this escalation will be attributable to an increase in type 2 diabetes, with the greatest impact expected in low- and middle-income countries (LMIC) due to rapid socioeconomic and lifestyle transformations [4–6].

Current estimates suggest that three-quarters of those affected by diabetes live in LMIC [1, 7]. This challenges previously held paradigms that distinguished chronic non-communicable diseases as problems of affluent countries alone. Although the greater absolute burden of diabetes may be partially explained by the larger population size of LMIC, the growth rates for non-communicable diseases in rapidly transitioning LMIC are much higher than those in more

affluent high-income countries (HIC) [8]. For example, it was previously estimated that by 2025, the number of people with diabetes will increase by 170% in LMIC, compared with a 41% increase in HIC [9].

Thus far, the attention on health burdens in LMIC has justifiably focused on the persistence of infectious diseases, reproductive health problems, and nutritional deficiencies. However, these same countries must also contend with 80% of the global mortality associated with chronic diseases [10, 11]. Projections suggest that this already overwhelming ‘double burden’ will be exacerbated by the further growth of non-communicable diseases such as diabetes. Altogether, projected increases in diabetes in all corners of the world will result in a corresponding escalation of burdens in the form of serious morbidity, disability, diminished life expectancy, reduction in quality of life, loss of human and social capital, and individual and national income losses. This chapter describes these burdens in a global context, and systematically introduces data regarding regional patterns and associated themes.

Prevalence

In recent decades, large increases in diabetes prevalence have been demonstrated in virtually all regions of the world, largely attributed to a rise in type 2 diabetes and its risk factors. In 2019, 1 in 11 adults aged 20–79 was living with diabetes (463 million people), of whom 79% were living in LMIC [1]. Quantification of the prevalence of diabetes is important for healthcare planning and resource allocation and facilitates the formulation of appropriate disease prevention and control strategies. However, there are still insufficient representative and rigorous epidemiological data from many LMIC to reliably capture the true global diabetes burden. Moreover, the utility of currently available estimates is hampered by methodological deficiencies (e.g. inconsistent diagnostic criteria, poor standardization of methods) and limited coverage (e.g. regional sampling with a predominance of urban studies even though many of the populations in question have large numbers of rural inhabitants) [12, 13]. To address these barriers, the IDF and World Health Organization (WHO) use sophisticated modelling approaches to provide global estimates, by country, for diabetes prevalence. In the

following, we highlight notable patterns in the three most common types of diabetes, type 1 diabetes, type 2 diabetes and gestational diabetes mellitus (GDM), and compare estimates by different income-group regions.

Type 1 diabetes

The prevalence of type 1 diabetes is increasing worldwide due to a combination of improved survival and an increase in incidence, thought to be driven by environmental and lifestyle-related changes [14], such as rapid weight gain and/or inappropriate feeding in infancy [15, 16]. In 2019, the number of children and adolescents aged 0–14 years and 0–19 years with type 1 diabetes was 600 900 and 1.1 million worldwide, respectively, with a large proportion residing in Europe and North America where incidence continues to increase [17–19] (Table 3.1). India, the USA, and Brazil have the largest numbers of children and adolescents living with type 1 diabetes, with 95 600, 94 200, and 51 500, respectively, as of 2019.

The prevalence of type 1 diabetes in adults is less well known and estimates typically rely on self-reporting of diabetes type and treatment status, thus are limited in their ability to accurately distinguish between type 1 and type 2 diabetes in adults [20, 21]. Consequently, a global perspective on the prevalence of type 1 diabetes in adults remains elusive.

Type 2 diabetes

In 2019, it was estimated that 9.3% of all adults aged 20–79 years (463 million) were living with diabetes, with the majority assumed to be type 2 diabetes. This is projected to increase to 10.9% (700.2 million) in 2045, with the greatest increases expected to be seen in LMIC. Age-adjusted comparative prevalence estimates are shown in Table 3.1 and vary by region, whereby the highest prevalence is seen in the Middle East and North Africa regions. The countries with the largest absolute number of adults aged 20–79 years with diabetes are China (116 million), India (77.0 million), and the USA (31 million), though countries with the highest age-adjusted prevalence of diabetes include some Pacific islands, Pakistan, Sudan,

Table 3.1 Estimated numbers of children and adolescents with type 1 diabetes and prevalence of type 2 diabetes in adults and gestational diabetes mellitus (GDM; hyperglycaemia in pregnancy) in pregnant women by region.

	Type 1 diabetes	Type 2 diabetes	GDM
Region	Number of children and adolescents (0–14 yr) with type 1 diabetes (in thousands)	Age-adjusted prevalence (%) and 95% confidence interval (CI) among adults aged 20–79	Age-adjusted prevalence (%) of GDM, and numbers of births (millions) among pregnant women
Africa	10.0	4.7 (3.2–8.1)	9.6 (3.5)
Europe	162.6	6.3 (4.9–9.2)	16.3 (2.0)
Middle East and North Africa	82.0	12.2 (8.3–16.1)	7.5 (1.9)
North American and Caribbean	121.4	11.1 (9.0–14.5)	20.8 (1.6)
South and Central America	69.0	8.5 (6.7–11.3)	13.5 (1.0)
South-East Asia	100.0	11.3 (8.0–15.9)	27.0 (6.6)
Western Pacific	56.0	11.4 (8.3–15.6)	12.3 (3.8)
World	600.9	8.3 (6.2–11.8)	14.4 (20.4)

Part 1 Diabetes in its Historical and Social Context

and other countries in the Middle East and North Africa. National prevalence estimates of 15–30% are reported in these countries.

The prevalence of type 2 diabetes also varies considerably between subpopulations within countries or regions. For example, in established market economies, those in lower socioeconomic groups (e.g. lower education, lower income) have a higher burden of diabetes relative to higher socioeconomic groups. In LMIC regions, the prevalence of diabetes typically remains lower in lower and middle socioeconomic classes; however, these groups tend to make up a larger proportion of the overall population and thus the absolute number of people affected by diabetes in these social groups is much higher than in their wealthier counterparts [22, 23]. Further, there are major differences in prevalence between ethnic groups. For example, both Hispanic and Asian populations have a higher prevalence of diabetes compared with European and sub-Saharan African populations [24, 25]. This is likely due to multiple factors, including genetic, epigenetic, lifestyle, and environment. More epidemiological data, especially from longitudinal studies, are needed to inform our understanding of pathophysiology, and studies are required to determine best practices and describe effective interventions to screen, prevent, and manage diabetes in country-specific settings. The following are some notable examples of within-country and within-region variations based on available data. The regions are based on groupings used by the IDF.

Sub-Saharan Africa

- Diabetes prevalence varies considerably between countries in this region, with age-adjusted prevalence estimates ranging from a low of 1.0% in Benin to a high of 12.7% in South Africa [1]. There is also great variability in rural versus urban prevalence, with urban areas facing the brunt of the burden [26–28]. The wide variation in diabetes prevalence may be explained partly by regional differences in lifestyle and body mass index (BMI).
- A higher prevalence of diabetes has been noted among people of Egyptian and Asian Indian origin as compared with Indigenous African people [13, 29].
- Data on diabetes prevalence in sub-Saharan Africa originate from just a few localized centres in certain parts of the continent, and estimates vary widely, between 0% and 3% in rural areas and 6% and 12% in urban environments [13, 30]. Further, data on population-level dietary and physical activity patterns, suspected to be key drivers leading to an increase in diabetes, are severely lacking in African countries.
- As human immunodeficiency virus (HIV) mortality declines through widespread uptake of anti-retroviral therapies, the direct (e.g. pancreatic dysfunction associated with therapy) and indirect (e.g. increased life expectancy) effects are likely to have an impact on diabetes prevalence [31].

Europe

- Across 56 countries that vary markedly in size, language, ethnic groups, and affluence, the age-adjusted prevalence ranges from 2.1% in Greenland to 11.1% in Turkey [1].
- Structural deprivation may explain part of the regional differences, along with individual socioeconomic status and ethnic mix [32, 33].

Middle East and North Africa

- The Middle East and North Africa region has some of the highest age-adjusted diabetes prevalence estimates in the world, ranging from 5.4% in Yemen to 22.1% in Sudan [1].

- The Gulf region has experienced an especially marked and sudden increase in rates of diabetes, where Kuwait (12.2%), Saudi Arabia (15.8%), and Bahrain (15.6%) now rank among the countries with the highest prevalence of type 2 diabetes worldwide [1].

North America and Caribbean

- Diabetes prevalence is, generally, higher in Caribbean than in North American countries, with age-adjusted estimates ranging from 6.6% in Haiti to 14.2% in the British Virgin Islands (vs 7.6% in Canada and 10.8% in the USA) [1].
- In the USA, the variations by race and ethnicity have been extensively described, with ethnic minorities more likely to have a higher burden of diabetes. For example, a 2019 study demonstrated that among adults, the prevalence was 12.1%, 20.4%, 22.1%, and 19.5% in adults of white European, non-Hispanic Black, Hispanic, and non-Hispanic Asian ancestry, respectively [34].
- In Canada and the USA, diabetes prevalence is considerably higher in Indigenous than in non-Indigenous groups. In Canada, First Nations people living on reserve have an age-adjusted prevalence of 17.2% compared to 10.3% among First Nations living off reserve, and 5.0% among non-Indigenous Canadians [35]. The US Pima Indians have the highest prevalence of type 2 diabetes in the world, with 34.2% for Pima men and 40.8% for Pima women (compared to 9.3% in the calendar year-matched general US population) [36].
- Life expectancy of people with diabetes in North America, although reduced compared with the general population [37], is markedly higher than in LMIC.

South and Central America

- The average age-adjusted prevalence of diabetes is 8.5%, but ranges from 5.5% in Ecuador to 13.7% in Puerto Rico [1], reflecting the diversity of ethnicities and stages of development between countries [7].
- Indigenous populations are estimated to have a high prevalence of metabolic dysfunction and diabetes, as has been noted in Brazil [38], but the patterns and proportions of Indigenous peoples in each country are not clearly documented [39].

South-East Asia

- The age-adjusted prevalence ranges from 7.2% in Nepal to 22.0% in Mauritius [1].
- South-East Asian adults are confronted with diabetes risk being manifest at younger ages and at lower BMIs compared with populations in other regions [40], possibly due to lower insulin secretion and a greater tendency for deposition of metabolically active visceral adiposity [41–43].
- Rural–urban differences in prevalence of diabetes among Asians suggests genetic, and environmental factors, and their interactions all have a role to play [44].

Western Pacific

- The age-adjusted prevalence ranges from 3.9% in Myanmar to 30.5% in the Marshall Islands [1].
- Indigenous populations in Australian and New Zealand, similar to those in Canada and the USA, are disproportionately burdened by diabetes. In Australia and New Zealand, Indigenous [45] and Māori and Pacific [46] peoples are three times more likely to have diabetes compared to their non-Indigenous counterparts.
- In China, rural areas have historically had a lower prevalence of diabetes compared with urban areas. However, a 2020 study reported that diabetes prevalence in rural regions has increased at a

rate 2.5 times that of urban areas (between 2013 and 2017 [47, 48]), such that prevalence estimates are now similar in rural and urban areas (12.0% and 13.7%, respectively) [47].

To prevent diabetes-related complications such as nerve, eye, kidney, and/or vascular diseases, type 2 diabetes should be diagnosed as early as possible [49–51]. Yet in 2019, 50% of the 463 million adults living with diabetes were unaware that they have the condition [1]. The slow progression and lack of symptoms in the early stages of disease often delay people seeking a glucose test, preventive care, and/or medical attention. Perhaps unsurprisingly, the proportion of diabetes that remains undiagnosed is much higher in low-income than in middle-income countries (75% vs 46%, respectively) [52]. Overall, it is estimated that 84% of all cases of undiagnosed diabetes are in LMIC, with Pacific Island nations showing the highest prevalence of undiagnosed diabetes [53]. These estimates point to an urgent need for developing and improving diabetes screening programmes.

Gestational diabetes mellitus

The prevalence of GDM, one of the most common pregnancy complications, has increased by more than 30% within one or two decades in several countries, including some developing countries [54]. Some of this increase is likely related to changes in diagnostic criteria. In 2019, an estimated 15.8% (20.4 million) of live births were affected by hyperglycaemia in pregnancy, of which 83.6% were due to GDM [1]. The prevalence of GDM increases with age: 37.0% of women aged 45–49 years have GDM compared with 10.1% in women aged 20–24 years. There are also regional differences in age-adjusted GDM: 27.0% of live births in South-East Asia compared with just 7.5% in the Middle East and North Africa (Table 3.1) [1]. More than 85% of women with GDM are seen in LMIC where access to antenatal care is often limited.

In the USA, Canada, and Australia, there are notable differences in the racial/ethnic-specific prevalence of GDM. For instance, in the USA, prevalence varies from 4.5% to 10.9% in non-Hispanic white compared to Filipina women [55]. In Australia, women of South Asian origin are more than four times as likely to develop GDM compared to their Australia/New Zealand-origin counterparts [56]. The reasons underlying the racial/ethnic differences are yet to be elucidated, but the mechanisms could be multifaceted, including differences in body composition, lifestyle (diet and physical activity), acculturation, genetic susceptibility, cultural beliefs and practices around prenatal behaviours, and healthcare systems and reporting practices [57].

Incidence of type 2 diabetes

Much of the epidemiology of type 2 diabetes has been described in terms of its prevalence and of the total numbers of people affected. This provides an excellent assessment of the population-level burden and can identify subgroups of the population who are more susceptible to diabetes. Within this framework of data, changing prevalence of diabetes over time is typically interpreted as changing risk for diabetes in the population. If the prevalence of diabetes rises, it is often assumed that lifestyle or other risk factors are deteriorating, leading to an increase in diabetes risk and an assumption

that perhaps measures to reduce risk have failed. However, the prevalence of diabetes, like that of any other condition, is determined by two factors – the rate at which people develop the condition and the rate at which people leave the condition. The former is the disease incidence and the latter comprises mortality, migration, and cure (or remission).

It is clear from this brief discussion that the prevalence of diabetes can rise simply because of falling mortality. Indeed, even if the incidence of diabetes is falling, it is possible that prevalence will rise, so long as the number of new cases each year exceeds the number of people with diabetes who die each year. Thus, in settings where the treatment of diabetes and related conditions is improving and mortality is falling, changes in the prevalence of diabetes may not accurately reflect changes in population risk. Incidence, however, is defined as the number of new cases arising within a disease-free population each year and is a much more direct measure of the population risk of diabetes than is prevalence. Therefore, assessments of population risk can only be reliably made from incidence studies, and only changes in incidence over time can be used to definitively infer changes in population risk.

Unfortunately, incidence studies can be difficult to conduct. The classic prospective cohort study is typically small and with only modest response rates, limiting generalizability and the ability to derive precise incidence estimates. Furthermore, such studies cannot easily be used to track changes in incidence over time. As a result, the population-level descriptions of diabetes epidemiology have remained focused on prevalence, despite the issues described above.

In recent years, analyses based on much larger data sources, such as registries and electronic health records, have started to fill this gap. These analyses often include whole populations and therefore can generate precise estimates, as well as limit selection biases. They are not, however, without limitations. For example, it is often difficult to standardize diagnostic approaches, as the data are collected through clinical practice rather than via research protocols. Furthermore, they give no measure of undiagnosed diabetes, and so can be influenced by changes in screening and diagnostic behaviour. Nevertheless, current incidence data from such sources provide an important addition to prevalence data and have already suggested a different pattern to that indicated by examining prevalence studies.

A recent systematic review of published studies reporting trends in the incidence of type 2 diabetes or total diabetes over time identified 47 relevant publications, and found that between 2006 and 2014 two-thirds of populations experienced either a stable or declining incidence of diabetes [58]. This contrasted with the period from 1990 to 2005, during which diabetes incidence rose in two-thirds of populations [58]. A subsequent analysis of new data from administrative datasets in over 20 countries, representing 5 billion person-years of follow-up, had similar findings [59]. From 2010 onwards, 19 of 23 country-specific data sources had a downward or stable trend, with annual reductions in diabetes incidence ranging from 1.1% to 10.8%. In this analysis, data from two of the populations indicated that changes in diagnostic testing for diabetes (i.e. testing frequency and the use of HbA_{1c} instead of glucose) were unlikely to explain the observed declines in the incidence of diabetes [59]. These findings apply only to HIC and a small number of middle-income countries, reflecting the distribution of these data systems. Nevertheless, they indicate that, at least in some parts of the world, the incidence of type 2 diabetes may now be falling.

The reasons for a fall in incidence remain uncertain. Since administrative data only report on clinically diagnosed diabetes, it is possible that reductions in screening activity could play a role,

although there is no evidence that such a reduction has occurred. In some countries, but not others, the fall in incidence occurred at a similar time to the introduction of HbA_{1c} as a diagnostic test, though as already noted, where data were available this did not account for reductions in incidence. Aggressive screening programmes in the early 2000s may have depleted the pool of people with undiagnosed diabetes, leading to a rebound fall in new clinical diagnoses thereafter. However, since the pool of people with undiagnosed diabetes is continually replenished as people age, such a rebound fall might be expected to be short-lived. This leaves the possibility that the huge public health and clinical focus on reducing the risk of developing type diabetes might have had some effect.

Trends in diabetes-related complications

Global increases in diabetes prevalence, predominantly type 2 diabetes, will increase the number of chronic and acute diabetes complications in the general population, with profound effects on quality of life, demand on health services, and economic costs. Macrovascular complications of diabetes, including coronary heart disease, stroke, and peripheral artery disease, and microvascular complications, such as end-stage renal disease, retinopathy, and neuropathy, along with lower-extremity amputations, a common consequence of peripheral artery disease and neuropathy, are responsible for much of the burden associated with diabetes. There is also growing recognition of a diversifying set of causally linked conditions, including cancers, ageing-related outcomes (e.g. dementia), infections, and liver disease. Since rates of all-cause and cardiovascular disease mortality are decreasing in individuals with diabetes [60–63], other complications of diabetes may become proportionately more prominent in the future.

Understanding the burden of diabetes-related complications is crucial for understanding the overall health burden associated with diabetes and provides important context to concurrent changes in the prevalence of diabetes. However, despite widespread international assessment of the growth of diabetes prevalence, quantification of the international burden and variation in the incidence of diabetes-related complications is notably lacking. This stems largely from the fact that data systems and population-based studies assessing diabetes complications are concentrated in Europe, North America, and other HIC in the Asia-Pacific region, with little to no availability in LMIC, leaving the global status of diabetes complication rates unclear. This gap in data stems largely from the lack of population-based systems quantifying healthcare utilization, because surveys and cohort studies are generally inadequate for the assessment of diabetes-related complications. The lack of both uniform diagnosis of diabetes and of standardized measurement of diabetes-related complications has caused additional barriers in comparing trends worldwide. In the following, we highlight notable patterns in several diabetes-related complications and, where possible, regional variations.

Macrovascular complications

Macrovascular, or cardiovascular disease, complications of diabetes include coronary artery disease (i.e. ischaemic heart disease, heart attack, sudden coronary death), cerebrovascular disease or stroke, and peripheral artery disease. People with diabetes have a two- to

fourfold increased risk of cardiovascular disease [64, 65], and these events generally occur at an earlier age compared to people without diabetes [65]. As the number of people with diabetes is predicted to increase, it is expected that the number of people with cardiovascular disease will also increase. In studies of middle-aged (50–69 years) adults with diabetes living in high- and middle-income countries, up to 41% report a history of cardiovascular disease, and 2–27 people in every 1000 die from cardiovascular disease each year [65].

In 2012, it was estimated that among 37.9 million deaths worldwide, 46% were due to cardiovascular disease [65]. The regions with the highest rates of age-standardized cardiovascular disease mortality are in Central Asia, the Middle East, and Africa [65], while populous countries such as China and India have the largest absolute number of people dying from cardiovascular disease. In general, countries with lower rates of age-standardized cardiovascular disease mortality are more likely to have a high gross national income per capita, have high total health expenditure as a proportion of gross domestic product, and have non-communicable disease monitoring systems [65]. This suggests a beneficial impact of investment in healthcare and access to essential medicines despite the high prevalence of cardiovascular risk factors such as diabetes, obesity, and elevated cholesterol in these countries. Indeed, several studies in HIC suggest that the risk of cardiovascular disease in people with diabetes has been declining [66]. For example, in the USA, Australia, and Canada, a 46–53% relative reduction in cardiovascular mortality has been seen in people with diabetes since the mid-1990s, as well as a reduction in the excess mortality risk between populations with and without diabetes [66]. Despite this, people with diabetes are still two- to fourfold more likely to die from cardiovascular disease compared with people without diabetes [64].

Type 2 diabetes and cardiovascular disease have common precursors such as insulin resistance, visceral adiposity, and excess inflammation [67–71], as well as a complex mix of mechanistic processes including oxidative stress, enhanced atherogenicity of cholesterol particles, abnormal vascular reactivity, augmented haemostatic activation, and renal dysfunction [72]. Hence simply managing glucose, at least in the short term, has not been found to reduce cardiovascular events and mortality in large randomized controlled trials [73–75]. This has resulted in recommendations for individualized, comprehensive, multifactorial risk management (i.e. treating all risk factors together) for people with type 2 diabetes [65, 76, 77], adding to the burdens on individuals with diabetes, providers, and health systems.

Lower-extremity amputations

Lower-extremity amputations are a major complication for adults with diabetes owing to their physical, economic, and psychosocial burden. Amputation rates are an important indicator of the success of preventive care such as targeted glycaemic and cardiovascular risk factor management, and screening and treatment of people at high risk of foot complications. Peripheral artery disease and neuropathy are major risk factors for lower-extremity amputations. Population-based studies indicate that, in general, there have been variable reductions in amputation rates (by ~3–85%) since the early 1980s [66]. For the 13 countries or regions with available data (from Europe, USA, UK, and Australia), declines in amputation rates appear to be driven by declines in major lower-extremity amputations (i.e. amputations above the ankle), possibly as a consequence of more minor amputations being performed in order to prevent major amputations [66]. More recently, preliminary data in the

USA suggest that rates of lower-extremity amputations may be increasing, particularly among young adults with diabetes, though the underlying causes remain elusive. Regardless, lower-extremity amputation rates remain higher in people of other than white ethnicity and men, and large, geographical, within-country variations in amputation rates have been reported, with the suggestion that part of this relates to availability of high-quality footcare services [78–80].

Microvascular complications

Microvascular complications of diabetes include lower-extremity amputations, end-stage renal disease, retinopathy, and neuropathy. Duration of disease, age, and glycaemic and blood pressure management have all been found to be prominent modifying factors of microvascular disease onset, progression, and outcomes [81]. As for all data on diabetes-related complications, what we know of microvascular complications in diabetes stems from a relatively small number of studies from HIC. Here we highlight some of these.

End-stage renal disease

Together with hypertension, diabetes is the leading risk factor for nephropathy and end-stage renal disease requiring dialysis or transplant [82, 83]. In HIC, diabetes accounts for almost half of all new end-stage renal disease cases [82]. Like all other diabetes-related complications, the increase in diabetes prevalence has occurred simultaneously with steep increases (~40–700%) in end-stage renal disease incidence in the general population of several countries (e.g. USA, Australia, Russia, Korea, Mexico) [66, 84]. However, among populations with diabetes, the incidence of end-stage renal disease may be declining. For example, in a nationwide Chinese study, end-stage renal disease incidence declined 6% in adults with type 2 diabetes between 2000 and 2012 [85] and by 28% between 1990 and 2010 in the USA [86]. Similarly to amputation rates, recent US data suggest a stalling in progress of end-stage renal disease since 2010, and perhaps more concerning is an observed increase in end-stage renal disease in young adults (18–44 years) with diabetes [78]. A similar pattern of increasing incidence of end-stage renal disease among younger adults with type 2 diabetes has also been reported in Australia [87].

Retinopathy

Visual impairment, mainly due to cataract development, and retinopathy in diabetes are increasingly common, and diabetes is the leading cause of adult-onset blindness globally [81]. Diabetic retinopathy has devastating personal and socioeconomic consequences, despite being potentially preventable and treatable [88–90]. The overall prevalence of diabetic retinopathy and vision-threatening retinopathy in people with diabetes is estimated to be 35% and 12% [81], respectively. While considerable variation in diabetic retinopathy exists within and between countries, it is difficult to make meaningful comparisons in the absence of internationally agreed screening and diagnostic criteria for diabetic retinopathy. A 2019 review examined changes in retinopathy incidence over time and reported that despite the frequency of diabetic retinopathy, few population-based data existed. Of the few studies available (in USA, UK, and Korea), a 50–67% reduction in diabetic retinopathy since the 1990s was observed, most likely due to better glycaemic and blood pressure management, reductions in smoking, and earlier identification and treatment of diabetic retinopathy [66].

Neuropathy

Peripheral neuropathy is the most common form of diabetes-related neuropathy and occurs in 16–87% of people with diabetes [91], with severe and painful neuropathy occurring in approximately 26% of people [92]. Lower-extremity sensory loss and compromised peripheral vascular circulation increase the risk of ulceration and subsequent infection [93, 94]. The combination of neuropathy, infection, poor wound healing, and poor distal circulation increases the risk of lower-extremity amputation 15–20 times and is more common in LMIC (vs HIC) [1, 95–97]. Whether prevalence and incidence of neuropathy have changed over time is unknown due to the lack of data from repeated population surveys. In the USA, rates of hospitalization for neuropathy increased by 42.1% between 2000 and 2014 [98], though this is likely influenced by changes in International Classification of Disease (ICD) coding of neuropathy, as well as by increased awareness of neuropathy among individuals with diabetes and providers alike.

Acute complications

Acute complications of diabetes, such as diabetic ketoacidosis (DKA), the hyperglycaemic hyperosmolar state, lactic acidosis, and hypoglycaemia, most often require immediate medical management and can have fatal repercussions if left untreated. These acute complications of diabetes, despite being largely preventable, still account for a high proportion of the morbidity and mortality burden and contribute significantly to the high costs of diabetes care [99].

Aside from atypical variants such as ketosis-prone type 2 diabetes in Africans [13, 30], most acute metabolic complications occur in people with type 1 diabetes. In the USA, the SEARCH for Diabetes in Youth study reported that 29% of individuals aged <20 years with type 1 diabetes, and 10% with type 2 diabetes, presented with DKA at diagnosis [100]. The incidence of DKA in children and adolescents with type 1 diabetes also remains high, with ~1–12 episodes per 100 person-years [99].

When treated properly, the mortality from acute hyperglycaemic episodes such as DKA is extremely low (e.g. in Taiwan, the USA, and Denmark death occurred in 0.67–4.0% of all DKA cases) [101, 102]. In general, DKA-related complications have decreased among people with diabetes since the early 1990s [66], though recent increases in DKA and hyperglycaemic hyperosmolar state have been observed in the USA with underlying causes unknown [103]. Though data in LMIC by comparison are limited, in some African countries mortality from DKA can be as high as 25–33% [13, 104, 105]. This higher risk relative to HIC is likely due to a series of complex, cumulative, and interconnected barriers, such as poor access to healthcare, inadequate therapeutic instruments and medication, and insufficient numbers of trained staff, which result in poor metabolic management and subsequent higher risk of mortality [106]. Consequently, early-life death in people with type 1 diabetes in low-resource settings is commonplace (e.g. the post-diagnosis life expectancy in some regions of Africa is just one year) [107].

Mortality

Diabetes is associated with a 1.4–6-fold higher risk of mortality, depending on age, sex, and region [108] compared with the general population, and shortens life expectancy by up to 15 years [109].

In 2019, the IDF estimated that approximately 4.2 million adults aged 20–79 died as a result of diabetes and its complications [1]. This is equivalent to one death every eight seconds. Diabetes is estimated to contribute to 11.3% of deaths globally, ranging from 6.8% (lowest) in the Africa region to 16.2% (highest) in the Middle East and North Africa [108]. About half (46.2%) of the deaths attributable to diabetes occur in people under the age of 60 years, and this is as high as 73.1% in the Africa region and as low as 31.4% in Europe [108].

The most common causes of death among people with diabetes are cardiovascular disease, cancer, end-stage renal disease, and infections (e.g. pneumonia). Historically, in HIC, cardiovascular disease accounted for an overwhelming majority (i.e. 65–75%) of deaths in people with diabetes [110, 111]. However, as cardiovascular-specific mortality continues to decline [61–63], a larger proportion of deaths are being attributed to non-vascular causes such as cancer. For example, in the UK, the proportion of deaths due to vascular diseases in individuals with diabetes declined from 44% in 2001 to 24% in 2018, while the proportion of deaths due to cancer increased from 22% in 2001 to 28% in 2018 [63]. Similar findings have been shown in Australia and the USA [61, 112]. In low-resource settings, acute metabolic emergencies are still a prevailing cause of death in people with diabetes, accounting for 8%, 9.3%, and 11.9% of all deaths in populations in Mexico, India, and Asia, respectively [113–115]. End-stage renal disease also carries a high mortality, due mainly to the inaccessibility (physical and financial) of treatment (dialysis and/or transplant) in most LMIC settings [30, 113].

Mortality rates due to diabetes are often estimated from vital statistics systems (based on death certificate data), the accuracy of which may be affected by coding practices and country-level awareness of diabetes. This approach depends on the certifying doctor's opinion as to whether or not diabetes contributed to the death. Since this is subjective, mortality rates among populations with diabetes should ideally be estimated among defined cohorts with diagnosed diabetes. This approach captures all deaths among people with diabetes, and allows estimation of excess risk overall and for specific causes of death by comparison to the population without diabetes. Our current understanding of trends in all-cause mortality among people with diabetes comes from a relatively small number of HIC within North America, Europe, Australasia, and Asia. A recent systematic review, including 35 studies and representing 17 countries/regions from North America, Europe, Australia, Korea, and Taiwan, reported that since 2000 nearly 80% of studies reported declines in all-cause mortality among people with diabetes, and these declines occurred at a greater or similar rate to those without diabetes [60]. These declines were seen among people of predominantly European background.

More aggressive management of risk factors with statins, anti-platelet therapy, and anti-hypertensive medications [113, 116, 117], improvements in glycaemic management [116, 117], and smoking cessation [113, 116, 117] may have contributed to the substantial reductions in mortality rates. Because people with diabetes started with a higher mortality risk than those without diabetes, population-wide changes in risk factors [118–120] are likely to have led to a greater absolute risk reduction among people with diabetes than among those without. Though positive, falling mortality in people with diabetes will likely lead to an increasing prevalence of diabetes, despite a stable or even declining incidence of diabetes. This will increase the total years of life spent living with diabetes and may drive the emergence of *new* diabetes-related complications that previously did not substantially contribute to the diabetes burden.

Emerging complications

The longer life expectancy among people with diabetes and fuller assessment of the overall impact of diabetes have driven the recognition of non-traditional complications of diabetes, including cancer, mental health disorders, and physical and cognitive disability [68]. There has also been an increasing interest in the impact of diabetes on infection risk. Here, we provide a high-level overview of the existing evidence describing these associations.

Cancer

A large body of epidemiological evidence now suggests that people with diabetes are at an increased risk for cancer, though the magnitude and direction of the association depend on the specific site of the cancer [121]. The strongest associations have been demonstrated for liver [122] and pancreatic [123] cancers, though these may also reflect some degree of reverse causality, with the cancer itself leading to the onset of type 2 diabetes. Risk of endometrial cancer [124] appears to be doubled in women with diabetes, and risks of breast [125], colorectal [126], bladder [127], stomach [128], kidney [129], and non-Hodgkin's lymphoma [130] are approximately 20–40% higher in people with type 2 diabetes. Interestingly, there appears to be a protective effect of diabetes for prostate cancer of ~10–15% [131], which is thought to be due in part to reduced levels of endogenous testosterone in men with type 2 diabetes. A 2015 Australian study, using a large national diabetes registry and including more than 1 million people, also demonstrated increased risks for gallbladder, lung, ovarian, and thyroid cancers, multiple myeloma, and leukaemia [132]. Many of these cancers are also associated with obesity [133] and this may be a key driver for the increased cancer risk in people with diabetes.

The majority of current evidence pertains to type 2 diabetes, though some studies show similar risks for type 1 diabetes [132, 134], suggesting the underlying causal mechanism may be hyperglycaemia, rather than hyperinsulinemia, though clinical trials are yet to demonstrate a causal association between reduced glucose levels and reduced cancer risk [135]. Studies examining anti-diabetes drugs, including insulin and metformin, have also shown some associations with cancer risk, though such studies are difficult to interpret as they are prone to bias due to confounding by indication.

Once diagnosed with cancer, people with diabetes are at increased risk for mortality. The same Australian study that examined cancer incidence in over 1 million people with diabetes demonstrated increased risks for overall cancer mortality and a number of site-specific cancers, similar to results for cancer incidence [132]. However, prospective studies on site-specific cancer mortality are extremely difficult to conduct owing to the relative rareness of cancer (and diabetes) and the need for very large sample sizes to conduct such studies. Smaller studies have also demonstrated that among those diagnosed with cancer, diabetes confers a 30% increased risk for all-cause mortality. The proportional shift of increasing cancer deaths in people with diabetes over time [61, 63, 112] suggests screening for several cancers should be prioritized in people with diabetes to minimize cancer-related mortality in the future.

Mental health disorders

People with diabetes are at increased risk for major depressive disorder [136], anxiety [137], eating disorders (particularly in female adolescents with type 1 diabetes) [138], and serious mental illness

(e.g. schizophrenia) [139]. Further, diabetes has been found to be a significant risk factor for suicidal ideation [140–142], hopelessness, and poor quality of life in adults [143]. These mental health issues interfere with optimal self-management and may lead to other diabetes complications and increased risk for all-cause mortality [144, 145].

Cognitive impairment

With an ageing population, dementia has become one of the most common conditions in modern society with devastating personal, societal, and economic consequences. Several meta-analyses have demonstrated an adverse effect of diabetes on cognition, with increased risks ranging from 21% to 91% depending on the impairment being measured [146–148]. A 2019 updated meta-analysis, representing 122 studies and over 9 million individuals from Western populations, found that diabetes was associated with a 49%, 43%, 43%, and 91% increased risk of mild cognitive impairment, all-cause dementia, Alzheimer's disease, and vascular dementia, respectively [149]. This same study also reported a non-linear dose response such that the risk of cognitive disorders increased by 20% with fasting plasma glucose above 7.75 mmol/l [149]. Diabetes has been associated with more specific cognitive impairments such as decrements in episodic memory, logical memory, executive functions (e.g. cognitive flexibility), and speed of processing, but not short-term or working memory [147]. Encouragingly, some evidence indicates that diabetes drugs may reduce the risk of dementia in people with diabetes. Pioglitazone, for example, an oral anti-diabetes drug, has been associated with a 47% reduction in dementia risk [149].

Disability

Diabetes can lead to disability in various ways. Excluding the medical aspects of diabetes-related complications that directly restrict bodily function, diabetes may be considered a *hidden* disability, whereby the individual concerned is hampered from partaking in routine activities but displays no physical manifestation of this illness. For example, children with type 1 diabetes may suffer discrimination at school or may not be permitted to engage in physical activities [150]. Adults in the workplace may suffer lower work performance by virtue of any number of symptoms (impaired fine motor skills and concentration, grogginess, urinary frequency) [151], or even a decline in cognitive functioning [152–154]. People with diabetes take more working days off and often report difficulties with completing work tasks [155, 156]. The physical manifestations of diabetes become more significant with the development of complications. Visual impairment, restricted mobility (due to shortness of breath, chest pain, or even amputation), and general ill-health (ranging from increased susceptibility to infection to uraemia related to irreversible renal dysfunction) may all contribute to physical disability [151, 157]. In a 2013 meta-analysis of 26 studies, Wong et al. demonstrated that diabetes (vs no diabetes) was associated with a 70% increased risk of mobility disability, a 65% increased risk for limitations in instrumental activities of daily living (e.g. shopping, using transport), and an 82% increased risk for limitations in activities of daily living (e.g. bathing, dressing, eating, using the toilet) [158]. A Global Burden of Disease study subsequently reported that in 2016, lower-extremity complications of diabetes (i.e. diabetic neuropathy, foot ulcer, and amputation) contributed 16.8 million years lived with disability (YLDs), or 2.1% of the global (YLDs) [159], an increase of 140.3% since 1990. This disability burden disproportionately affects men

and those aged 50–69 years. By region, the highest YLD rates were seen in North Africa and the Middle East, Latin America, Oceania, and the Caribbean, while the lowest rates were in East Asia, Western sub-Saharan African, Australasia, and Western Europe [159]. Diabetes management strategies, including interdisciplinary foot-care services, are necessary to reduce the disability burden through the prevention of diabetes-related complications.

Infections

Individuals with diabetes have an increased risk for tuberculosis, severe Gram-positive infections, hospital-acquired postoperative infections, urinary tract infections, and tropical diseases compared with people without diabetes [160]. This increased risk is of particular concern in LMIC, where the relative burden of these communicable diseases remains high [161]. This challenge is not just one of parallel epidemics, as diabetes predisposes both to higher risk of infections [162] and possibly poorer outcomes for those who contract infections. Data from observational studies increasingly show that tuberculosis disease severity (e.g. sputum smear grade [163, 164], haemoptysis, cavitation [163, 165–167], and drug resistance [167]), treatment failure, tuberculosis relapse, and death appear greater among those with tuberculosis and diabetes than those with tuberculosis alone. According to 2012 American Diabetes Association data, ~25% of all inpatient hospital stays are incurred by people with diabetes [168]. In a 2019 US study, infection-related hospitalizations were almost four times as high in adults with versus without diabetes, and as much as 15.7 times as high for some infection types [169]. Concerningly, between 2000 and 2015, increasing rates of sepsis, influenza, kidney infections, osteomyelitis, and cellulitis were observed in people with diabetes, and rates of pneumonia, foot infections, and mycoses declined in adults without, but not with, diabetes [169], highlighting the need for greater infectious risk mitigation in adults with diabetes, even in HIC. Covid-19 does not appear to be substantially more frequent in people with diabetes, but a large UK study reported that mortality risks for Covid-19 were doubled in type 2 diabetes and trebled for type 1 diabetes [170].

Economic costs of diabetes

Diabetes is an economically costly disease. In 2019, the global direct health expenditure of diabetes was estimated to be US \$760 billion, with the highest spending in the USA (\$294.6 billion), China (\$109.0 billion), and Brazil (\$52.3 billion). This spending is expected to grow substantially, with estimates projecting expenditures of \$825 billion by 2030 [171]. Also by 2030, 90% of the global expenditure for diabetes will be in the world's richest countries [172, 173], even though the majority of individuals with diabetes live in LMIC [1]. This exemplifies Julian Tudor Hart's [174] *inverse care law*, where 'the availability of good medical care tends to vary inversely with the need for it in the population served'.

Though staggering, these costs likely underestimate the true economic toll of diabetes, as associated cardiometabolic conditions, secondary complications of diabetes, and costs among people with undiagnosed diabetes are not included in overall estimates [175]. Persistent hyperglycaemia results in ~30% higher annual pharmaceutical costs, 70% higher laboratory and diagnostic costs, and 85% higher consultation costs compared with

well-managed diabetes [176]. Roughly, for every 1 percentage point (11 mmol/mol) increase in HbA_{1c} over 7% (53 mmol/mol), there is a 10% increase in related costs [177]. Given that the prevalence of undiagnosed diabetes is high globally, particularly in low-income countries (LIC), the true cost of diabetes remains underestimated [1, 53]. Finally, total diabetes costs should reflect costs associated with recommended lifestyle adaptations. For instance, the two-year cost of walking three miles daily is up to \$400, calculated by including the cost of time, exercise apparel and shoes, transportation, and gym memberships [178], and dietary modification costs make up 20% of the direct ambulatory care costs for people with diabetes [179].

For a chronic condition requiring long-term medical care, management plans of varying complexity, and screening and management of secondary complications, diabetes costs are multifactorial and complex. The total cost of diabetes reflects direct costs (costs of treatment and care including outpatient consultations, inpatient care, screening and diagnostic testing, therapeutic procedures, medications, and paramedical care as well as associated costs such as transport to appointments), indirect costs (lost economic productivity due to disability, morbidity or mortality due to diabetes), and intangible costs (costs associated with psychosocial impacts or altered quality of life).

Diabetes costs vary by both clinical and demographic characteristics. Although type 1 diabetes accounts for a relatively small proportion of the total cost of diabetes, the per capita cost is almost twice that of type 2 diabetes [180], likely driven by the need for more frequent consultations, universal use of insulin, and faster progression to retinopathy and nephropathy compared with type 2 diabetes [51, 181]. Among individuals with type 2 diabetes, coexisting hypertension and dyslipidaemia are a more significant component of total costs [175, 177]. Per capita diabetes-related costs are also higher for men than for women and among older age groups [182, 183].

Between-country comparisons of total diabetes costs are challenging. The approaches used to estimate economic costs of disease vary in terms of perspective taken (e.g. individual, society), methodology used, data sources, and year of estimation. Country-wide or region-wide costs are reliant on diabetes incidence and prevalence data, which may be uncertain, incomplete, or based on unstandardized data. Furthermore, different settings can vary widely in purchasing power and clinical patterns. For example, auxiliary services such as dieticians or home nursing are more likely to contribute to costs in HIC settings where these services are more widely available and used. Similarly, medication costs vary across settings due to drug costs and availability, and use of medications among those with diagnosed diabetes is markedly lower in LIC compared to HIC (29.6% vs 74.0%) [184].

Broadly, healthcare expenditure among those with diabetes is ~2–5.6-fold times that of the general population [168, 182, 185–187], although the patterns of spending and costs vary across settings. In HIC, these costs are largely driven by the high costs of complications and associated hospital care, while costs in LIC are largely driven by medication costs [175, 188, 189]. Medication spending accounts for 32–60% of total diabetes expenditures in countries such as Mexico, India, Pakistan, and Sudan [188]. The difference in country-level diabetes expenditure and total diabetes costs trickles down to households and individuals. In industrialized countries, availability of public or private insurance and financing of the healthcare system bears some or all of the cost of diabetes care, while in LMIC this cost is largely born

by the household. Out-of-pocket spending for diabetes ranges from 40% to 60% in LMIC [30, 107, 190, 191], and in LIC the cost of insulin can be as high as 65% of the total household income [184]. These costs can be catastrophic for the poorest individuals, with the lowest income groups paying the largest portion of their household income towards diabetes care [191, 192]. This added expense can lead to further poverty, less ability to access necessary care and medications, and further increasing risk of life-threatening complications [189]. On a national level, the economic impact of this is also greater in LMIC, where the burden of diabetes is highest among the individuals in the most economically productive age range (15–59 years) [193]. A higher burden among the working-age population can slow the economic development of transitioning countries, further decreasing the ability of these countries to slow disease progression [2]. The resulting spiral of disease and poverty exacerbates already marked disparities between HIC and LIC.

Socioeconomic costs of diabetes

In addition to medical or biological dysfunction, diabetes may impair a person's ability to perform domestic and occupational activities and restrict them from fully integrating into society. For example, those requiring insulin may be limited by highly structured activities of daily living (glucose monitoring, insulin administration, timed eating), recurrent hospitalizations, hyper- and hypoglycaemic episodes, and regular preventive or therapeutic medical visits. This is likely to be exacerbated in LMIC where access to insulin pumps, continuous glucose monitoring, and other technologies are not available. In the DAWN2 study, ~40% of participants reported that their medication interfered with their ability to live a normal life, and 57% reported that they were not working because of their disease [194]. Mental health burdens, such as depression, can also have a significant impact on workplace absence and/or poor productivity [195].

Given a large number of people with diabetes are of working age, particularly in LMIC, understanding the impact of diabetes on workforce productivity is of growing interest for employers and governments alike. Productivity loss in the workplace occurs because of absenteeism (absence from work due to illness) as well as presenteeism (reduced efficiency while at work) [196]. In the USA, as much as \$58 billion annually is lost to diabetes as a result of loss of earnings owing to unemployment, reduced work efficiency, permanent disability, and death [168]. For LIC, the impact of diabetes on workplace productivity is expected to be proportionally larger as premature deaths are more common, including among those of economically productive age [1].

One measure that is being increasingly used to describe the socioeconomic impact of diabetes is productivity-adjusted life years (PALYs), a novel measure developed to adjust the years of life lived for productivity loss attributable to diabetes, similar to the measure of quality-adjusted life years (QALYs) that adjusts for a reduction in quality of life [197]. For example, in Australia, diabetes reduces PALYs by 11.1%, equivalent to 1.4 PALYs lost per person, with the greatest impact on the youngest adults [197]. In Germany, mean PALYs lost per person with type 2 diabetes in 2020 were 2.6 years, with younger age groups and women expected to lose more PALYs compared with older age groups and men. Though this metric, to date, has not been reported broadly by many

countries, it represents a useful measure, in addition to QALYs, of the economic impact of diabetes on the broader society.

In addition to the workplace, diabetes can have a negative impact on individuals' interpersonal relationships. In the DAWN2 study, 20% of surveyed participants reported that diabetes had had negative impacts on their family and peer relations [194]. Some studies have also shown that people with diabetes have low levels of social integration (e.g. low contact with family) and support (e.g. living without a partner) [198, 199]. Strong social networks and good social support are associated with fewer psychosocial problems and better self-management among people with diabetes and should be considered as part of a multifaceted approach to diabetes care [195, 200].

One in five people with diabetes and their families experience some form of discrimination [194, 201]. The reasons for discrimination are varied; one involves perceiving that people with diabetes are using up societal resources [202]. As a result, stigma is common among people with diabetes and prevents them from disclosing their disease. For instance, adolescents with type 2 diabetes have reported hiding their diagnosis from their peers because they fear their reaction [203], and adults with diabetes have reported that disclosing their disease to their supervisors and colleagues would jeopardize their job [202] or, possibly, their educational opportunities or marital prospects [204, 205]. Owing to the stigma attached to type 1 diabetes, some parents choose not to disclose the condition of their child to relatives [205]. Use of insulin adds to the stigma, as people with diabetes report feeling mistaken for intravenous drug users [202, 203]. Societal stigma and discrimination are significant barriers to self-management and to improving care and social support for individuals with diabetes.

The individual and societal dysfunction associated with disability is difficult to quantify. Several methods have been used in attempts to quantify diabetes-related disability, but most suffer from at least some imperfection owing to the necessity for making judgements about the value of activities and subjectivity of responses. This is especially difficult where there are cultural and ideological dissimilarities between the evaluator and the population being appraised.

Gaps and future directions

Diabetes imposes serious health, social, and economic burdens worldwide. However, we still need more widespread and reliable data regarding burdens, access, and expenditures, especially in LMIC where the greatest burdens of diabetes occur. Few longitudinal studies are available in LMIC, thus limiting our understanding of incidence, risk factors, pathophysiology, variations in phenotypes, and natural history in these settings. In addition, studies are needed that include both long-understood and emerging complications of diabetes, such as cognitive function, to create better estimates of diabetes-attributable mortality, morbidity, and cost. Assessing burdens using reliable, consistent methods will aid our comprehension of the complex mix of programmed, predisposing, and modifiable factors associated with diabetes and lay a foundation for policy development and advocacy.

Despite varied estimates, the pattern is consistent: people with diabetes experience more symptoms, morbidity, comorbidities, and higher mortality rates than those without diabetes. They suffer diminished functional capacity and more psychosocial illness, and they incur greater costs for healthcare, self-care, and losses in earning potential and societal roles. Needless to say, intervening before diabetes onset may hold great benefit in reducing global burdens. However, although there is evidence from large trials demonstrating that prevention can forestall conversion from pre-diabetes to diabetes [206–209], widespread translation of these findings is hampered by multi-level barriers (political, social, cultural, behavioural, and economic factors). Preparation for the increasing diabetes burden requires progress in the wider collection of reliable data, collected in a standardized manner across various countries (especially assuaging the scarcity from LMIC regarding diabetes-related mortality, complications, disability, and costs), and a greater emphasis on cost-effectiveness studies that may inform better resource allocation [210]. On the shoulders of compelling evidence, greater investment and political will are required to overcome low accessibility and awareness, and also to translate the evidence into the practical, real-life implementation of proven and effective prevention strategies.

² Oslo Diabetes Research Centre, Oslo University Hospital, Oslo, Norway

³ Department of Public Health, University of Helsinki, Helsinki, Finland

⁴ National School of Public Health, Madrid, Spain

⁵ Diabetes Research Group, King Abdulaziz University, Jeddah, Saudi Arabia

Key points

- Type 1 diabetes develops in genetically susceptible individuals after a pre-clinical phase of variable length, usually with immune-mediated destruction of pancreatic β cells, and requires lifelong treatment with insulin.
- Type 1 diabetes can occur at any age, but the incidence peaks around puberty. Distinguishing between type 1 diabetes and type 2 diabetes becomes increasingly difficult with age in adults.
- In childhood, the incidence is not much different in girls and boys, but especially in high-incidence populations there is usually a male excess. There is a 1.3–2.0-fold male excess in incidence after the age of ~15 years in most populations.
- The incidence in childhood varies enormously between countries. Some Asian and American native populations have low incidences (<5 per 100 000 population per year), while Finland has the highest incidence, at around 60 per 100 000 population per year in 2006. Kuwait, Sweden, and Norway also have high incidences (>35 per 100 000 population per year). North America and Australia have moderate to high incidences, while eastern European countries have low to moderate incidences. Most European countries have incidences that have recently risen to 20 per 100 000 population per year.
- About 10–20% of children with newly diagnosed type 1 diabetes have an affected first-degree relative. Those with an affected sibling or parent

have a cumulative risk of 3–7% up to about 20 years of age, compared with a cumulative risk of 0.2–0.8% in the general populations. The cumulative incidence among the monozygotic co-twins of individuals with type 1 diabetes is less than 50%, even after >30 years of follow-up.

- Some of the geographical differences and familial aggregation may be explained by human leucocyte antigen (HLA) haplotypes.
- The incidence of childhood-onset type 1 diabetes has increased by 3–4% per calendar year, and there has been a tendency towards younger average age at onset over time. Finland and a few other countries seem to have experienced a plateau or decrease in incidence among children since 2005, but whether this is due to random variation need to be confirmed. The causes of the changing trends are unknown.
- Virus infections and nutritional factors have been implicated, but no specific environmental risk factor has been established.
- Even though insulin replacement therapy and other advances in the management of type 1 diabetes have improved the prognosis of people with type 1 diabetes, their mortality is still at least two times (~two- to eight-fold) higher than in the background population in high-income countries. This is because of both acute and chronic diabetes-related complications, including cardiovascular disease from the age of ~30 years. In low- and middle-income countries mortality in type 1 diabetes remains very high.

Type 1 diabetes in most cases results from an immune-mediated destruction of the pancreatic β cells due to an unknown cause leading to a lifelong requirement for insulin treatment. This occurs after a pre-clinical period of varying length when autoantibodies to insulin, glutamine acid decarboxylase (GAD), insulinoma-associated antigen 2 (IA-2), and other islet autoantigens can be detected [1]. These autoantibodies are markers of ongoing β -cell destruction, but are not thought to be pathogenic. Persistent positivity for two or more islet autoantibodies in early life is associated with a high probability of developing type 1 diabetes in genetically susceptible individuals – approximately half of such people develop type 1 diabetes within 5–7 years [2, 3].

Genetic factors influence the susceptibility to type 1 diabetes, particularly HLA genes (Chapter 12) [4, 5]. The combination of HLA class II haplotypes DR3-DQ2 and DR4-DQ8 confers a very high risk of type 1 diabetes, while those who carry only one of the two risk haplotypes have a moderately increased risk. Several other HLA alleles, including those in class I loci, further influence the genetic risk. More details on the role of genetic factors and the pathological process are covered in Chapter 14. Diagnosis of type 1 diabetes among children is usually relatively simple, typically with severe symptoms and marked hyperglycaemia, but classification and early detection of type 1 diabetes become increasingly difficult with increasing age.

Occurrence of type 1 diabetes by age, sex, place, and time

The World Health Organization (WHO) DIAMOND Study (Multinational Project for Childhood Diabetes) [6] and the EURODIAB ACE Study [7] have collected standardized incidence data for type 1 diabetes among children aged under 15 years, based on notification by the diagnosing physician and date of diagnosis, defined as the date of first insulin injection. In both projects, the degree of undercounting of cases has been estimated using a second source of information. Later, additional population-based incidence studies have been published from various countries [8].

Incidence rates are calculated as the number of new cases per 100 000 person-years. Person-years are typically estimated by the mean population size in each calendar year, sex, and age group. The proportion of the population expected to develop the disease by a certain age – that is, the cumulative incidence – can be approximated by multiplying the average incidence rate in an age group by the number of years covered by the age group. For instance, if the average incidence rate among 0–14-year-olds is 20 per 100 000 person-years, then approximately ($[20 \text{ per } 100\,000] \times 15 = 0.003 =$) 0.3% of children will develop disease before 15 years of age. Note that this corresponds closely to the prevalence at age 15 years (not accounting for mortality), while the prevalence in the age group 0–14 years will be substantially lower.

Most of the currently available incidence data come from studies of European children. Incidence data from Africa are still sparse, but increased information about the incidence of type 1 diabetes among Asian and South American populations has changed the understanding of the global patterns of variation in incidence [8].

Occurrence of type 1 diabetes by age

Type 1 diabetes may occur at any age and the incidence rate varies by age (Figure 4.1). Type 1 diabetes is not present at birth and is rare in the first two years of life. Onset of type 1 diabetes before 12 months, and even before 6 months, may occur in rare instances, but monogenic or syndromic forms should be suspected, as these represent a sizeable proportion of cases with diabetes diagnosed in this age group [11].

The incidence rate increases from age 6 months to peak at around 9–14 years, a common finding over time and across populations with different incidence rates [6, 9, 10, 12–16]. The incidence among 15–29-year-olds is lower than among 0–14-year-olds in most studied populations. In some populations there appears to be an additional rise in incidence after the age of ~25–30 years [17–19].

There are few population-based incidence studies for older age groups above 35 years of age and especially few covering the whole age range [16]. For many years, the only two sources of the latter were Minnesota, 1945–1969 [20], and a nationwide study from Denmark, 1973–1977 [21]. More recent data have been published from China 2010–2013 in a nationally representative sample of approximately 10% of the population [10] (Figure 4.1b) and Olmsted county, Minnesota [22]. In the Olmsted county study between 1994 and 2010, approximately half of the 233 individuals with incident type 1 diabetes developed the condition below 15 years of age, 25% between 15 and 30 years, and 25% after 30 years of age [22]. The corresponding proportions among the over 5000 individuals with incident type 1 diabetes in the Chinese study were 25% below 15 years, 33% among 15–29-year-olds, and nearly 40% after 30 years of age [10].

It may be difficult to distinguish type 1 diabetes from type 2 diabetes in some adults, especially after ~30 years of age. In the Swedish nationwide prospective incidence study of 15–34-year-olds, 78% of the newly diagnosed individuals were classified as having type 1 diabetes and 15% as having type 2 diabetes at the time of the diagnosis [23]. The follow-up showed that 92% of the individuals diagnosed before 30 years of age were treated with insulin later [24]. These findings are consistent with incidence data from Finland among people aged 15–39 years [25, 26]. In these studies, the incidence of type 2 diabetes exceeded that of type 1 diabetes after the age of ~30 years. By contrast, in Turin, Italy, which has a much lower incidence of type 1 diabetes, the incidence of type 2 diabetes is about three times higher than that of type 1 diabetes at the age of 30 years [17]. Although beyond the scope of this chapter, it is important to consider the possible clinical heterogeneity and increasing difficulty of classification of diabetes with increasing age. Some of the apparent heterogeneity may represent extremes along a continuum [27].

Incidence by sex

The peak in incidence rate among children occurs slightly earlier in girls than in boys (Figure 4.1a), suggesting an influence of puberty [9, 12, 22]. During the 1970s there was a male excess of type 1 diabetes in children in populations of European origin and a female excess in populations of African and Asian origin [28]; however, during the early 1990s the sex-specific pattern in incidence among children changed towards more modest differences. Only 6 of 112 centres with data during 1990–1999 showed a significant excess among females (Beijing, Hong Kong, and Zunyi in China; New South Wales in Australia; Puerto Rico and the Afro-American ethnic group in the USA), while 6 centres showed a significant male excess (West Bulgaria, Finland, Attica in Greece, Switzerland, Oxford in the UK, and the Dominican Republic), and all differences were generally of modest magnitude [6].

In young adults, there is a male excess in the majority of studied populations [16]. While the male-to-female ratio among children in most populations is 0.9–1.1 [6], the ratio among young adults ranges from about 1.3 up to 2.0 in many populations [15, 16, 29]. In the study of incident cases across all ages in China, the male-to-female ratio was 0.90 under the age of 15, but 1.35 after 15 years of age, directionally consistent with that seen in high-incidence countries [10].

Incidence by country

The incidence of type 1 diabetes among children shows a vast geographical variation worldwide, with high rates in the Nordic countries and Kuwait, and low in South-East Asia and parts of South America (Figure 4.2). During 1990–1999, the age-adjusted incidence rate of type 1 diabetes ranged globally from 0.1 in Zunyi (China) and Caracas (Venezuela) to 37.8 in Sardinia and 40.9 per 100 000 per year in Finland [6]. More recently, the highest recorded incidence of childhood-onset type 1 diabetes was ~60 per 100 000 in 2006 in Finland [30, 31].

Many European countries have robust type 1 diabetes registries, which demonstrate an approximately 10-fold difference between the highest- and lowest-incidence countries in Europe around the turn of the millennium [32]. A six- to eightfold difference within Europe has later been recorded after increasing incidence, with a majority of European countries showing rates of 20 per 100 000 per year or higher during 2008–2013 [7]. In general, the incidence is lower in eastern European than western and northern European countries.

Data in people aged 15–29 years in European centres (in Belgium, Lithuania, Romania, Sardinia, Slovakia, Spain, Sweden, and the UK) showed incidence rates between 5 and 12 per 100 000 per year during 1996–1997 [15]. Incidence rates among 15–29-year-olds within this range have also been reported, albeit from earlier time periods, in other European centres, such as 5.5 per 100 000 year in Rzeszow, Poland, 1980–1992 [33]; ~7 per 100 000 per year in Turin, mainland Italy 1984–1991 [17, 34]; and ~13 per 100 000 per year in two regions of Denmark, 1970–1976 [35]. While Sweden and Sardinia have higher incidence rates among children, the incidence rate among young adults was not much higher in Sardinia and Sweden than in the other centres in the multicentre study [15]. Older data from Norway (1978–1982) [14] indicated a higher incidence rate of 17 per 100 000 per year and more recent data from

Finland (1992–2001) [25] reported an incidence rate of 18 per 100 000 per year among 15–29-year-olds. Recent data on new users of insulin (and no other anti-diabetes drugs) indicated stable incidences over 30 per 100 000 per year among individuals aged 5–29 years in Norway during 2006–2010 [36]. In addition to problems with correct classification of type of diabetes in adults, incomplete ascertainment may also be a greater problem for young adults than among children [37], while incomplete ascertainment is not a likely problem with the insulin use data. Differences between countries in the incidence among young adults should be interpreted with caution until more data are collected using comparable methodology.

The USA is represented in the DIAMOND project with the data collected during the 1990s from Allegheny County in Pennsylvania,

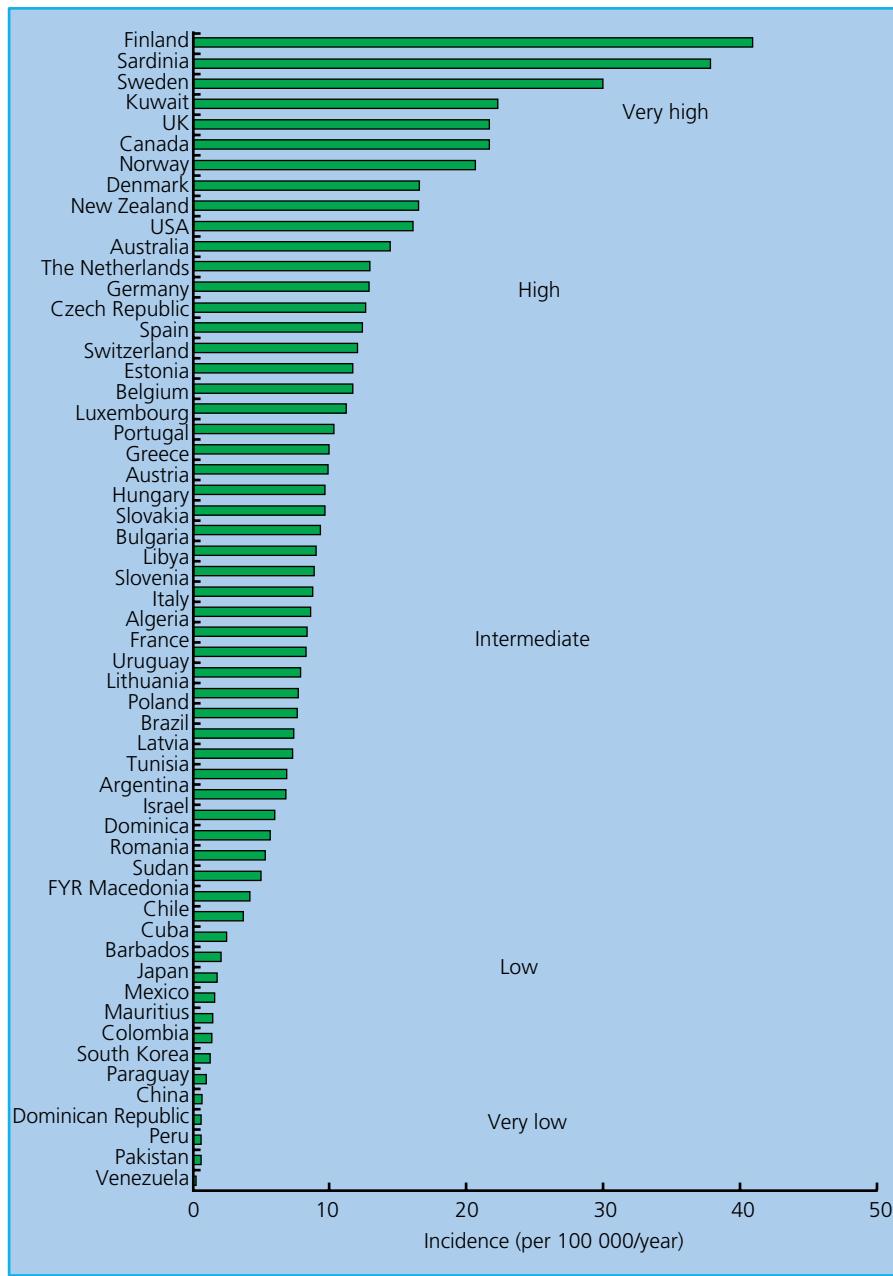

Figure 4.2 Geographical variation in childhood-onset type 1 diabetes incidence rates, 1990–1999. Most registries were not nationwide and several countries display within-country variation.

Source: Reproduced from the DIAMOND Project Group 2006 [6] with permission from John Wiley & Sons Ltd, Chichester.

Chicago, and Jefferson County in Alabama, with incidence rates in the range 11–18 per 100 000 per year among children. Newer data from the USA from around 2000–2017 have suggested an incidence of ~20 per 100 000 per year [38–40]. Alberta and Calgary in Canada had slightly higher rates (~23 per 100 000 per year; Figure 4.2) [6], while the data from the Avalon Peninsula, Newfoundland, indicated a higher incidence rate of 35.9 per 100 000 per year [41].

In South America, children in centres in Venezuela, Paraguay, and Colombia had incidence rates of less than 1 per 100 000 per year; Chile (Santiago) had ~4 per 100 000 per year; while Argentina and Brazil had an average of ~8 per 100 000 per year. Data from Argentina and Brazil came from populations with a low proportion of Indigenous Indian populations, whereas the other countries had

a significant proportion of Indigenous people. Many centres in Central America and the West Indies (except Puerto Rico and St Thomas's) generally have low to intermediate incidence rates [6].

Data from New Zealand and parts of Australia show moderate to high incidence rates (15–25 per 100 000 per year) among children [6]. Data from other Pacific Island countries are lacking and would be difficult to interpret because the populations in most island countries are small. In Asia, the mean incidence rate among the 23 centres in China during the early 1990s was 0.8 per 100 000 per year. In a recent study in China, the incidence varied between 1.2 and 3.6 [10]. Kuwait had a dramatic increase in incidence from 17.7 in 1992–1994 to a rate of 40.9 per 100 000 per year in 2011–2013 [42].

There is limited information on the incidence rate of type 1 diabetes from sub-Saharan Africa [43]. The five DIAMOND centres

were in North Africa (Algeria, Libya, Sudan, and Tunisia) and Mauritius. Incidence rates reported from these centres ranged from low to intermediate, but these countries cannot be said to be representative of all of Africa. Additional incidence data from other regions are discussed in later sections.

Trends in incidence over time

Most countries have experienced an increasing incidence of type 1 diabetes among children over recent decades, with differences in time trends between countries and calendar periods (Figure 4.3).

The methodology for population-based incidence registries was not standardized until the late 1980s, but several older data sources have been reviewed to assess possible time trends. There is a general impression that the incidence of type 1 diabetes increased markedly after the middle of the twentieth century [55, 56], although in Denmark the incidence among 0–29-year-olds seemed stable from 1924 to the 1970s [35]. An analysis of incidence trends of more standardized registry data from 1960 to 1996 in 37 populations worldwide showed a significant increase in incidence rates over time in the majority of populations, with a steeper relative increase in low-incidence than in high-incidence populations [57].

In the 103 centres participating in the WHO DIAMOND project for at least three years during 1990–1999, the overall relative increase in incidence rate was 2.8% per year [6]. By continent, overall increasing trends per year were estimated at 5.3% in North America, 3.2% in Europe, and 4.0% in Asia [6]. The only region with an overall decreasing trend was Central America and the West Indies [6].

In general, the increasing trend appeared to be most marked in the centres with high and very high incidence rates during the

1990s. In the centres with low and very low incidence rates, there were no significant increases in incidence rates over time. However, the time trends in Europe reported to EURODIAB for 1989–2013 indicated an overall mean increase in incidence rate of 3.4% per year, with a tendency towards bigger relative increases in the countries with the lowest average incidence rates during the initial years of registration [7].

A smaller relative increase in incidence rate over time among older individuals than among younger ones has been seen in some European studies covering wider age ranges [9, 18, 19, 58, 59]. This latter observation is in line with a model where a certain pool of genetically susceptible individuals develop diabetes at younger ages [9, 18, 60]. The few available data, however, are not entirely consistent with this idea. An increasing incidence rate has also been seen among older age groups in some populations [19, 26, 34], but the lack of standardized incidence data covering the whole age range makes it difficult to draw firm conclusions. Despite the time trends indicated in Sweden with decreasing average age of onset, the peak incidence rate remained around the age of puberty [9].

While a greater relative increase over time among 0–4-year-olds than among 10–14-year-olds was seen in European children during 1990–1999 in the DIAMOND project, this was not seen in Asia and North America [6]. More recent data from Europe show that the relative increase over time has been similar across age groups in the long run [7]. The recent declining incidence in Finland and Australia (discussed shortly) was seen for 0–14-year-olds overall, but was most marked among children aged 0–4 years [31, 61].

In Finland, the incidence rate increased linearly from the mid-1960s to the mid-1990s [44] and thereafter even more steeply,

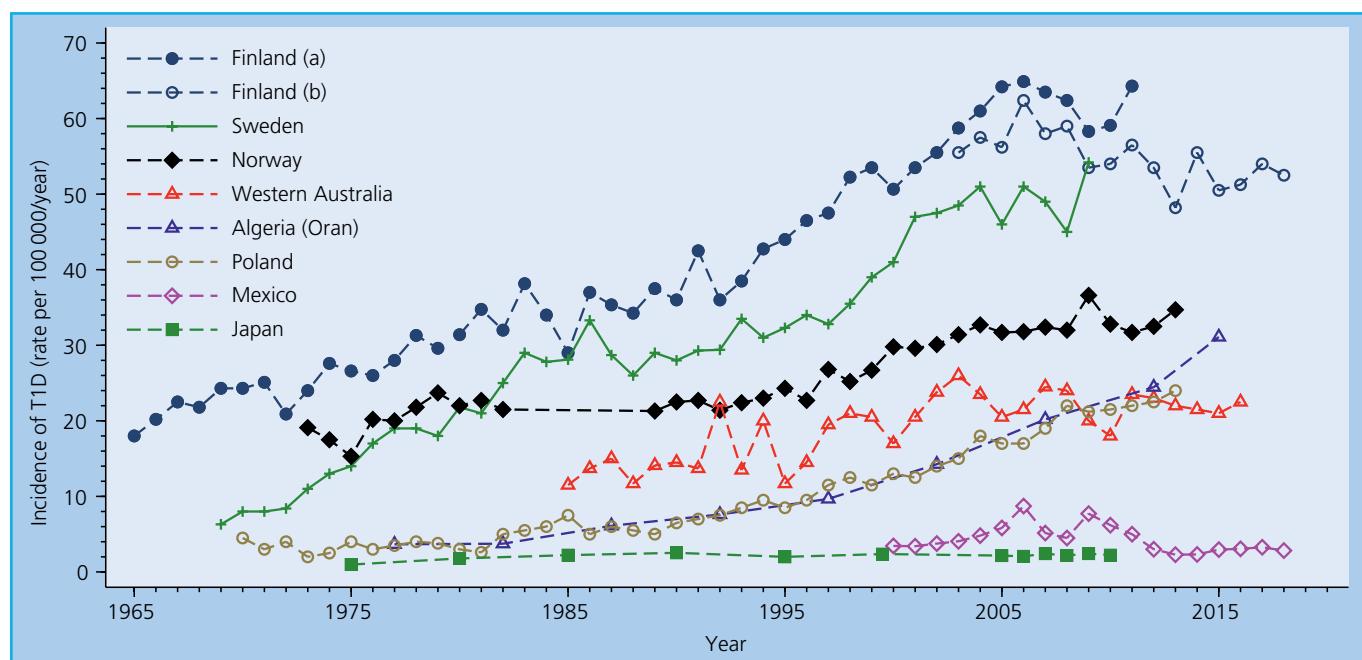

Figure 4.3 Long-term time trends in incidence rate of type 1 diabetes (T1D) in children in selected countries. Source: Data for Finland (a) are from Tuomilehto et al. 1999 [44] for 1965–1979, Harjutsalo et al. 2013 [45] for 1980–2006, and (b) from Parviainen et al. 2020 [31] for 2003–2018. Swedish data are from Husseen et al. 2013 [46], Norwegian data are from Joner and Søvik 1989 [47] and

Skrivarhaug et al. 2014 [48]. Data for Western Australia are from Haynes et al. 2018 [49], Algerian data from Niar et al. 2015 [50], Polish data from Chobot et al. 2017 [51], Mexican data from Wacher et al. 2019 [52], and Japanese data for 1973–2001 from Kawasaki et al. 2006 [53] and for 2005–2012 from Onda et al. 2017 [54].

reaching almost 60 per 100 000 per year in 2006. After a peak in 2006, the incidence among children in Finland seems to have plateaued [45] and decreased [31] (Figure 4.3). In Sweden, data from the Swedish Childhood Diabetes Register suggested a possible plateau in incidence in 2006 [62], but other register data showed a continued increase up to 2009 [46]. Furthermore, Germany [63], Israel [64], the USA [65], Yorkshire, UK [66], and Shanghai, China [67] are examples of countries or areas with a continuing rise in incidence up to recent years.

In Western Australia (Figure 4.3) there was an increasing incidence from 1985 to around 2000–2002 when the incidence plateaued until 2016 [49]. Nationwide data showed a declining incidence between 2002 and 2017 [61]. Superimposed on these trends in Australia, there has been a cyclical pattern with approximately 3–5-year cycles [49, 61].

Cyclical patterns have been observed elsewhere, but there does not seem to be a general pattern [7]. In Norway, there was a plateau in the type 1 diabetes incidence from 2004 to 2012 [48], but the incidence rose up to 2013 and the overall pattern is consistent with a long-term increase [7]. When stratified by sex and age groups, the year-to-year variation in most studies becomes large and trends should be interpreted with caution. From the observed long-term trends (Figure 4.3), reliable predictions of incidence more than a few years into the future are difficult.

Variation in incidence within countries including by ethnicity

In several countries, marked within-country variations in the incidence of type 1 diabetes have been reported, even in relatively homogeneous populations. There is also marked ethnic variation, generally in line with the differences in countries or regions already discussed, and some geographical differences may be in part due to differences in the distribution of ethnic groups. Potential methodological problems should be considered when making inferences based on epidemiological studies of different ethnic groups and immigrants. These include differential ascertainment and definition of ethnic group, underestimation of the base population in some ethnic groups, genetic admixture, and possible heterogeneity in clinical presentation [68, 69]. Among childhood-onset cases, however, it seems that the large majority, even in Japan [53], have classic autoimmune type 1 diabetes.

Historically, the incidence of type 1 diabetes has been higher in populations of European origin, particularly those living in Europe, than among populations of non-European origin [68, 70]. The incidence rates of type 1 diabetes in most South American studies with standardized registries seem to be much lower than among Latino people in the USA and lower than the incidence rate of Spaniards living in Spain [68]. Data from the USA show clear ethnic differences in incidence and time trends for type 1 diabetes among youths during 2002–2015 (Figure 4.4). The highest incidence was among white youths (25–27 per 100 000 per year), while Black and Hispanic youths had similar rates, around 15–17 per 100 000 per year by 2010, and among Black youths the rate increased more sharply to nearly 20 per 100 000 in 2015 [38]. Asian Pacific Islanders and American Indian youths had a much lower incidence at ~5–10 per 100 000 per year. Other studies have indicated that the differences in incidence among ethnic groups in the USA are less dramatic, at least for some groups in some regions [6, 70]. Many ethnic groups in the USA have considerable admixture with people from European ancestry that may dilute potential differences between ethnic groups.

Data are from the SEARCH study – in geographically defined populations in Colorado, Ohio, South Carolina, Washington, and Kaiser Permanente Southern California health plan enrollees. API denotes Asian and Pacific Islanders; AI denotes American Indians.

Up to 1.5-fold differences in incidence have been described among regions within Finland, Sweden, and Norway [71–73]. In Italy during 1990–2003, the incidence rate among children varied from approximately 40 per 100 000 per year on the island of Sardinia, to 11–19 per 100 000 per year in regions of northern (mainland) Italy, and 8–12 per 100 000 per year in the central-southern part of mainland Italy [74]. Sardinia's population history is different to that of the rest of Italy. Children born in families who moved to mainland Italy from Sardinia kept their high type 1 diabetes incidence [75]. In New Zealand, the 1.5-fold higher incidence among children in the South Island compared with that in the North Island was largely explained by the 4.5 times higher incidence among children of European origin compared to that among Maoris, whose proportion is higher in the North Island [76]. In China, there was a 12-fold geographical variation (0.13–1.61 per 100 000), generally with higher incidence in the north and the east. In addition, there was a sixfold difference between the Mongol (1.82 per 100 000) and Zhuang (0.32 per 100 000 per year) ethnic groups [77]. In the nationally representative 10% sample of the Chinese population studied during 2010–2013, there was a 3.6-fold variation in incidence among 13 large regions, ranging from 3.6 in Harbin to 1.19 in Shanghai [10].

Considering immigrants as a single group, the time trends in incidence differed significantly from ethnic Swedes from the late 1980s onwards [46]. In Israel, there was a parallel increase over time, but consistently lower incidence in childhood-onset type 1 diabetes among non-Jews (mainly Palestinians) than among Jews

during 1997–2010 [64]. There also seemed to be a systematically lower incidence among South Asian than among non-South Asian children in Yorkshire [66]. The incidence of type 1 diabetes among children of immigrant parents in Germany, Sweden, and mainland Italy correlates with the incidence in the country or region of origin of their parents, whether the incidence in the country of origin was higher or lower [75, 78, 79]. The incidence among immigrants from Pakistan to the UK (or their children), however, was similar to that among the native Britons [80, 81], despite the very much lower incidence recorded in Karachi, Pakistan [6].

In summary, although there are clear ethnic differences in the incidence of type 1 diabetes and strong evidence for a role of genetic factors, some of the studies mentioned also suggest a possible role for yet unidentified environmental factors.

Seasonal variation in diagnosis of type 1 diabetes

Several studies have reported a peak in the number of cases diagnosed in the autumn and winter, and a smaller proportion of cases diagnosed in the spring or summer, consistent in both the northern and southern hemispheres [13, 32]. Although reasonably consistent, there is some variation in exact peak and nadir between countries, age groups, sexes, and periods. Generally, the degree of seasonal variation is stronger among those diagnosed at age 10–14 years than in younger children (Figure 4.5) [32]. Different methods have been used in the analysis of seasonal variations, and often with data covering relatively short periods of time and a limited number of cases; the results are therefore not necessarily comparable. Interpretation of seasonal variation must be carried out in light of the long and variable pre-clinical period in type 1 diabetes, and it is speculated that viral or other periodic factors

have a role in the timing of the precipitation or onset of the disease in susceptible individuals who would develop it sooner or later.

Familial clustering and twin studies

Besides providing clues regarding the relative importance of genetic and non-genetic factors in the aetiology of disease, data on risk of type 1 diabetes among people with affected relatives may also aid the clinician in counselling family members of newly diagnosed individuals. Around 80–90% of persons with newly diagnosed type 1 diabetes do not have any affected siblings or parents, but first-degree relatives of a person with type 1 diabetes are at increased risk. By the age of 20 years, approximately 4–6% of siblings of type 1 diabetes probands develop type 1 diabetes in European-origin populations [82–84], compared with around 0.2–1.0% in the corresponding background populations. The offspring of affected fathers have a 1.5–3 times increased risk of type 1 diabetes compared with the offspring of affected mothers [85, 86]. By 20 years of age, 5–8% of the offspring of men with type 1 diabetes, but only 2–5% of the offspring of women with type 1 diabetes, are affected. There is currently no accepted explanation for this phenomenon.

Given the well-established effect of genetic factors, it is no surprise that the concordance rate for type 1 diabetes in monozygotic twins is much higher than that in dizygotic twins [87, 88]. In one study from North America, the cumulative risk 10 years after onset in the proband (diagnosed before age 40 years) was ~25% in monozygotic twins and ~11% in dizygotic twins [89]. Corresponding 10-year cumulative risks from Finland were estimated as 32% for

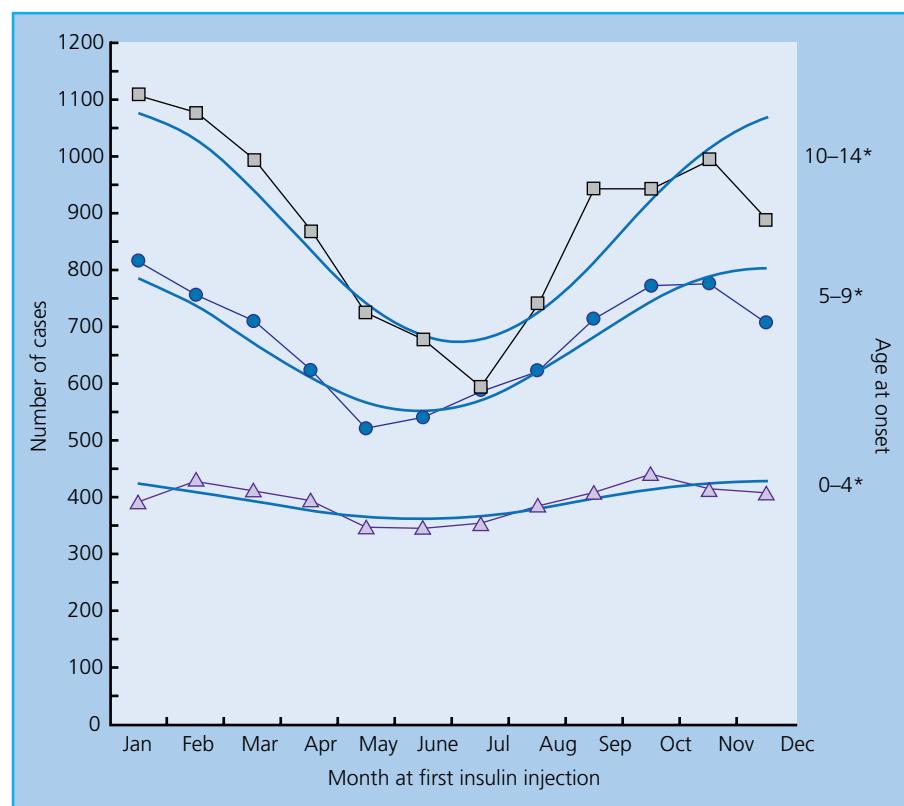

Figure 4.5 Seasonal variation in diagnosis of type 1 diabetes among >22 000 children diagnosed 1989–1998 in European centres, by age at onset. *Age (years) at first insulin injection. Source: Reproduced from Green and Patterson 2001 [32], with permission from Springer-Verlag.

monozygotic twins and 3.2% for dizygotic twins [88]; comparable estimates were also found in the Danish twin registry, although the exact age at onset was unknown [87]. In general, the risk for the co-twins was higher and the discordance time shorter the earlier the type 1 diabetes diagnosis in the proband [88–90]. In a long-term follow-up of discordant monozygotic twins from the USA and the UK, more than 50% of monozygotic pairs remained discordant for type 1 diabetes (Figure 4.6) [90]. Because monozygotic twins share 100% of their genomic DNA, this suggests that genetic susceptibility alone is in most cases insufficient for the development of disease.

Despite the relatively high proportion of monozygotic twins being discordant for clinical type 1 diabetes, many of the co-twins without diabetes of individuals with type 1 diabetes develop islet autoimmunity [91]. Together with the limited variation in prevalence of positivity for islet autoantibodies between countries [60] and animal studies suggesting a two-stage disease process [92], this supports the idea that environmental factors may have an important role in the progression from islet autoimmunity to overt disease.

Environmental risk factors for type 1 diabetes: clues from epidemiological studies

The time trends described earlier must be ascribed to changes in the environment, even in the event that the increase is brought about by a change in the age distribution. Some of the variation in incidence rates between European countries can be explained by differences in the frequency of HLA susceptibility genotypes [93], but not all [94]. The proportion of people with newly diagnosed type 1 diabetes who carry the highest-risk genotype (DR3-DQ2 per DR4-DQ8) has decreased over three to four decades, while moderate-risk and low-risk genotypes have become more common among those with type 1 diabetes [95]. It may be speculated that

increased exposure to some risk factor or decreased exposure to some protective factor has caused more individuals with moderate-risk (*permissive*) genotypes (e.g. either DR3-DQ2 or DR4-DQ8, but not both) to develop type 1 diabetes in recent years. Although there is overwhelming evidence for an essential role of genetic factors in the aetiology of type 1 diabetes, available evidence strongly suggests that some yet unknown non-genetic factors are also involved.

In general, environmental factors may be envisioned to have a role in:

- Initiating the autoimmune disease process;
- Modulating the progression from islet autoimmunity to clinical type 1 diabetes; or
- *Precipitating* disease in individuals with advanced pre-clinical disease.

Little is known about the initiation of autoimmunity in humans, but breakdown of immunological self-tolerance is thought to be involved. An incidence peak in islet autoimmunity in the second year of life and early seroconversion for islet autoantibodies among children who develop type 1 diabetes suggest that potential environmental factors can operate very early in life [96]. Limited geographical variation in the prevalence of islet autoimmunity despite the large differences in incidence of type 1 diabetes between countries suggests that environmental factors may influence the progression from islet autoimmunity to type 1 diabetes [60]. However, this is difficult to reconcile with the observation that in the long run, most children with multiple autoantibodies go on to develop type 1 diabetes [2]. Geographical differences in the prevalence of advanced islet autoimmunity can be confounded by the fact that prevalence is influenced by both incidence of islet autoimmunity and rate of progression to type 1 diabetes. The multinational TEDDY study investigated both. With standardized recruitment of children with increased genetic risk, there were modest differences in both incidence of islet autoimmunity and progression from autoimmunity to type 1 diabetes between Finland,

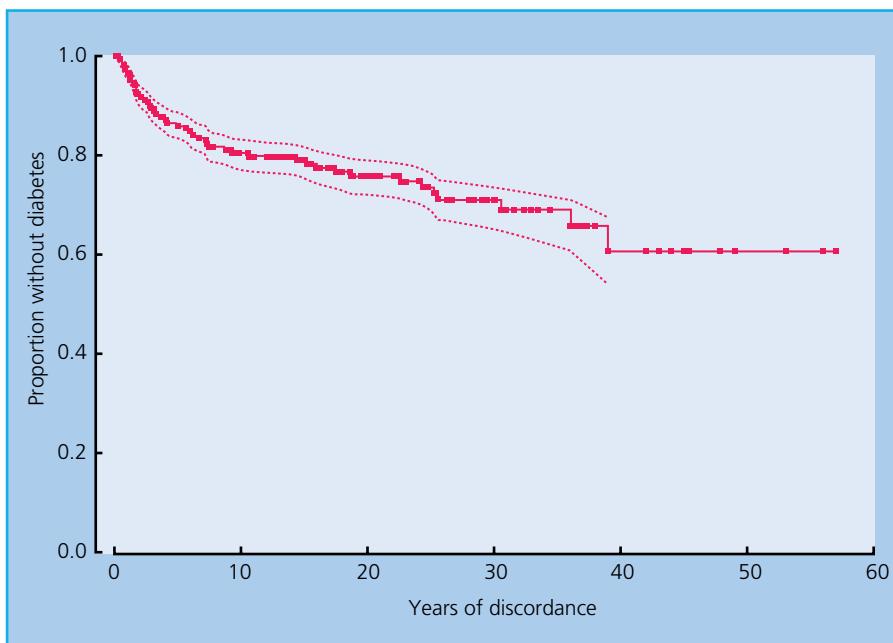

Figure 4.6 Diabetes-free survival in monozygotic twins without diabetes whose co-twin had type 1 diabetes, after several years of follow-up. Dotted lines represent 95% confidence intervals. Source: Reproduced from Redondo et al. 2001 [90], with permission from Springer-Verlag.

Germany, Sweden, and the USA [3, 97]. *In vitro* experiments have suggested that active insulin-secreting β cells hyperexpress islet autoantigens such as GAD and are more susceptible to toxic effects of the cytokine interleukin-1 β [98]. It may be speculated that factors that increase the stress on β cells may non-specifically contribute to the precipitation of clinical disease [98]. This includes insulin resistance or other mechanisms implied in infections, puberty, and growth spurts. Insulin resistance is difficult to measure reliably in children, but measures of insulin resistance relative to first-phase insulin response during an intravenous glucose tolerance test are predictive of progression to type 1 diabetes [99]. A 2020 review found that among the potential aetiological factors studied so far, no single factor has been convincingly associated with risk of type 1 diabetes with a magnitude of association and changing exposure pattern over time compatible with explaining the changing epidemiology of type 1 diabetes over the past decades [100]. More likely, several factors combine to explain the changing incidence, or yet unknown factors are responsible. Methodological problems such as measurement errors, confounding, and selection bias should also be kept in mind when reviewing aetiological studies.

Specific putative environmental factors

Microbes

There is a large body of literature linking infections and type 1 diabetes, including plausible mechanisms involved, but the link has not been unequivocally established as causal in humans [101–103]. Studies vary in design, from *in vitro* studies [104], experiments with various animal models [105], studies of individuals with disease including of pancreatic tissue [104, 106–109], and epidemiological case-control and cohort studies [13, 110–112]. Congenital rubella syndrome has been associated with a several-fold increase in the incidence of type 1 diabetes [113]. Although not contributing to the incidence of type 1 diabetes in most countries today because of vaccination, this observation has been cited as a proof of principle that intrauterine factors and viral infections in general can influence the risk of type 1 diabetes in humans. However, the consistency of the available evidence and the absolute risk of type 1 diabetes associated with congenital rubella may have been overstated [114, 115].

Several early studies based on assays for antibodies to enteroviruses in cases with type 1 diabetes and controls initially seemed promising, but systematic review of the data showed too much heterogeneity in methodology and results to draw any firm conclusion [110]. Prospective study design and detection of enterovirus RNA represent important contributions to the methodology of such studies in recent years, but a careful review of available data shows that they are not consistent across studies [112].

Increased risk of childhood-onset type 1 diabetes has been associated with evidence of maternal enterovirus infections during pregnancy in some studies, but not in all [112, 116]. Using both serum enterovirus antibodies and RNA as indications of postnatal infection, prospective studies did not find consistent associations between enterovirus and islet autoimmunity [112]. Earlier studies suggested that the presence of virus particles in the blood was more strongly correlated to type 1 diabetes than their presence in the stool [111, 112, 117]. A recent analysis of the DIPP study from Finland reported an association between faecal enterovirus shedding and the later risk of islet autoimmunity [118]. The multinational TEDDY study found that long duration of faecal shedding of

enterovirus B was associated with a higher risk of islet autoimmunity, but not with type 1 diabetes [119]. Recently, metagenomics approaches with next-generation sequencing of the virome have been used in epidemiological studies of islet autoimmunity or type 1 diabetes, but they have been small, methods have varied, and they have suggested at best only weak associations, mostly with enteroviruses [120].

An immunohistochemical study of stored sections of pancreatic biopsies obtained post mortem in young individuals with recent-onset type 1 diabetes found that the β cells of multiple islets stained positive for enterovirus capsid protein VP1 in 44 of 72 cases, while few controls stained positive [108]. This study substantiated previous evidence based on a few individuals [106, 107] and indicated problems with the methods used in a previous study where no such evidence was found [121]. Based on early data [106], the coxsackie B4 serotype of human enterovirus has been suspected to be particularly diabetogenic. Technical difficulties in the detection and interpretation of low quantities of virus particles remain, but a recent study found signs of enterovirus by multiple techniques and in different labs, in fresh pancreatic tissue obtained from six young adults with newly diagnosed type 1 diabetes [109]. Recently, application of serotype-specific neutralizing antibody tests to the prospective DIPP study suggested a novel association between the coxsackie B1 serotype and risk of islet immunity [122]. In this study, there tended to be an inverse association between coxsackie B4 and risk of islet immunity [122], an association in the opposite direction to what has been suggested in other studies.

The so-called *hygiene hypothesis* comes in different versions, but essentially proposes that reduced microbial exposure in many populations over the past few decades has caused a concomitant increase in incidence of immune-mediated diseases, including type 1 diabetes [123]. Some infections and microbial agents reduce the incidence of autoimmune diabetes in experimental animals [124]. Epidemiological studies have investigated non-specific infections and infectious symptoms, but the results have been inconsistent. Daycare attendance is usually associated with increased exposure to microbial agents, and a recent meta-analysis concluded that there is some evidence for a lower risk of type 1 diabetes among children who attended daycare centres early in life, although the results were not sufficiently homogenous to allow a strong conclusion [125]. Enterovirus infections are common and the frequency of infection has decreased with improved hygiene in recent decades, opposite to the trend seen for type 1 diabetes. It has been postulated that the increasing incidence of type 1 diabetes in children may in part be explained by decreased protection from maternal enterovirus antibodies [126]. A direct test of this hypothesis is still lacking. Antibiotics modify the gut microbiota at least temporarily. However, use of antibiotics is also a proxy for infections, and infections themselves may influence immunity and the composition of the microbiota. Most large studies have not found any consistent association between use of antibiotics in childhood or by pregnant women and subsequent risk of islet autoimmunity or type 1 diabetes [127–134]. However, a weak but significant positive association was found in a study from Sweden [135], and for broad-spectrum antibiotics in a Danish study [129], with relative risks of around 1.1–1.2, but stronger in children born by caesarean section. The gut microbiota is excessively complex and has been hypothesized to influence type 1 diabetes based on relatively small studies [136]. The largest prospective study in the field found few or no significant

differences between cases of islet autoimmunity or type 1 diabetes and controls [137, 138].

Regular childhood vaccinations are not associated with risk of type 1 diabetes, although this is a challenging research question in case–control or cohort studies in populations where the large majority of infants are vaccinated [139]. While rotavirus is a common cause of early childhood gastroenteritis, vaccinations against this pathogen were introduced in many countries in the 2000s. Comparing birth cohorts before and after the introduction, an association with type 1 diabetes was not seen in Finland [140], but a suggestive inverse tendency was reported from Australia [141] and the USA [142]. A randomized trial of rotavirus vaccination in Finland with later follow-up for type 1 diabetes in a subset of participants did not find any significant difference in the incidence of type 1 diabetes [143].

To summarize, there are many promising observations on microbes. However, the current evidence that infections have an important and causal role in human type 1 diabetes is inconclusive. Designing a vaccine that covers the relevant type or types is challenging, but work on an enterovirus vaccine is in progress [144]. Others have suggested it may be possible to develop a vaccine that can reproduce the potential beneficial effects of virus infections (cf. the hygiene hypothesis) regardless of the existence or identification of one or a few diabetogenic viral serotypes [124]. It has been hypothesized that Covid-19 may increase the risk of type 1 diabetes. The future will bring more data on the topic, but at least some countries experienced a higher incidence of type 1 diabetes during the Covid-19 pandemic than in earlier years [145]. Three nationwide studies based on complete population register linkages, each with over one million children and adolescents, have investigated the potential association between a positive SARS-CoV-2 polymerase chain reaction (PCR) test and risk of type 1 diabetes 30 or more days later in the period 2020 to early 2022. No significant association was reported in Scotland (hazard ratio [HR] 0.86, 95% confidence interval [CI] 0.62 to 1.21 for 0–34-year-olds and consistent results in those <16 years old [146]) and in Denmark (HR 0.85, 95% CI 0.70 to 1.04 [147]). In Norway, there was a significantly increased risk (HR 1.63, 95% CI 1.08 to 2.47 in <18-year-olds [148]). The reasons for the discrepant results are unclear, but it is important to note that the absolute risk of type 1 diabetes after SARS-CoV-2 infection was low (0.13% in the infected vs 0.08% in those with no registered infection). Future studies and longer follow-up will likely provide more answers.

Toxins and environmental chemicals

Several environmental chemicals may influence the immune system and potentially the risk of type 1 diabetes [149]. The rodenticide Vacor has been associated with type 1 diabetes in humans after ingestion of large doses [150]. There are structural and mechanistic similarities between Vacor and streptozotocin and alloxan [150]. Some epidemiological studies have assessed intake of nitrates and nitrites, which may be converted to N-nitroso-compounds, but most studies have used ecological study designs and assessed levels in community drinking water, which is probably a poor indicator of total exposure. In a case–control study nested within a cohort of pregnant women, persistent organochlorine pollutants in stored sera were not associated with later risk of type 1 diabetes in the offspring [151]. If anything, there was a tendency towards an inverse association. More recent studies have also attempted to link air pollution and various environmental chemicals to risk of type 1 diabetes, although the

evidence remains inconclusive [152]. In conclusion, few high-quality studies are available on the potential influence of environmental chemicals on type 1 diabetes incidence in the population, and there is currently little direct evidence for an important involvement of such factors in human type 1 diabetes.

Nutritional factors

Several possible plausible mechanisms have been proposed to link dietary factors to type 1 diabetes, including *molecular mimicry* and a detrimental effect of bovine insulin in cow's milk [153].

Infant feeding

A reduced risk conferred by prolonged breastfeeding or delayed introduction of cow's milk has been suggested in many case–control studies, but most of these studies were susceptible to recall bias and the issue is controversial [154]. Large prospective studies have found no clear association between the duration of exclusive or total breastfeeding and risk of islet autoimmunity or type 1 diabetes [155–157]. It is difficult to differentiate the role of the duration of breastfeeding versus the time of introduction of weaning foods in observational studies. However, the TRIGR trial tested the hypothesis that delaying the introduction of intact cow's milk proteins (regardless of breastfeeding duration) prevented type 1 diabetes, although it did not show any efficacy [158].

Vitamin D

The immunomodulatory effects of vitamin D and preventive effect of high doses of vitamin D on diabetes development in experimental animals have been documented with early intervention [159]. The consensus among large-scale human studies linking maternal or newborn vitamin D status (circulating 25-hydroxyvitamin D) to the risk of type 1 diabetes in the offspring is now that there is no association [160–162]. For vitamin D status in early life, despite mixed results from previous smaller studies, recent longitudinal studies in high-risk cohorts have linked higher levels with a slightly lower risk of islet autoimmunity or type 1 diabetes [163, 164]. However, a large Mendelian randomization study did not find any significant association between vitamin D status and type 1 diabetes, providing some evidence against a causal relation between the two [165].

In summary, the causal role of nutritional factors in the aetiology of type 1 diabetes remains uncertain.

Perinatal factors and postnatal growth

Offspring of mothers without diabetes aged 35 years or more when giving birth have an approximately 20–30% increased risk compared with offspring of mothers who are 25 years or less [166, 167]. Results for birth order and for paternal age have not been consistent [166, 168, 169]. Birth by caesarean section was recently associated with an approximately 20% increased risk of type 1 diabetes in children according to a meta-analysis of 20 published studies [170]. Although there is some potential for selection bias in the case–control studies, and the mechanism is unknown, it was speculated that delayed colonization of the infant's intestine associated with caesarean section may be involved. On the other hand, a recent study of discordant sibships did not find any association between caesarean section and type 1 diabetes [171].

Increased birth weight has been associated with a relatively weak but significant increase in risk of childhood-onset type 1 diabetes in

large-cohort studies based on linkage of population registries, independent of maternal diabetes and other potential confounders [172]. There are also studies reporting no significant association, but these were generally smaller case-control studies. Birth weight is certainly only a marker of some other phenomenon and the mechanisms involved remain to be defined.

Associated factors such as postnatal growth or excess body weight might be of relevance. Studies have indicated that children developing type 1 diabetes are taller, heavier, or gain more weight or height prior to diagnosis compared to their peers [173]. However, there was substantial heterogeneity between studies in methodology and results, such as age at measurement of body size, which body size or growth measurement was associated with type 1 diabetes, and how data were analysed statistically. Many of the published studies were case-control studies, which are prone to selection bias, although a large Mendelian randomization study found evidence for a causal effect of childhood body mass index on risk of type 1 diabetes [174]. Also, two recent large-scale cohort studies found that for each standard deviation (approximately 1 kg) increase in weight or weight gain up to age 12 months, the risk of type 1 diabetes [175] or multiple islet autoantibodies [176] increased by approximately 20%.

In summary, environmental factors may influence individuals differently, depending on the genetic background, although direct evidence for specific gene-environment interactions from humans is scarce. No specific environmental factor has been identified thus far. Taking into account the multifactorial nature of type 1 diabetes, specific environmental risk factors with sufficiently large impact to be of clinical importance and detectable in epidemiological studies may not exist. However, identification of potential environmental risk factors and their role in the disease process is important in the potential prevention of type 1 diabetes in the future, and the lack of consistent findings may reflect a lack of properly conducted prospective studies.

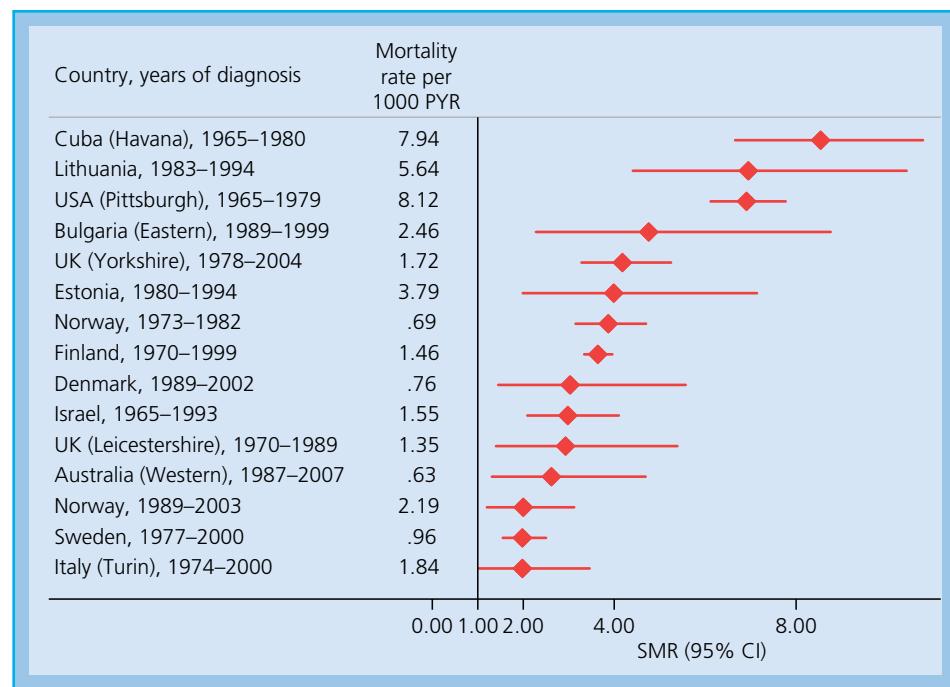

Mortality

Before the discovery of insulin in 1922, type 1 diabetes led to almost certain death soon after its onset. After the initiation of insulin replacement therapy, a dramatic improvement in survival occurred. Another major improvement in survival occurred in people diagnosed with diabetes in the 1950s [177]; however, even today type 1 diabetes is associated with an approximately two- to eightfold higher mortality rate than that in the background population [178-180] (Figure 4.7). Relative mortality varies between countries and periods. Also shown in Figure 4.7 are the absolute mortality rates, which tend to correlate with the standardized mortality ratio (SMR). For instance, the SMR for individuals with type 1 diabetes in Finland was lower than in Lithuania, Estonia, and Japan [181, 182]. A higher mortality has been reported in African American compared to white individuals with type 1 diabetes in the USA, and this difference seems to be attributable to acute complications [183].

In Europe, short-term mortality was two times higher in individuals followed from diagnosis of type 1 diabetes in childhood than in the respective general populations, with variation in the SMR from about 1.1 to 4.7 in different countries [184]. In a nationwide cohort of people with type 1 diabetes in Norway followed from onset before 15 years of age and up to 40 years' duration (mean 17 years), the SMR was 3.6 [179]. In a UK cohort of more than 7000 prevalent cases of type 1 diabetes with a mean age of 33 years at baseline, the SMR after up to 7 years of follow-up (mean 4.5 years) was 3.7 [185]. Many studies have reported that the SMR varies with age and with diabetes duration, or both, but results are not consistent among studies.

Ascertainment of cause of death in young people with type 1 diabetes is difficult, but around one-third of the early deaths in the recent European multicentre study were attributable to diabetic ketoacidosis, while about half of the deaths seemed unrelated to

Figure 4.7 Standardized mortality ratios (SMRs) for individuals followed from diagnosis of childhood-onset type 1 diabetes. Source: Data are from different studies, summarized by Morgan et al. 2015 [178]. Only studies with at least 10 observed deaths are shown here. An SMR of 1.0 means a mortality rate among persons with type 1 diabetes that is equal to that in the background population for the same age, sex, and calendar period. Studies were sorted by the earliest year of diagnosis of type 1 diabetes, and secondarily by SMR. There were differences in duration of follow-up and other minor methodological differences between studies. CI, confidence interval; PYR, person-years at risk.

diabetes [184, 186, 187]. After about 10–15 years of diabetes duration, microvascular and macrovascular chronic diabetes complications start to make an impact, and after about 30 years of age cardiovascular causes become increasingly important [188]. Relative mortality from cardiovascular causes is in most populations higher in women than in men [189]. SMRs of 8–40 have been reported for cardiovascular causes of death in individuals with type 1 diabetes, and depend strongly on the presence of nephropathy [180, 188, 190–192].

A few recent data are available on mortality due to Covid-19, caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV2). In a study of 264 000 individuals with type 1 diabetes in the UK, the risk of in-hospital mortality with Covid-19 in early 2020 was threefold higher than among people without diabetes [193]. Only 6 of 464 observed deaths occurred in individuals aged below 40 years. However, while the absolute risk of death increased with age, the relative risk of death in persons with type 1 diabetes tended to be higher in the younger age groups. Mortality was around sixfold higher in 50–59-year-olds compared with people of the same age without diabetes. Higher glycated haemoglobin (HbA_{1c}) was associated with significantly higher Covid-19-related mortality in individuals with type 1 diabetes, after adjusting for other risk factors [194].

Better glycaemic levels and improved risk factor management, such as lowering of blood pressure and lipids, are associated with reduced risks of late complications and improved survival [195]. Long-term follow-up in the DCCT and EDIC studies showed that multiple daily insulin injections (today's standard mode of treatment) compared to less intensive insulin treatment for 1–15 years resulted in a significant reduction in total mortality [196]. Nevertheless, a large proportion of individuals with type 1 diabetes have suboptimal HbA_{1c} levels. Despite the relationship between higher HbA_{1c} and increased mortality, a Swedish study found that even those with low HbA_{1c} seem to have a significantly higher mortality than people without diabetes [180]. In line with the impression that treatment is gradually improving, people diagnosed with type 1 diabetes in more recent years seem to have lower short-term mortality compared with individuals diagnosed in earlier time periods [197–199]. Many authors have estimated the loss in life expectancy due to type 1 diabetes at around 8–18 years, depending on time period, sex, and age at onset [189, 200, 201].

Because individuals with type 1 diabetes have higher mortality than the background population at all ages, and life expectancy is a summary measure of mortality in a current period across all age groups, it is perhaps unsurprising that the estimated reduction in life

expectancy is greater for those with young age at onset [189, 202]. Despite the apparent ease of interpretation of loss in life expectancy, this estimate is a complex summary applicable only to hypothetical individuals who probably do not exist [202]. Nevertheless, despite continuing improvement in care, a major gap in mortality compared to the general population remains in recent large-scale studies from high-income populations. In many low- and middle-income countries, mortality in people with type 1 diabetes is very high [203]. A continuing challenge is also deaths among those with undiagnosed type 1 diabetes and individuals without access to insulin and health care in low- and middle-income countries.

Conclusion

Type 1 diabetes is one of the most common chronic diseases diagnosed in childhood, but the condition can occur at any age. Its incidence varies drastically between populations and even within populations. Type 1 diabetes has a strong genetic component and familial clustering, but the majority of cases have no affected siblings or parents. Only a minority of carriers of the susceptibility genes develop type 1 diabetes. The incidence of type 1 diabetes is increasing in most studied populations at an average rate of approximately 3–4% per year, but has plateaued or even decreased in some countries recently. Some environmental factors may contribute to the development of diabetes, but no definite causal environmental factor for type 1 diabetes has yet been identified.

Type 1 diabetes was a fatal disease before the insulin era. Although mortality in individuals with diabetes has drastically decreased, both acute and late complications lead to increased morbidity and premature mortality in type 1 diabetes. Primary prevention of type 1 diabetes would be the only solution to these problems, but unfortunately no practical preventive measures are currently available.

Key points

- The prevalence of type 2 diabetes continues to increase worldwide.
- Approximately 537 million people worldwide were living with diabetes in 2021, making it one of the commonest non-communicable diseases globally.
- The largest increase is observed in regions with rapidly developing economies and urbanization.
- The ageing population, with an increase in the proportion of people aged >65 years in most countries, has contributed significantly to this increase in prevalence.
- The age of onset of diabetes is decreasing in many countries, giving rise to an increasing proportion of young people of working age being affected by the disease.
- Several risk factors are known to be associated with an increased risk of type 2 diabetes. Many of these risk factors are associated with a Westernized lifestyle and increase with urbanization, although novel environmental risk factors have emerged.
- Areas with a high ratio of impaired glucose tolerance to diabetes are at an earlier stage of the diabetes epidemic, and thus may be a particular target for preventive strategies.
- The Pacific Islands and Middle East are the regions with the highest diabetes prevalence rates.
- The largest increase in diabetes prevalence is predicted to occur in Africa.
- Diabetes is associated with approximately twofold increased mortality in most populations, with the excess risk decreasing with increasing age.
- The increase in diabetes prevalence, particularly among young adults, along with the increased morbidity and mortality associated with microvascular and macrovascular complications, is likely to lead to an escalation of healthcare costs and loss of economic growth.
- Recent data suggest stable or declining diabetes incidence in some high- and middle-income countries where data are available.
- Prevention efforts require widespread public education and coordinated multisector efforts to encourage physical activity and a healthy diet.
- Maternal health and the intrauterine environment have also emerged as an important window of opportunity for prevention.
- Remission of type 2 diabetes is possible through intensive lifestyle modification or metabolic surgery, highlighting the benefits of weight loss. This may complicate epidemiological analyses on diabetes prevalence.

Type 2 diabetes is one of the commonest forms of chronic disease globally and few societies or ethnic groups are spared. It accounts for ~95% of cases of diabetes in most populations [1]. In 2021, the International Diabetes Federation (IDF) estimated that 536.6 million people worldwide had diabetes, of whom 75% live in low- and middle-income countries. Globally, among those aged 20–79 years, ~10.5% had diabetes, of whom an estimated 44.7% remain undiagnosed. The highest number of people with diabetes was in the Western Pacific region, with 205.6 million, and the region with the highest prevalence rate, at 16.2%, was the Middle East and North Africa [2]. These estimates are generally in line with estimates from other sources. For example, the NCD Risk Factor Collaboration has estimated from 751 population-based studies, including 4.4 million participants, that the number of adults in the world living with diabetes in 2014 was 422 million [3].

The number of people with diabetes is expected to reach 783.2 million by 2045, an increase of 46% [2]. The largest increases have been in countries with rapidly growing economies, such as India and China, and the largest increase over the next two decades is predicted to occur in Africa. With the increasing consumption of high-energy food, and increasing adoption of sedentary lifestyles and urbanization, growing numbers of individuals are developing type 2 diabetes, and the age at which individuals are diagnosed is decreasing. Individuals exposed to longer periods of hyperglycaemia will undoubtedly have greater risks of developing diabetes-related complications. The potential healthcare costs and burden of diabetes in these regions will have a significant impact on the economic growth of these regions, as discussed in Chapter 3.

The epidemiology and prevalence of diabetes are partly determined by the diagnostic criteria used to diagnose diabetes, and these have

been modified on several occasions. The diagnostic criteria for diabetes and impaired glucose tolerance are based on epidemiological evidence relating microvascular complications to specific degrees of hyperglycaemia, and the fasting glucose cut-off has been modified as new data emerged. These changes have major implications for the interpretations of current and future epidemiological studies on diabetes. In 1999, the diagnostic threshold of fasting glucose was lowered from 7.8 mmol/l (140 mg/dl) to 7.0 mmol/l (126 mg/dl). A fasting glucose level between 6.1 and 6.9 mmol/l (111–125 mg/dl) was considered to be *pre-diabetic* and the term *impaired fasting glucose* was used. Subsequent lowering of the *normal fasting glucose* level to 5.6 mmol/l (100 mg/dl) further increases the number of people with pre-diabetes. Impaired glucose tolerance, on the other hand, is another pre-diabetes state, which is only identified by oral glucose tolerance testing, with a post-load glucose level of 7.8–11.0 mmol/l (140–199 mg/dl). It is estimated that ~541 million people or 10.6% 20–79 years old have impaired glucose tolerance [2].

Risk factors for type 2 diabetes

Several risk factors are known to be associated with increased risk of type 2 diabetes, including increasing age, obesity (especially central obesity), dietary excess, dietary factors such as increased intake of animal fats and sugar-sweetened beverages, sedentary lifestyle, positive family history, history of gestational diabetes, polycystic ovary syndrome, presence of hypertension, hyperlipidaemia, or other cardiometabolic risk factors (Figure 5.1). Many of these risk factors are associated with a Westernized lifestyle and increase with increasing urbanization and mechanization. The recognition of the role of these factors in the pathogenesis of type 2 diabetes has led to recommendations for selective screening for type 2 diabetes in people with these risk factors [1, 2, 4].

Several large studies, including the Nurses' Health Study in the USA and the InterAct Study in Europe, have contributed to improved understanding of the role of dietary factors and the risk of incident type 2 diabetes. Dietary factors that increase the risk for type 2 diabetes include the following [5, 6]:

- Increased fat intake.
- Increased intake of red and processed meat.
- Consumption of fried food.
- Increased intake of white rice.
- Consumption of sugar-sweetened beverages.

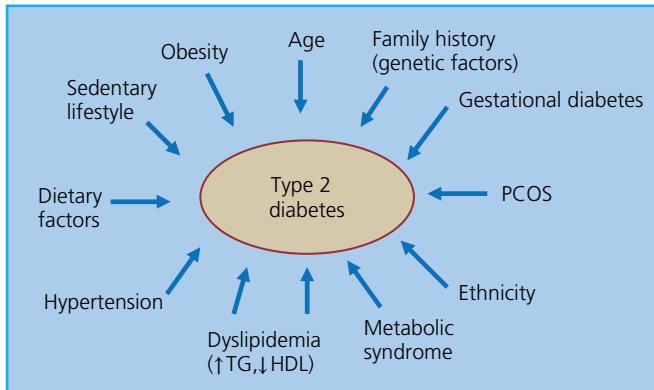

Figure 5.1 Risk factors in the development of type 2 diabetes. HDL, high-density lipoprotein cholesterol; PCOS, polycystic ovarian syndrome; TG, triglycerides.

Dietary factors that decrease the risk for type 2 diabetes include the following [5, 6]:

- Increased fruit and vegetable intake.
- A Mediterranean diet pattern.
- Consumption of fermented dairy products.
- Intake of oily fish.
- Drinking tea.

Obesity accounts for 80–85% of the overall risk of developing type 2 diabetes, and underlies the current global spread of the disease [7]. The risk of type 2 diabetes increases as the body mass index (BMI) increases above 24 kg/m², although the risk appears to be present with a lower BMI in Asians [8, 9]. Although central obesity is a particularly strong factor, it can impart further risk regardless of the overall level of general obesity. This obesity-related risk is more marked in certain ethnic populations such as Pima Indians, Black Africans, South Asians, Chinese, and other Asian populations [10–14], and may be related to increased visceral adiposity. Obesity, particularly central adiposity, is associated with insulin resistance and also β -cell dysfunction, partly through increased free fatty acids and lipotoxicity (Chapters 16–18). Obesity is also associated with other metabolic abnormalities such as dyslipidaemia and hypertension.

The clustering of some of the risk factors, namely hypertension, elevated blood glucose, elevated triglyceride, low high-density lipoprotein (HDL) cholesterol, and abdominal obesity, is termed the *metabolic syndrome*. Presence of the metabolic syndrome, according to the definition, is associated with a two- to fivefold increased risk of developing diabetes in most populations [15].

A positive family history is an important risk factor for type 2 diabetes. In the InterAct case-cohort study, a family history of type 2 diabetes was associated with a 2.7-fold risk of incident diabetes [16]. There have been advances in our understanding of the genetic basis of type 2 diabetes over the last few years, with more than 1000 genetic variants so far identified as being associated with type 2 diabetes (Chapter 12) [17]. Nevertheless, the identified genetic variants explain <10% of the heritability of type 2 diabetes. In the InterAct study, a genetic risk score composed of known genetic variants for type 2 diabetes explained only 2% of the family history-associated risk of the disease, suggesting that there are still unexplained factors that contribute to the association between family history and type 2 diabetes, including yet to be identified genetic factors, shared environment and behaviour, epigenetic factors, and possibly other factors [16]. Most of the known genetic variants for type 2 diabetes were identified in European populations. Although several type 2 diabetes-associated genetic variants have been identified in other populations, including East Asians and South Asians, our current knowledge of genetic variants associated with type 2 diabetes cannot explain the marked geographical and ethnic variations in diabetes prevalence [14, 18].

Traditional risk factors such as increasing age, adiposity, physical inactivity, dietary factors, positive family history, and presence of other cardiometabolic risk factors are well-recognized factors for diabetes and many are considered to be on the causal pathway. Current approaches to diabetes prevention are mostly focused on addressing these risk factors, in particular unhealthy diet and physical inactivity. In the prospective Whitehall II study, it was estimated that traditional modifiable risk factors such as health behaviour and obesity, when measured repeatedly over time, explain approximately half of the social inequalities in incidence of type 2 diabetes [19].

Emerging risk factors

Sugar-sweetened beverages

Consumption of sugar-sweetened beverages is now recognized as an important contributor to the recent rapid escalation in obesity and diabetes [20, 21]. Sugar-sweetened beverages include carbonated soft drinks, fruit juices, iced tea, and energy and vitamin water beverages, and are similar in having high sugar content, low satiety, and low nutritional value. The intake of such beverages has increased markedly over recent decades, and consumption trends often mirror those of obesity and diabetes prevalence in different parts of the world [22]. Sugar-sweetened beverages contain added sugars in the form of fructose, chronic exposure to which can lead to hepatic steatosis, insulin resistance, central obesity, and metabolic abnormalities [23].

Decreased sleep

In addition to changes in diet and physical activity, it is increasingly recognized that there is a U-shaped relationship between sleep duration and diabetes risk, with short sleep duration, another facet of our modern lifestyle, being an important contributor to the increasing prevalence of type 2 diabetes. Early seminal work highlighted the detrimental effects of sleep deprivation on glucose tolerance and insulin sensitivity [24]. Subsequent cross-sectional studies have suggested an association between short sleep duration and diabetes [25] and obesity [26]. In a prospective study of >70 000 women in the Nurses' Health Study, short sleep duration was associated with a ~57% increase in diabetes risk over the 10-year study period [27]. Similar data were obtained from the First National Health and Nutrition Examination Survey (NHANES I), which noted that people with a sleep duration of ≤5 hours had a 47% increase in incident diabetes over a 10-year period [28]. The exact mechanism whereby sleep restriction increases diabetes risk is unclear, although it may be related to activation of the sympathetic nervous system, decrease in cerebral glucose utilization, changes in the hypothalamic–pituitary–adrenal axis, and other neuroendocrine dysregulation [28]. In addition to short duration, other sleep disturbances and altered circadian rhythm, for example during shift work, are associated with an increased risk of diabetes [29].

Depression and treatment of depression

There is a bidirectional relationship between depression and diabetes and impaired glucose tolerance (Chapter 65). The incident rate of type 2 diabetes is modestly higher among those with baseline depressive symptoms. Once type 2 diabetes was diagnosed, there was a positive association with depressive symptoms, illustrating the emotional burden of having diabetes [30]. The use of second-generation antipsychotic agents, commonly referred to as *atypical antipsychotics*, has been linked with hyperglycaemia and diabetes [31]. A complex association exists between mental illness, use of psychiatric medications, and diabetes [32].

Drug-induced metabolic changes

There is increasing recognition that some commonly used medications may be associated with adverse metabolic effects and increased risk of diabetes (Chapter 21) [33]. High-dose thiazide diuretics worsen insulin resistance and β-blockers can impair insulin secretion. The increasing use of highly active antiretroviral therapy (HAART) has dramatically reduced the mortality of people with human immunodeficiency virus (HIV) infection. However, protease inhibitors and, to a lesser extent, nucleoside reverse

transcriptase inhibitors are associated with insulin resistance, deranged glucose and lipid metabolism, and an increased risk for type 2 diabetes. The growing use of such agents will likely have a significant impact on the epidemiology of diabetes in areas where HIV/AIDS is endemic, such as Africa [34].

Environmental toxins

Whereas most studies on the increasing burden of diabetes with a Westernized lifestyle have focused on changes in dietary patterns and increasingly sedentary behaviour, some studies suggest that environmental pollutants may represent a previously unrecognized link between urbanization and diabetes [35, 36]. For example, there is a strong cross-sectional association between serum concentrations of chlorinated persistent organic pollutants with diabetes [37] and also components of the metabolic syndrome [38]. Brominated flame retardants, bisphenol A, and perfluorinated compounds have emerged as other classes of organic pollutants that are associated with diabetes [39, 40]. These environmental toxins may accumulate in adipose tissue and act as endocrine disruptors, leading to dysregulation of glucose and lipid metabolism.

Low birth weight and fetal malnutrition

There is a relationship between the intrauterine environment, fetal malnutrition, and the risk of diabetes and cardiovascular disease later in life [41, 42]. Maternal undernutrition and low infant birth weight, along with rapid postnatal growth, are associated with increased risk of diabetes in the offspring. This *mismatch* of a metabolic phenotype programmed during intrauterine development and the nutritionally rich postnatal environment may be most important in regions that are undergoing rapid economic development, and may be an important factor contributing to the rapid rise in diabetes in Asia and the Pacific region [43].

Maternal obesity, maternal hyperglycaemia, and other factors in early development

Offspring of women with obesity or women with diabetes have an increased risk of diabetes and cardiometabolic abnormalities [44, 45]. This is partly caused by the effects of maternal overnutrition and of intrauterine hyperglycaemia on fetal growth, although it may also involve epigenetic changes [46]. With increasing numbers of women with obesity or young-onset diabetes, this is likely to exacerbate the epidemic of diabetes further by setting up a vicious cycle of diabetes begetting diabetes [42, 47, 48]. There is also increasing interest in the potential link between assisted reproduction technology and risk of diabetes and obesity in the offspring, though this remains an area of controversy, with limited and conflicting data [49].

Despite the increasing recognition of these novel risk factors, the main risk factors associated with diabetes remain the traditional ones such as increasing age, adiposity, physical inactivity, dietary factors, positive family history, and presence of other cardiometabolic risk factors, as outlined in Figure 5.1.

Methodological issues in the epidemiology of type 2 diabetes

In comparing epidemiological data in type 2 diabetes, one must be aware of the importance of the study methodology. Survey methods must be robust to allow comparison and standardization. A large, truly random sample of a community, with a good response rate,

is best; workplace samples may demonstrate *healthy worker* effects, whereas selective samples (e.g. volunteers or people with another disease) are the least useful because of inbuilt recruitment bias. The age distribution of sample populations is crucial in studying type 2 diabetes, whose prevalence rises with age; study populations must be age stratified and any comparisons age-adjusted, either within the dataset or standardized against a reference population. Finally, ascertainment methods are important, for example whether participants undergo an oral glucose tolerance test, with or without preliminary blood glucose screening. Although reference is often made to the global and national estimates of diabetes prevalence in the *IDF Diabetes Atlas*, one must be aware of several important limitations of these estimates. For countries in which prevalence studies are available, the data are presented in the *Atlas*. However, for many countries for which no updated prevalence studies are available, the estimates are based on modelled data from nearby countries matched in terms of percentage urbanization, ethnicity, and income group [50]. Owing to these methodological issues, prevalence figures for countries where estimates are based on modelling are not necessarily accurate, and not directly comparable with those from countries in which nationwide epidemiology surveys have been conducted, though these issues have been addressed to a certain extent in the latest version of the *Atlas* [1, 50].

Studies conducted in different regions of the world have highlighted an increase in the prevalence of type 2 diabetes. Although few would argue that this translates into an increasing burden associated with diabetes, it is important to recognize the factors that have contributed to this increased prevalence. Several factors directly affect the prevalence of diabetes and may partly account for the increasing prevalence (Figure 5.2). These include:

- Changes in the ratio of diagnosed to undiagnosed cases of diabetes.
- Population demographic changes with an ageing population.
- Earlier age at onset of diabetes.
- Longer survival in people with diabetes.
- Increasing incidence of diabetes [51].

The different factors may have different contributions depending on the population being studied, although most, if not all, are of some importance in most populations. The differences in the contributions of different factors to the prevalence of diabetes are illustrated by the fact that, for example, in Europe the incidence of

diabetes has stabilized but longevity and higher case finding now explain the increased numbers, whereas in Africa and parts of Asia there is still an increase in incidence [1, 2, 43, 50].

Effects of changes in the definition of diabetes

Although it has long been established that diabetes is a condition associated with hyperglycaemia, there was no widespread accepted definition until the 1980s, when the World Health Organization (WHO) Expert Committee on Diabetes Mellitus defined diabetes as a state of chronic hyperglycaemia that may result from many environmental and genetic factors often acting together [52]. The precise degree of hyperglycaemia that defines diabetes has evolved with time and relies on epidemiological studies regarding the distribution of glucose levels within various populations.

There are several consequences of the changes in the definition of diabetes with time on the epidemiology of diabetes. First, the American Diabetes Association (ADA) and 1999 WHO classification lowered the diagnostic threshold of fasting glucose from 7.8 to 7.0 mmol/l, thereby increasing the number of individuals in any given population who fulfilled a diagnosis of diabetes mellitus.

It is important to appreciate whether the diagnosis was based on elevated fasting glucose or post-load values during an oral glucose tolerance test. Although the lower fasting glucose level of 7 mmol/l was chosen to resemble the diagnostic significance of the two-hour post-load concentration more closely, numerous studies have demonstrated that the fasting glucose and post-load criteria identify slightly different people in most populations [53–55]. The use of fasting glucose alone will reduce the overall prevalence of diabetes compared with that identified by two-hour post-load glucose values [56]. Furthermore, there is an increasing number of epidemiological studies that utilize the measurement of glycated haemoglobin ($\text{HbA}_{1\text{c}}$) as an indicator of dysglycaemia [57], and several professional organizations, including the ADA in 2010 and the WHO in 2011, have now included $\text{HbA}_{1\text{c}}$ for the diagnosis of diabetes [4, 58], though this remains an area of debate [4, 58–60].

The WHO and ADA recommendations for the diagnostic criteria for diabetes and intermediate hyperglycaemia are summarized in Table 5.1. Although the lower ADA threshold for diagnosing impaired fasting glucose will result in more people being diagnosed with intermediate hyperglycaemia compared with the WHO recommendation, increased diagnostic activity, for example through the use of the oral glucose tolerance test, will increase the ratio of diagnosed to undiagnosed diabetes, and may have an impact on the prevalence rate reported in epidemiological studies. In a study utilizing 96 population-based cohorts to compare the different diagnostic criteria on population prevalence of diabetes, the prevalence based on $\text{HbA}_{1\text{c}}$ was in general slightly lower than that based on fasting blood glucose. Furthermore, diabetes diagnosed on $\text{HbA}_{1\text{c}} \geq 6.5\%$ (48 mmol/mol) had a pooled sensitivity of ~53% (95% confidence interval [CI] 51.3–54.3%), compared with a definition of fasting glucose of $\geq 7.0 \text{ mmol/l}$ for diagnosing individuals without a previous known history of diabetes [61].

In an earlier comprehensive report on the global prevalence of diabetes [62], the most important demographic change to diabetes prevalence across the world was the increase in the proportion of people aged >65 years. Another major factor that has affected the prevalence of diabetes is the increasing age-specific prevalence, especially in the younger age groups [62]. This suggests an earlier age of onset of diabetes, which may be of particular importance in developing countries. The tendency is for the prevalence of impaired glucose tolerance to decline as that of diabetes rises,

Table 5.1 Comparison of World Health Organization (WHO) and American Diabetes Association (ADA) recommendations for the diagnostic criteria for diabetes and intermediate hyperglycaemia.

	WHO (2006/2011)	ADA (2003/2010)
<i>Diabetes</i>		
Fasting plasma glucose	$\geq 7.0 \text{ mmol/l (126 mg/dl)}$ or $\geq 11.1 \text{ mmol/l (200 mg/dl)}$	$\geq 7.0 \text{ mmol/l (126 mg/dl)}$
2 h plasma glucose ^a	(Since 2011) $\geq 6.5\% (48 \text{ mmol/mol})$ (if assay standardized and accurately measured)	(Since 2010) $\geq 6.5\% (48 \text{ mmol/mol})$ (if assay standardized and accurately measured)
<i>Impaired glucose tolerance</i>		
Fasting plasma glucose	$< 7.0 \text{ mmol/l (126 mg/dl)}$ and $\geq 7.8 \text{ and } < 11.1 \text{ mmol/l (140 and 200 mg/dl)}$	
2 h plasma glucose ^a		
<i>Impaired fasting glucose</i>		
Fasting plasma glucose	$6.1\text{--}6.9 \text{ mmol/l (110\text{--}125 mg/dl)}$	$5.6\text{--}6.9 \text{ mmol/l (100\text{--}125 mg/dl)}$
2 h plasma glucose ^a	$< 7.8 \text{ mmol/l (140 mg/dl)}$	

^aVenous plasma glucose 2 h after ingestion of 75 g oral glucose load.

suggesting that areas with a high ratio of impaired glucose tolerance to diabetes are at an earlier stage of the diabetes epidemic and thus may be a particular target for preventive strategies. Changes and variations in the ratio of impaired glucose tolerance to diabetes prevalence, the so-called *epidemicity index*, may provide a useful marker for the scale of the epidemic in that particular region [63].

Emerging data on the incidence of type 2 diabetes

While the prevalence of diabetes provides a good estimate of the total burden of diabetes in different parts of the world, diabetes prevalence can increase due to better care and longer survival of people with diabetes. Hence the incidence rate of diabetes is a better reflection of the risk of developing new-onset diabetes. However, data on the incidence of type 2 diabetes are comparatively limited. In a systematic review of studies reporting incidence of diabetes in adults between 1980 and 2017, it was noted that among the 47 studies included, the majority (66%) reported increases in diabetes incidence between 1990 and 2005, whereas the majority of studies between 2006 and 2014 noted stable or declining incidence [64]. In a more recent analysis of trends of incidence of diagnosed diabetes from different high- and middle-income settings, data from 22 million diabetes diagnoses from 19 high-income and 2 middle-income countries or regions suggest that the incidence of diagnosed diabetes may be stabilizing or declining in the high-income countries represented [65]. While this might be encouraging news, there is no room for complacency, as the rates of overweight and obesity continue to increase globally, and continued efforts to track and battle diabetes and its associated burden remain a major public health priority [1, 2, 50, 66].

Regional and ethnic patterns of type 2 diabetes worldwide

This section considers the geographical distribution and secular changes in the prevalence of type 2 diabetes and intermediate hyperglycaemia in the major regions of the world. Whenever possible, the

most representative recent prevalence studies are presented. In addition, owing to a lack of recent prevalence studies, data from the *IDF Diabetes Atlas*, which utilized age- and sex-specific estimates for diabetes prevalence from available epidemiological surveys to extrapolate prevalence in related countries using a combination of criteria including geographical proximity, ethnic, and socioeconomic similarities, are also presented when necessary.

Current estimates of the total number of people with diabetes in each region of the world and in those countries with the highest overall numbers are shown in Figure 5.3. Table 5.2 shows the countries with the highest prevalence, and Table 5.3 lists the countries with the greatest number of people with diabetes. These estimates are based on modelling of data available from countries in which prevalence data were obtained from epidemiological surveys, and hence are only estimates that must be treated with caution [50].

Africa

Type 2 diabetes in the African continent provides contrasting pictures between more urbanized and more rural regions. Whereas poverty and malnutrition are still a major problem affecting sub-Saharan Africa, a region where diabetes is comparatively rare, urbanized areas such as North Africa are reporting increasing prevalence rates [66]. The IDF estimated that overall, ~4.5% of the adult population in the African region are currently affected by diabetes and this is projected to increase to 5.2% by 2045 [2]. Other important epidemiological issues in the region include a low incidence of type 1 diabetes, except in Eastern Africa, where rates of type 1 diabetes are comparatively high. There is also the occurrence of atypical *ketosis-prone* diabetes. This initially presents as type 1 diabetes with severe hyperglycaemia and ketosis, but subsequently has long-term remission with a clinical course more compatible with type 2 diabetes [67]. In addition, there is also a form of early-onset diabetes termed malnutrition-related diabetes mellitus that is associated with past or present malnutrition and sometimes accompanied by pancreatic calcification [34]. Although infective diseases such as HIV infection and tuberculosis are currently the main causes of mortality in sub-Saharan Africa, the increasing prevalence of diabetes and other non-communicable diseases is likely to overtake infections as major causes of mortality.

In sub-Saharan Africa, only a small proportion of the population reaches ages at which type 2 diabetes becomes a major health problem. Although greater access to highly active antiretroviral therapy (HAART) has led to markedly reduced mortality, the improvement in life expectancy, coupled with the adverse metabolic effects of HAART, is likely to contribute to further increases in the prevalence of type 2 diabetes within the region [34, 68].

Sub-Saharan Africa

There is a relative paucity of prevalence data from sub-Saharan Africa, with most of the studies coming from Ghana, Cameroon, Nigeria, Tanzania, and South Africa [67, 69]. In a systematic review

of prevalence data from Ghanaians and Nigerians, diabetes was rare at 0.2% in urban Ghana in 1963 and 1.65% in urban Nigeria in 1985. The prevalence of diabetes had risen to 6.8% in Nigeria in 2000 (for adults aged ≥ 40 years) and 6.3% in Ghana in 1998 (for adults aged ≥ 25 years) [70, 71]. In Cameroon (West Africa), adults aged 24–74 years had an overall diabetes prevalence of 1.1%, with an impaired glucose tolerance rate of 2.7%. Prevalence rates in the capital of Cameroon (Yaounde) were 1.3% for diabetes and 1.8% for impaired glucose tolerance, compared with rural prevalences of 0.8% for diabetes and 3.9% for impaired glucose tolerance [72]. Undiagnosed cases accounted for most cases in these studies, again reflecting a region in the early stages of a looming diabetes epidemic. In a recent systematic review of 41 studies of the prevalence

of diabetes among older adults on the African continent, overall prevalence was substantially higher at 13.7% among adults aged 55 or older, and was higher among studies using the oral glucose tolerance test (OGTT) than fasting glucose, and higher in urban versus rural settings [73].

In South Africa, both diabetes and impaired glucose tolerance are commoner in both urban and rural communities. In Cape Town, age-adjusted prevalence was 8% for diabetes and 7% for impaired glucose tolerance [74]. A study conducted in a rural South African community based on a 75 g OGTT and the 1998 WHO criteria reported overall age-adjusted prevalence of diabetes of 3.9%, impaired glucose tolerance of 4.8%, and impaired fasting glycaemia of 1.5%. Notably, 85% of the cases with diabetes were uncovered by the survey [75]. In addition to exposure to an urban environment, other factors that determine the risk of type 2 diabetes in African populations include positive family history, ethnic origin, central adiposity, and physical inactivity [76]. Possible ethnic differences have been examined in several studies. In both Tanzania and South Africa, migrant Asians have higher diabetes prevalence rates than Indigenous Africans [77], but this could reflect lifestyle differences. In Tanzania the difference was particularly marked (1.1% in Africans vs 9.1% in Asians), which again emphasizes the low prevalence in urban East Africans. In a recent systematic review including 11 studies of the prevalence of type 2 diabetes in South Africa published between January 1997 and June 2020, the pooled prevalence in adults aged 25 or above was 15.25% (95% CI 11.07–19.95%) for type 2 diabetes, 9.59% (5.82–14.17%) for impaired glucose tolerance, 3.55% (0.38–9.61%) for impaired fasting glycaemia, and 8.29% (4.97–12.34%) for newly diagnosed type 2 diabetes [78].

The emerging epidemic of type 2 diabetes is further compounded by the various problems hampering the delivery of effective diabetes care within this region. This has resulted in poor glycaemic management among most people with diabetes, and also a high frequency of chronic microvascular complications. The rising prevalence of diabetes may also hamper tuberculosis control efforts by increasing the number of susceptible individuals in endemic areas [74]. Better access to healthcare and treatment, improvements in infrastructure to support services (for example, by aligning diabetes care with screening and healthcare delivery for infectious diseases such as HIV and tuberculosis) and healthcare information systems, and also primary prevention measures are urgently needed to reduce the burden of acute and chronic complications of diabetes in the region [34, 67, 68, 79, 80].

North America

Diabetes and its complications are common and a significant cause of morbidity in North America. The NHANES reported a crude prevalence of total diabetes in 1999–2002 of 9.3%, comprising 6.5% diagnosed and 2.8% undiagnosed [81]. This was significantly increased compared with a crude prevalence of total diabetes of 5.1% in 1988–1994, mainly through an increase in diagnosed diabetes. There was a marked variation in prevalence between ethnic groups, with age- and sex-standardized prevalence of diagnosed diabetes approximately twice as high in non-Hispanic Black Americans (11%) and Mexican Americans (10.4%) compared with non-Hispanic white Americans (5.2%). The prevalence of diabetes among older people of these minority groups was particularly high, exceeding 30% [81].

The high prevalence rates in US Hispanic people and Black Americans are well documented. In 1991, the age-adjusted

prevalence of diabetes was 6% in white Americans, 9% in Cubans, 10% in Black Americans, 13% in Mexican Americans, and 13% in Puerto Ricans [82]. Rates have risen in all groups, but these differences appear to persist. Between 1987 and 1996, the 7–8-year incidence of type 2 diabetes approximately tripled in both Mexican Americans and non-Hispanic white Americans, although the absolute rate was twice as high in the Mexican Americans [83]. Type 2 diabetes is also significantly commoner among older Puerto Ricans (38%) and Dominicans (35%) than among non-Hispanic white Americans (23%) [84]. Economic disadvantage may explain much of the excess prevalence of type 2 diabetes among African American women [85].

Other populations in the USA that are particularly at risk of type 2 diabetes are the Indigenous communities, notably the Pima, of whom 50% have diabetes [86]. Reports have highlighted the developing epidemic of type 2 diabetes in Indigenous American youth [87]. Among 15–19-year-olds, diabetes affected 5.1% of Pima (a sixfold increase in prevalence over the previous 20 years) and 0.2% of Canadian Cree and Ojibway. The overall prevalence among all US Indigenous peoples of this age is 0.5%. This epidemic of type 2 diabetes in young Indigenous Americans is supported by secular trends in the incidence rate of type 2 diabetes over the previous 40 years in Pima, which showed a more than fivefold increase in incidence rates among Pima aged 5–14 years [88].

A similar situation was seen in Canada, where Indigenous peoples had more than a twofold increase in prevalence compared with the general population [89]. Other minority groups are also not spared. Among native Hawaiians (Polynesians), the crude (i.e. not age-adjusted) prevalence rates of type 2 diabetes and impaired glucose tolerance were reported in 1998 to be 20% and 16%, respectively. The age-adjusted rate for type 2 diabetes was four times higher than among the US NHANES II study population [90]. In 1991, second-generation Japanese Americans had prevalence rates of 16% (diabetes) and 40% (impaired glucose tolerance) [91], and incidence rates remained high at 17.2 per 1000 person-years [92]. This may be due to the increase in visceral adiposity in a population predisposed to impaired β-cell function [93]. Other Asian populations living in the USA that are particularly prone to diabetes include Asian Americans, in whom linguistic difficulties may be a particularly relevant barrier to diabetes education and effective care delivery [94].

It has been estimated that the number of adults in the USA with diagnosed diabetes will rise from 11 million in 2000 (overall prevalence 4.0%) to 29 million in 2050 (overall prevalence 7.2%). The fastest growth is expected to be among Black Americans. The projected increase of 18 million is accounted for by approximately similar contributions from changes in demographic composition, population growth, and secular trends [95]. In 2021 it was estimated that 32.2 million people in the USA had diabetes, of whom 4.0 million were undiagnosed [2]. The US Centres for Disease Control and Prevention (CDC) reported a crude prevalence of total diabetes in 2018 of 13.0%, comprising 10.2% diagnosed and 2.8% undiagnosed [96]. The direct and indirect medical cost attributed to diabetes in the USA in 2017 was \$327 billion [97]. The percentage of diagnosed people reaching glycaemic goals and achieving risk factor control has improved over the last two decades, although only 14% met all three targets regarding glycaemic, blood pressure, and lipid management, along with smoking cessation [98]. There has been a substantial reduction in the rates of diabetes-related complications over the last two decades, especially regarding myocardial infarction and acute hyperglycaemic emergencies [99].

An increasing number of younger people will be affected. In the SEARCH for Diabetes in Youth Study, a multiethnic, population-based study, the incidence of diabetes was 24.3 per 100 000 person-years. The incidence rates of type 2 diabetes were highest among Indigenous Americans and African American adolescents, varying from 17 to 49.4 per 100 000 person-years, compared with 5.6 per 100 000 person-years in non-Hispanic white Americans [100].

Caribbean

Studies in Jamaica exemplify the secular trend in the West Indies. Rates in the 1960s (underestimated owing to the screening procedure used) [101] were low, but rose in the 1970s to 4% in those aged 25–44 years and 8–10% in those aged 45–64 years [102, 103], and to an overall rate of 7.4% in 1996 [104]. A report in 1999 indicated prevalence rates of 16% in women and 10% in men (13% overall). As elsewhere, this exceeds the rate of rise among European-origin populations and parallels the spread of obesity [105].

Central and South America

Data from this region are scarce. In the Indigenous Mapuche in rural Chile, the prevalence of type 2 diabetes estimated in 2001 was 3% in men and 5% in women [106], which represents a substantial rise above the very low prevalence of <1% reported in 1985 [107]. Diabetes is clearly much more common in urban communities, for example 14% in Mexico City in 1994 [108], compared with a 5–10% prevalence nationwide [109]. Surveys in Brazil and Colombia in the early 1990s indicated age-adjusted prevalence rates of ~7% [110, 111]. A study in Brazil revealed a rate of self-reported diabetes of 10.1% [112]. A systematic review and meta-analysis of prevalence studies between 1980 and 2015 noted an increase in prevalence over the last three decades, from 7.4% (95% CI 7.1–7.7%) in the 1980s to 15.7% (9.8–24.3%) in the 2010s [113]. A high prevalence of abdominal obesity was noted in these populations, affecting more than 80% of women [109].

Europe

This region contains a diverse mix of countries that have marked differences in affluence and includes some of the most developed countries in the world. Nevertheless, updated nationwide survey data are only available in some countries. In the *IDF Diabetes Atlas*, data sources were available for 39 of the 59 European countries and territories, including recent data from the last five years for 14 countries [2]. National prevalence of diabetes ranged from 4.0% in Ireland to 15.9% in Turkey [2, 50] (Table 5.4).

United Kingdom

Type 2 diabetes imposes particular burdens on inner cities with multiethnic populations, as those originating from the Indian sub-continent have a high diabetes prevalence. In typical studies [114, 115], the age-adjusted prevalence rates were 3% and 5% in white European men and women, respectively, compared with 12% and 11% in their Asian counterparts in the UK. Asians also show a higher prevalence of impaired glucose tolerance, a male preponderance, a younger age at diagnosis, and a lower proportion of undiagnosed diabetes [115].

Poverty and social deprivation apparently contribute to the increasing prevalence of type 2 diabetes among inner-city residents: for example, in all ethnic groups in inner-city Manchester there was a surprisingly high age-standardized prevalence, including a rate of 20% among white Europeans [116]. Social deprivation, obesity,

Table 5.4 National estimates of diabetes in Europe in 2021.

physical inactivity, and smoking tend to co-segregate, which may explain this phenomenon. The importance of dietary factors was highlighted by two studies, which demonstrated an association between high dietary energy density or unhealthy dietary patterns (characterized by a high intake of sugar-sweetened beverages, burgers and sausages, and snacks) and incident type 2 diabetes [117, 118]. In the Ely Study, a population-based longitudinal study, the 10-year cumulative incidence of diabetes was 7.3 per 1000 person-years [119]. It has been estimated that the UK National Health Service spends at least £10 billion a year on diabetes, equivalent to ~10% of its budget, with 80% of this being spent on treating complications of diabetes [120].

Scandinavia and Nordic Countries

Here, the more homogenous population may indicate more accurately the true prevalence of type 2 diabetes among white Europeans. A survey in northern Sweden revealed a prevalence of diabetes of 8.1% in 2002 [121]. Similar data were obtained in a study in Finland, with the age-standardized prevalence of diabetes in 45–64-year-olds being 10.2% for men and 7.4% for women [122]. Lower prevalence data were noted for Iceland [123].

In the early 1990s type 2 diabetes was rare in northern Finland, but the prevalence of impaired glucose tolerance was 29% in men and 27% in women [124], comparable to that in a homogenous white female Swedish population aged 55–57 years (28%) [125]. In Denmark, ~15% of the population had impaired glucose tolerance in 2003 [126]. The high prevalence of impaired glucose tolerance in Finland prompted the Finnish Diabetes Prevention Study [127], which examined whether lifestyle changes could prevent the development of type 2 diabetes. Strikingly, nutritional advice and

increased physical activity reduced the risk of developing diabetes by 58% in people with impaired glucose tolerance, and the effect was sustained over subsequent follow-up [127]. A more recent study in three regions in Finland noted prevalence of impaired glucose tolerance of 10.5% and 9.2% in men and women, respectively, substantially lower than previously reported figures from northern Finland. It is unclear whether this difference is due to regional differences or to changes in the diabetes-to-impaired glucose tolerance ratio [122].

Using a register of people with diabetes, the calculated incidence rate of diabetes in Denmark was 1.8 per 100 000 at age 40 years and 10 per 100 000 at age 70 years. The incidence rate increased by 5% per year before 2004, but then stabilized. The lifetime risk of diabetes was estimated at 30% [128]. Another study in Finland noted an alarming increase in the incidence of type 2 diabetes among young adults, with the age-adjusted incidence of type 2 diabetes among 15–39-year-olds being 11.8 per 100 000 per year. The incidence rate increased by 7.9% per year. Interestingly, despite the country having the highest incidence of childhood type 1 diabetes in the world, the incidence of type 2 diabetes among young adults in Finland is approaching that of type 1 diabetes among the 15–39-year-old age group (age-adjusted incidence of type 1 diabetes 15.9 per 100 000 per year) [129].

Continental Europe

A population-based survey in Verona, Italy, revealed an overall prevalence of type 2 diabetes of 2.5%, which increased significantly after the age of 35 years [130]. In northern Italy, the age-adjusted prevalence of type 2 diabetes was 9% in men and 8% in women over the age of 44 years [131]. In a study that compared the prevalence of diabetes in Casale Monferrato in northwest Italy in 1988 and 2000, the age- and sex-adjusted prevalence of diabetes had increased from 2.1% in 1988 to 3.1% in 2000, with higher age-specific prevalence rates of diabetes in every age group in the later survey, including a twofold increase in the risk for those aged ≥ 80 years [132].

In France, the MONICA study estimated the adjusted prevalence of type 2 diabetes to be 7% in men and 5% in women aged 35–65 years and the adjusted prevalence of impaired fasting glucose to be 12% in men and 5% in women [133]. The prevalence of diabetes increased to 19% in men and 9% in women aged over 60 years [134]. In the more recent French Nutrition and Health Survey conducted between 2006 and 2007, the prevalence of diabetes according to elevated fasting plasma glucose or $\text{HbA}_{1c} \geq 6.5\%$ (48 mmol/mol) was 5.6%, with undiagnosed diabetes contributing to fewer than 20% of all cases of diabetes [135].

In the Netherlands, type 2 diabetes affects 8% of older white Dutch [136]; 65% of those with impaired fasting and post-load glucose levels went on to develop diabetes within six years [137]. In a prospective population-based study between 1998 and 2000, the age- and sex-adjusted prevalence of diagnosed diabetes was 2.2% at baseline and 2.9% after two years of follow-up, with people aged ≥ 70 years accounting for 50% of the population with type 2 diabetes [138].

In Greece, the prevalence of diabetes increased from 2.4% in 1974 to 3.1% in 1990 [139], as the population aged and obesity became more widespread [140, 141]. The prevalence of type 2 diabetes was 7.6% in men and 5.9% in women in a survey conducted between 2001 and 2002 [142]. In a follow-up study on those free of cardiovascular disease at baseline, the incidence rate of diabetes within a five-year period was 5.5% [143]. In Turkey, the overall prevalence rates of type 2 diabetes and impaired glucose

tolerance were 6% and 9%, respectively. Low levels of occupational activity, family history, and obesity were all associated risk factors [144, 145]. Adherence to a Mediterranean diet may have protective effects against diabetes [146].

Prevalence data from eastern Europe are comparatively sparse. The age-adjusted prevalence of type 2 diabetes for men and women in Fergana, Uzbekistan, was estimated to be 8% in both urban men and women, with impaired glucose tolerance affecting 5% of men and 6% of women. Lower prevalence rates for both type 2 diabetes and impaired glucose tolerance were reported for semirural inhabitants [147]. A survey in a rural area in the Sirdaria province of Uzbekistan confirmed similar age-adjusted prevalence rates of diabetes for men (10%) and women (7.5%). However, prevalence rates of impaired glucose tolerance in Sirdaria women (14%) and men (11%) were higher than for semiurban or urban inhabitants in Fergana [148]. In Russia, the estimated prevalence was 6% in men and 7% in women for diabetes and 6% and 13%, respectively, for impaired glucose tolerance; clustering of hyperlipidaemia, obesity, hypertension, and low 10-year survival was observed among those with diabetes [149]. A survey conducted in Moscow found a low incidence of reported diagnoses of diabetes (2%) [150], which was supported by another study based on self-reported doctor diagnoses [151]. In addition to underdiagnosis, undertreatment and infrequent insulin use are also likely to contribute to the burden of morbidity [151]. Many of the estimated prevalence data in other eastern European countries have been extrapolated from data from Poland, where the prevalence of type 2 diabetes increased from 3.7% to 10.8% between 1986 and 2000, with a similar increase in prevalence of impaired glucose tolerance from 2.9% to 14.5% [152].

South-East Asia

India

India is the second most populous country in the world and also second in terms of the number of people with diabetes, with ~ 69.2 million affected in 2015, a figure that is projected to rise to 123.5 million by 2040 [2]. Sequential surveys in India [153–156] indicate that the prevalence of diabetes has risen steadily since the 1970s, although methodological differences hamper direct comparisons between prevalence studies.

The National Urban Diabetes Survey, carried out in six cities in 2001, found age-standardized prevalence rates of 12% for diabetes (with a slight male preponderance) and 14% for impaired glucose tolerance; people ≤ 40 years old had prevalence rates of 5% (diabetes) and 13% (impaired glucose tolerance) [156]. Diabetes was positively and independently associated with increasing age, BMI, and waist/hip ratio, and a family history of diabetes, impaired glucose tolerance, higher monthly income, and physical inactivity. Impaired glucose tolerance showed associations with age, BMI, and family history of diabetes. Subsequent studies showed an increasing prevalence, with a prevalence rate of 14.3% reported in the Chennai Urban Rural Epidemiology Study (CURES-17) [157] and 18.6% in the city of Chennai in another study [158]. In the large Indian Council of Medical Research-INdiaDIABetes (ICMR-INDIAB) study involving $>13\,000$ adults across 188 urban and 175 rural sites in four different regions, the prevalence of diabetes was 10.4% in Tamil Nadu, 8.4% in Maharashtra, 5.3% in Jharkhand, and 13.6% in Chandigarh [159]. This gave rise to estimates of 62.4 million people with diabetes and 77.2 million people with pre-diabetes in India in 2011 [152]. In addition to the

increasing prevalence of diabetes, there appears to be a decreasing prevalence of impaired glucose tolerance [157]. Another secular trend is the shift towards younger onset of diabetes, especially in urban areas, where up to 36% of those with diabetes are aged ≤44 years [157, 158].

Urban–rural differences in the prevalence of diabetes have been consistently reported in different studies in India. A study in Chennai noted a progressive increase in prevalence rate with increasing urbanization: 2.4% in rural areas, 5.9% in semiurban areas, and up to 11.6% in urban areas [155, 160]. Likewise, more recent data revealed a prevalence of 18.6% in the city of Chennai compared with 16.4% in a town, and 9.2% in peri-urban villages [158]. In a study of 77 centres in India (40 urban and 37 rural), the standardized prevalence rate for diabetes in the total Indian, urban, and rural populations was 4.3%, 5.9%, and 2.7%, respectively. Although the prevalence rates of diabetes and impaired glucose tolerance are significantly higher in urban than rural areas, it appears that the rural–urban gradient is becoming increasingly attenuated [161]. In a recent nationwide cross-sectional study of 15 states in India, overall prevalence of diabetes was 7.3% (95% CI 7.0–7.5%), with 47.3% being undiagnosed. A further 10.3% (95% CI 10.0–10.6%) had pre-diabetes, with both diabetes and pre-diabetes showing large differences in prevalence between the different states [162].

The Chennai Population Study (CUPS) in 2008 reported alarming rates of incident diabetes (20.2 cases per 1000 person-years) [163]. This has been confirmed by a recent study, which reported an incidence of 22.2 per 1000 person-years, where 59% of those with pre-diabetes progressed to diabetes during a mean follow-up of 9.1 years [164]. Identification of those at high risk and increasing the awareness of the population are much needed. A risk score specific for the Indian population, the Indian Diabetes Risk Score (IDRS), has been developed. It utilizes four clinical variables: age, family history, regular exercise, and waist circumference. A score of >21 identifies those with diabetes with a sensitivity and specificity of close to 60% [165]. This will help target high-risk individuals for early intervention, since lifestyle modification is effective in reducing the progression from impaired glucose tolerance to diabetes in the Indian population [166]. The pilot phase of a National Programme on Diabetes, Cardiovascular Disease, and Stroke (NPCDS) was launched by the Ministry of Health and Family Welfare in 2008, with the aims of improving awareness of lifestyle-related diseases, disease prevention through screening and targeted intervention, and coordinating the multisector effort that is urgently needed to address the epidemic of obesity and diabetes in India [167].

Pakistan, Bangladesh, and Sri Lanka

The situation in these countries largely mirrors that in India. Diabetes is particularly common (16% of men, 12% of women) in the rural Sindh province in northern Pakistan [168]. A more recent study in Pakistan indicated similar prevalence rates of 10–11% in urban and rural men and urban women, although lower rates were seen in rural women (5%). However, impaired glucose tolerance rates in women were twice those in men [169]. Combining the data from the four provinces of Pakistan, the prevalence of diabetes in the urban areas was 6.0% in men and 3.5% in women, with a total of 22% of the urban population estimated to have some degree of glucose intolerance [170]. In rural Bangladesh, diabetes prevalence was reported in an older study to be 2.1% compared with an impaired glucose tolerance prevalence of 13%, despite a mean BMI

of only 20.4 kg/m² [171]. A recent study based on fasting glucose criteria alone that included >7000 adults reported a prevalence of 9.7% [172].

In addition to urbanization, the main factor for the high prevalence of diabetes and metabolic abnormalities among Asians is the tendency for central obesity and insulin resistance [9, 155, 173–175]. Despite being born smaller, with a lower birth weight, Indian babies have more body fat, which persists into adulthood, thus putting them at increased risk of cardiometabolic complications [176]. Interestingly, one study showed that maternal nutrition and, in particular, low maternal vitamin B₁₂ and high folate might be associated with increased adiposity and risk of type 2 diabetes in the offspring [177], suggesting that in addition to increased intake of fat and calorie-rich foodstuffs, other dietary factors may play a contributory role.

Mauritius

The high prevalence of diabetes and cardiovascular disease on the island of Mauritius, in the Indian Ocean, has been intensively studied. Here, diabetes is common in an urbanized setting: across several ethnic groups (Asian Indian, Chinese, and Creole) in 1990 the prevalence rates were 10–13%, rising to 20–30% in those aged 45–74 years [178]. A repeat survey in 1998 revealed a rise in prevalence of type 2 diabetes to 17.9%. In both studies, the highest prevalence was seen in Asian Indians [178, 179]. The age-standardized prevalence of diabetes in 2009 was 22.3% among men and 20.2% among women, representing an increase of over 60% compared with figures from 1987 [180].

Middle East

Marked socioeconomic changes in many countries in the region, especially among the affluent oil-producing countries, have led to dramatic changes in lifestyle, with changes in nutritional intake, decreased physical activity, and increased obesity and smoking. This, coupled with increasing urbanization and improved life expectancy, has led to a marked increase in the prevalence of diabetes and impaired glucose tolerance (Table 5.5). A recent review of the prevalence of diabetes in the Middle East highlighted the paucity of data and large differences in prevalence rates among different countries. Obesity and age appeared to be the main drivers of high prevalence [193]. Saudi Arabia, Kuwait, and Qatar are among the countries with the highest prevalence rates of diabetes [2], highlighting this region as one that requires concerted public health action to reduce the potential impact of diabetes [194].

North Africa

Egypt is among the top 10 countries with the highest burden of people with diabetes [2]. Prevalence rates are also relatively high (3–8%) in Sudan and Tunisia. An Egyptian study of adults aged >20 years showed an impaired glucose tolerance prevalence rate of 10% [195]. Urban–rural differences were demonstrated: in Cairo city diabetes was more common (prevalence 14–20%, depending on socioeconomic status), whereas the impaired glucose tolerance prevalence was lower (6–9%). The converse applied in a rural setting, with a diabetes prevalence of only 5% but a higher impaired glucose tolerance prevalence of 13%. This may reflect the diabetes epidemic being at an earlier stage in rural populations. In the Tunisian National Nutrition Survey, the prevalence of diabetes was 9.9%, giving an age-adjusted prevalence of 8.5%, with marked urban–rural differences [196].

Table 5.5 Prevalence of diabetes from reported epidemiology studies in selected countries in the Middle East.

Year	Country [Reference]	Prevalence (%)	
		Type 2 diabetes	Impaired glucose tolerance
1998	Lebanon [181]	13.2	6.0
2006	Oman [182]		
	Men	11.8	
2000	Women	11.3	
	Oman [183]		
1995	Men	11.8	7.1 (IFG)
	Women	11.6	5.1 (IFG)
2011	Oman [184]		
	Men	9.7	8.1
2000	Women	9.8	12.9
	Saudi Arabia [185]		
1995	Men	34.7	
	Women	28.6	
2014	Saudi Arabia [186]		
	Men	26.2	14.4
1992	Women	21.5	13.9
	Saudi Arabia [187]		
2014	Men	11.8	10.0
	Women	12.8	9.0
2014	Iran [188]		
	Urban men	7.1	8.9
2014	Urban women	7.6	14.9
	Rural	7.3	7.2

2009	Qatar [192]	16.7	
	Men	15.2	
	Women	18.1	

IFG, Impaired fasting glycaemia.

Western Pacific region

Australia

The first report of the AusDiab Study [197], published in 2000, provides information about diabetes in a high-income country. The overall prevalence of diabetes in Australians aged ≥ 25 years was 7.5% (8% for men and 7% for women), rising from 2.5% in those aged 25–44 years to 24% among those aged ≥ 75 years; the prevalence had more than doubled since 1981 [198, 199]. Around 50% of cases discovered in this survey were previously undiagnosed. The combined prevalence of impaired fasting glucose and impaired glucose tolerance was 16% (men 17%, women 15%); hence almost 25% of Australians aged ≥ 25 years have abnormal glucose metabolism. In Australia, type 2 diabetes accounts for over 85% of cases and type 1 diabetes for 10%. Using data from the AusDiab study, it has been estimated that the prevalence of diabetes is likely to rise from 7.6% in 2000 to 11.4% by 2025 [200]. In the 2012 AusDiab Study Report, the annual incidence of diabetes was reported to be 0.8% per year for men and 0.6% per year for women [201].

Type 2 diabetes is commoner in Indigenous Australian populations, for example 16–30% of adults in the Aboriginal and Torres Strait Islander communities [202]. In this population, diabetes was associated with higher rates of hypertension (69% vs 21%), obesity (44% vs 16%), elevated triglyceride, and lower HDL cholesterol concentrations compared with those who have normal glucose tolerance.

New Zealand

In New Zealand, type 2 diabetes is consistently commoner among Polynesians (Māoris and Pacific Islanders) than in white New Zealanders: it accounts for 89% of diabetes in white New Zealanders and 95% in Polynesians. Polynesians are also diagnosed, on average, 5–10 years younger than white New Zealanders and have a four- to eightfold higher prevalence of diabetic nephropathy. Strikingly high prevalence rates of diabetic nephropathy of 37–75% were reported for unemployed men, emphasizing again the role of socioeconomic status [203]. In the 2006–2007 New Zealand Health Survey, prevalence rates reported for adults aged >30 years were 4.3% for white New Zealanders, 5.8% for Māoris, 6.5% for Asians, and 10.0% for Pacific Islanders [204, 205].

Pacific Island countries

The Melanesian, Micronesian, and Polynesian populations of the Pacific Islands show great variations in diabetes prevalence, largely attributable to differences in economic development and lifestyle. Some of the highest prevalence rates worldwide come from this region, notably from Nauru and Papua New Guinea. The Micronesian population of Nauru, made wealthy by bauxite mining and with a longer history of Westernization than other Pacific Island countries, currently has an age-standardized prevalence rate of 40%. High prevalence rates in Nauru have been maintained since the late 1970s, but now appear to have stabilized as bauxite mining is exhausted [43, 206].

Fiji has a largely biethnic population consisting of native Fijians of Melanesian ancestry together with migrants from India. Recent surveys from Fiji are lacking, but a survey conducted over 30 years ago showed that diabetes prevalence rates were already higher among Indian migrants than in Melanesians. In adults above 20 years of age, crude prevalence rates were 13% among Indian migrants (with no significant urban–rural gradient), but 7% and 1.7% among urban and rural Melanesians, respectively [207]. At the time, these results were thought to indicate a difference in ethnic (genetic) predisposition, but this conclusion has since been tempered by the finding of high prevalence rates in urbanized Melanesians in Papua New Guinea.

The situation in Papua New Guinea provides an excellent example of the damage inflicted by rapid urbanization: diabetes is virtually non-existent in highland populations [208], in stark contrast to the age-standardized prevalence rate of over 40% among urbanized Koki people (Melanesians) in Port Moresby [209]. Intermediate rates are reported in Austronesians of coastal ancestry.

High prevalence rates of diabetes have been reported in Polynesian populations, conspicuously associated with obesity, both conditions being particularly common in Polynesian women. In Western Samoa, diabetes prevalence was reported in 1991 to be 7–9% in two rural communities and 16% in Apia; the prevalence had doubled since 1978 [210]. In the Kingdom of Tonga, situated south of Samoa, the age-standardized prevalence of diabetes was 15.1%, of which 80% was undiagnosed [211].

Diabetes remains undiagnosed in most Pacific Island people with the disease, perhaps 80–100% in some communities, compared with around 25–50% in high-income countries [199]. This is likely to contribute to high rates of complications and frequent presentation with diabetes-related problems, such as foot sepsis [212].

Japan

Type 2 diabetes has become commoner in Japan since the 1960s, and data from rural parts of the country suggested a prevalence of 9.1% in men and 10.8% in women, with corresponding impaired glucose tolerance prevalence rates of 12% and 16.5% for Japanese men and women, respectively [213]. A National Diabetes Survey conducted in 2002 estimated a prevalence of 9% [214]. In the National Health and Nutrition Survey in 2007, it was estimated (using HbA_{1c}) that the prevalence of diabetes was 15.3% in men and 7.3% in women [215]. The emerging problem of type 2 diabetes among Japanese children is now recognized as a critical problem in that country. Type 2 diabetes cases outnumber type 1 diabetes in children and adolescents by a ratio of 4 : 1 [216], and the incidence rate of type 2 diabetes for 1981–1990 was 4.1 per 100 000 person-years, approximately twice the incidence rate of type 1 diabetes [217]. Nutritional factors are believed to play an important part, with the prevalence of diabetes among Japanese Americans approximately twice that among Japanese in Japan [218].

The causes of death in people with type 2 diabetes have also shifted, possibly because of Westernization of diet and increased fat and total calorie intake; higher death rates from renal disease than in white European populations are now being supplanted by rising deaths from coronary artery disease [219]. To reduce the burden of diabetes, the Japanese government has launched a large national strategic research project named J-DOIT to reduce diabetes, improve follow-up, and reduce complications of diabetes [220].

Korea

In the Korean National Health and Nutrition Survey conducted in 2001, the age-adjusted prevalence of diabetes was reported to be 7.6%. The prevalence of impaired fasting glucose was an alarming 23.9% [221], suggesting a future epidemic of diabetes in the Korean population, similar to that in other Asian countries [222]. In the Korean National Health and Nutrition Survey conducted in 2010–2012, the prevalence of diabetes was reported to be 10.1% [223].

China and Chinese populations

The rapid increase in the prevalence of type 2 diabetes in China provides one of the most striking examples of the impact of urbanization on increasing diabetes prevalence. China, with its current population of nearly 1.4 billion, is the world's most populous country. Diabetes used to be rare: prevalence rates reported between 1980 and 1990 were consistently $\leq 1.5\%$ even in urban areas such as Shanghai [224], and as low as 0.3% in rural Guangdong province. Recently, however, the prevalence has risen rapidly, a trend first demonstrated by studies conducted in the Da Qing area of north-eastern China. There, the prevalence in 1986 was 1.0%, but by 1994 it had increased over threefold to 3.5% [225, 226]. The 1994 survey of 200 000 people aged 25–64 years in 19 provinces that included Da Qing found overall prevalence rates of 2.3% for diabetes and 2.1% for impaired glucose tolerance. A community-based survey of

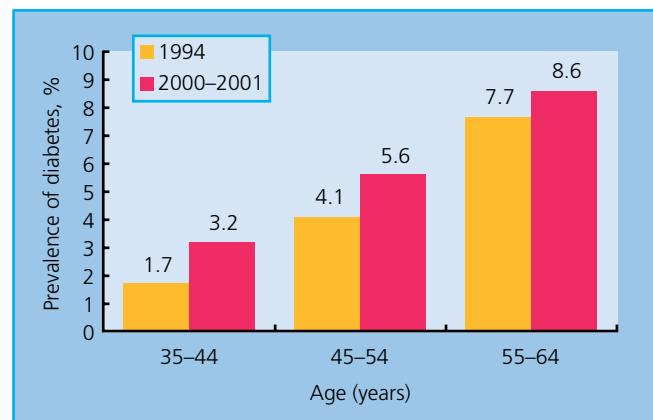

Figure 5.4 Changes in prevalence of diabetes among Chinese adults aged 35–64 years. Source: Data from the 1994 Chinese National Survey and the 2000–2001 InterASIA study; Gu et al. 2003 [228].

40 000 people aged 20–74 years in China between 1995 and 1997 confirmed this rising trend and also demonstrated urban–rural gradients in prevalence rates. Age-standardized prevalence rates were 3.2% for diabetes and 4.8% for impaired glucose tolerance, with the highest prevalence in provincial cities and the lowest in rural areas [227]. The International Collaborative Study of Cardiovascular Disease in Asia, conducted in 2000–2001, revealed a further increase in the prevalence of diabetes (undiagnosed and diagnosed) to 5.5%, with another 7.3% affected by impaired glucose tolerance [228] (Figure 5.4). Furthermore, among the 20 million Chinese people estimated to have diabetes based on fasting blood glucose, only 30% were previously diagnosed [228]. The large proportion of those with impaired glucose tolerance is particularly alarming. In the community-based Shanghai Diabetes Study, people with impaired glucose tolerance and/or impaired fasting glycaemia had an 11.7-fold increased risk of diabetes compared with those with normal glucose tolerance over a three-year follow-up period [229].

Chinese populations in affluent societies such as Hong Kong SAR, Singapore, Taiwan, and Mauritius all show higher prevalence rates compared with mainland China. In Hong Kong, the prevalence of diabetes increased from 8% to 10% between 1990 and 1995 [230, 231]. Studies in Taiwan indicate prevalence rates of 9–11%, although methodological discrepancies make direct comparisons difficult [224]. The annual incidence rate in Taiwan was reported in 1997 to be 1.8% [232]. In a review summarizing the findings from prevalence studies conducted in Chinese populations in 1995–2003, it was noted that Chinese people in Hong Kong and Taiwan have a 1.5–2.0-fold increased risk of diabetes adjusted for age and diagnostic criteria compared with their mainland counterparts [233].

The rapid increase in diabetes prevalence in China is likely to have been driven by the increase in obesity, particularly among children and adolescents [9, 234]. The 2002 National Nutrition and Health Survey noted a prevalence of overweight of 4.1% among children aged 7–12 years and 5.6% among those aged 12–18 years, with obesity rates of 2.5% and 1.6%, respectively [235]. In Hong Kong, a community-based study involving >2000 adolescents aged 11–18 years found alarming rates of obesity, with 8–10% of those aged 12–13 years fulfilling criteria for obesity [236]. In a national screening programme among schoolchildren in Taiwan between 1992 and 1999, the rate of newly identified diabetes was 9.0 per

100 000 for boys and 15.3 per 100 000 for girls. Obesity was found to be the major risk factor for the development of type 2 diabetes, where children with BMI in the ≥95th percentile had an ~19-fold increase in risk of type 2 diabetes compared with those with BMI in the <50th percentile [237].

Such alarming data for Chinese populations highlight the potential for further rises within China itself. Unless effective measures can be implemented, given the huge population of China, the consequences could be devastating. Indeed, two recent large nationwide epidemiological studies, involving >46 000 and 98 000 adults, respectively, reported diabetes prevalence rates of 9.7% in 2008 [238] and (if including elevated HbA_{1c} as a diagnostic criterion) 11.6% in 2010 [239]. This translates to a staggering estimate of 92.4 million individuals with diabetes and 148.2 million adults with pre-diabetes in China in 2008 [238].

South-East Asian Peninsula

There is considerable economic diversity within this region, although the recent emerging data showed that despite the relatively traditional lifestyle in many of the countries, diabetes is increasingly common within the region. A survey performed in two villages in Cambodia in 2004 revealed a diabetes prevalence rate of 5% in the rural community in Siem Reap but up to 11% in a semiurban community [240]. A study conducted in adults in Ho Chi Minh City in southern Vietnam indicated that the prevalence of diabetes increased substantially from 2.5% in 1993 to 3.8% in 2001 [241]. A more recent study using data from 2013 reported an age-standardized prevalence of 6.0% [242]. Similar increases have been reported in Indonesia [243] and the Philippines [244]. Prevalence rates in Thailand appear to be approaching those reported in Malaysia and Singapore, with prevalence of diabetes and impaired glucose tolerance in a 2004 national survey reported to be 6.7% and 12.5%, respectively [245].

In Singapore, serial studies since 1975 showed a rising prevalence of diabetes from 2% in 1975 to 4.7% in 1984, 8.6% in 1992, and 9% in 1998. Two more recent surveys indicate that the rate of rise may have stabilized. Ethnic Indians and Malays (especially Malay women) have the highest rates of diabetes (16.7–14.3%) and also the highest rates of obesity. A further 15% of the adult population have impaired glucose tolerance. In a survey conducted in 2004 by the Ministry of Health, Singapore, the prevalence of diabetes among the adult population was estimated to be 8.2% [246]. A more recent survey conducted by the Ministry of Health in 2010 noted a diabetes prevalence of 11.3% [247]. Obesity and adoption of a Westernized diet and lifestyle are again closely associated. Type 2 diabetes in childhood is also highlighted as an emerging problem. The prevalence of diabetes increased by more than twofold over 20 years in Malaysia, with the most recent nationwide survey reporting a prevalence of 22.6%, compared with a prevalence of 11.6% in 2006 [248].

Impact of diabetes

The epidemic of diabetes has a major impact on both personal and societal aspects. The major burden of diabetes stems from the treatment cost of its complications, such as stroke, blindness, coronary artery disease, renal failure, amputation, and infection. An estimated 6.7 million adults died of diabetes and its related diseases in 2021 [2]. Most people die from cardiovascular disease (particularly coronary artery disease and stroke) and end-stage renal disease. In a study on the trends in the incidence of diabetes-related

complications in the USA, the rates of lower-extremity amputations, end-stage renal disease, acute myocardial infarction, stroke, and death from hyperglycaemic crisis declined from 1990 to 2010, although there remains a substantial healthcare burden due to the rising diabetes prevalence [94].

There are geographical differences in both the magnitude of these problems and their relative contributions to overall morbidity and mortality [242]. In white European and American populations, macrovascular complications, such as coronary artery disease and amputation, are major causes of disability. In contrast, end-stage renal disease and stroke are more prevalent among Chinese and Asian ethnic groups [13].

The occurrence of vascular complications of diabetes is related to the duration of hyperglycaemia. With the earlier onset of type 2 diabetes, more people will have an increased risk of developing these complications [249–251]. Despite the high prevalence of complications of diabetes and hence the high costs of management, simple, inexpensive measures are effective in preventing the development of diabetes and its vascular complications. Rather than merely focusing on the management of hyperglycaemia, global risk reduction with attention to cardiovascular risk factors has been found to be the most effective way of reducing the burden of diabetes. The challenge is to provide a platform whereby effective care can be delivered at an affordable cost [1].

Mortality and morbidity

Diabetes is associated with approximately twofold increased mortality in most populations, with the excess risk decreasing with increasing age [1, 252–254]. Although initial data suggest that the excess mortality associated with diabetes may be higher in Asian populations, this is probably related to differences in death certificate coding practices [255–257]. It was recently estimated that diabetes accounted for 12.2% of global all-cause mortality among people aged 20–79 years, with close to half of deaths due to diabetes being in people under the age of 60 years [2].

The most systematic comparative data, using standardized methodology, originate from the WHO Multinational Study of Vascular Disease in Diabetes, which has drawn from 14 centres in 13 countries since the 1980s. A follow-up report from 10 of these centres [258] shows that coronary heart disease and limb amputation rates varied 10–20-fold among different centres; there was also marked variation in the prevalence of clinical proteinuria and renal failure, but less variation in retinopathy and severe visual impairment. Striking features include the relative rarity of ischaemic heart disease and lower-extremity amputation in Hong Kong and Tokyo, contrasting with a high incidence of stroke, especially in Hong Kong. A high incidence of stroke was also found in Arizona and Oklahoma, the two Indigenous American centres. The highest rates of ischaemic heart disease were seen in the European centres, notably among women in Warsaw. Myocardial infarction was also common in Indigenous Americans, especially among men, while renal failure and proteinuria rates were highest among Indigenous Americans and in Hong Kong.

Other issues include the apparent vulnerability of Pacific Island populations to diabetes-related foot problems associated with neuropathy and of South Asians to coronary heart disease [42]. Importantly, the risk of coronary heart disease is already increased twofold at the stage of impaired glucose tolerance [259].

Another cause of morbidity and mortality that is increasingly recognized is the increased risk of cancer in people with diabetes. Various epidemiological studies in different populations have

suggested a link between diabetes and increased risk of pancreatic, hepatocellular, endometrial, breast, and colorectal carcinoma [260–262]. Although some of this may be due to the presence of common risk factors, such as obesity and dietary factors, a large prospective study demonstrated that cancer risk increases with increasing fasting glucose at baseline [263]. In a large population-based study in Australia, both type 1 diabetes and type 2 diabetes were associated with increased risk of incidence and mortality for cancer overall and for a number of site-specific cancers [264].

Intensive multifactorial interventions to reduce cardiovascular risk factors are effective in reducing cardiovascular mortality in diabetes [265, 266]. Although intensive blood glucose management does not lower cardiovascular mortality in the short term [267, 268], it may have beneficial effects in reducing cardiovascular and total mortality in the longer term, as suggested by long-term follow-up data from the UK Prospective Diabetes Study (UKPDS) [269]. It appears that the relative mortality of diabetes is decreasing in some countries [270, 271], and this may be related to the increased utilization of drugs to manage hyperlipidaemia, hyperglycaemia, and hypertension [272].

Healthcare burden and economic costs

The increase in the prevalence of diabetes, particularly among young adults, along with the increased morbidity and mortality associated with microvascular and macrovascular complications, is likely to lead to an escalation of healthcare costs and reduced economic growth. The IDF estimated that in 2021, diabetes-related health expenditure would reach US \$379.5 billion in the USA, \$165.3 billion in China, and \$42.9 billion in Brazil [2]. The global health expenditure for diabetes in 2021 was estimated to be \$966 billion, of which close to half would have been spent in North America (~\$415 billion) and one-quarter in Asia (\$241.3 billion). In the USA, the estimated total costs (direct and indirect) of diabetes increased from \$23 billion in 1969 to \$132 billion in 2002 [273, 274]. The cost of diabetes in the USA in 2007 was estimated by the ADA to be \$174 billion, which includes \$116 billion in excess medical expenditures and \$58 billion in reduced national productivity [275]. These estimates were revised in 2017 to a total estimated cost of diagnosed diabetes of \$327 billion, including \$237 billion in direct medical costs and \$90 billion in reduced productivity [97]. The largest components of medical expenditures attributed to diabetes are hospital inpatient care and medications to treat complications of diabetes and anti-diabetes medications, diabetes supplies, and more clinic visits [97]. However, the actual burden is likely to be even greater, since other non-monetary effects such as changes in quality of life, disability and suffering, care provided by unpaid caregivers, and other factors cannot be included in such analyses. The burden of diabetes affects all sectors of society, including higher insurance premiums paid by employees and employers, reduced earnings through productivity loss, and reduced overall quality of life for people with diabetes and their families and friends.

The cost of medical care for diabetes varies greatly among the different regions (Table 5.6). Although it is a very costly disease, interventions used to prevent or manage diabetes differ greatly in their cost-effectiveness [277]. The cost-effectiveness and feasibility of diabetes interventions in developing countries, as assessed by the World Bank, are listed in Table 5.7. Cost-effective interventions that are technically and culturally feasible should be implemented with the highest priority [278].

Table 5.6 Estimated direct medical costs of diabetes by region, 2003.

Region	Direct medical costs (US\$ millions)	
	Low estimate	High estimate
Developing countries	12 304	23 127
East Asia and Pacific	1368	2656
Europe and Central Asia	2884	5336
Latin America and the Caribbean	4592	8676
Middle East and North Africa	2347	4340
South Asia	840	1589
Sub-Saharan Africa	273	530
Developed countries	116 365	217 760
World	128 669	240 887

Prevention of type 2 diabetes

There are entirely too many diabetic patients in the country. Statistics for the last thirty years show so great an increase in the number that, unless this were in part explained by a better recognition of the disease, the outlook for the future would be startling. Therefore, it is proper at the present time to devote attention not alone to treatment, but still more, as in the campaign against the typhoid fever, to prevention. The results may not be quite so striking or as immediate, but they are sure to come and to be important.

(Elliot Joslin, 1921)

Given the cost of diabetes, it is essential to prevent or delay the onset of diabetes and its associated complications. With improved understanding of the natural history of the development of type 2 diabetes and the role of various modifiable risk factors in its pathogenesis, several randomized clinical trials have examined the effect of lifestyle intervention to prevent type 2 diabetes. A large body of evidence has accumulated from these studies on the effectiveness of lifestyle measures in the prevention of diabetes, as summarized in Table 5.8. Most of these interventions include structured education and exercise programmes, reducing fat intake and increasing fibre intake, moderate exercise for at least 30 min per day, and moderate weight reduction of $\geq 5\%$. Importantly, in addition to being highly cost-effective, the effect of structured lifestyle intervention on reduction of diabetes risk appears to be maintained over a long duration of follow-up [269, 270]. In a follow-up of the China Da Qing Diabetes Prevention Study, participants who received lifestyle intervention had a 51% lower incidence of diabetes during the six-year active intervention period and a 43% lower incidence of diabetes over 20 years [285]. Furthermore, with follow-up extended to 23 years, those randomized to lifestyle intervention had a 41% reduction in cardiovascular mortality and a 29% reduction in all-cause mortality [280].

In addition to lifestyle intervention, several drugs used in the treatment of type 2 diabetes and obesity have been evaluated in clinical trials and are effective in preventing diabetes, including metformin, the thiazolidinedione class of compounds, acarbose, orlistat, and insulin itself (Table 5.9). The largest body of evidence for pharmacological prevention of diabetes is with metformin

Table 5.7 Summary of cost-effectiveness of interventions for treatment and prevention of diabetes.

Intervention	Cost/QALY (2001 US\$)							
	East Asia and Pacific	Europe and Central Asia	Latin America and Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa	Feasibility ^a	Implementing priority ^b
<i>Level 1</i>								
Glycaemic management in people with HbA _{1c} ≥ 9% (75 mmol/mol)	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	++++	1
Blood pressure control in people with pressure >160/95 mmHg	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	++++	1
Footcare in people with a high risk of ulcers	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	++++	1
<i>Level 2</i>								
Pre-conception care for women of reproductive age	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	++	2
Lifestyle interventions for preventing type 2 diabetes	80	100	130	110	60	60	++	2
Influenza vaccinations among old people for type 2 diabetes	220	290	360	310	180	160	++++	2
Annual eye examination	420	560	700	590	350	320	++	2
Smoking cessation	870	1170	1450	1230	730	660	++	2
ACE inhibitor use for people with diabetes	620	830	1020	870	510	460	+++	2
<i>Level 3</i>								
Metformin intervention for preventing type 2 diabetes	2180	2930	3630	3080	1820	1640	++	3
Cholesterol management for people with total cholesterol >200 mg/dl (5.2 mmol/l)	4420	5940	7350	6240	3680	3330	+++	3
Intensive glycaemic management for people with HbA _{1c} ≥ 8% (64 mmol/mol)	2410	3230	4000	3400	2000	1810	++	3
Screening for undiagnosed diabetes	5140	6910	8550	7260	4280	3870	++	3
Annual screening for microalbuminuria	3310	4450	5510	4680	2760	2500	++	3

^a Feasibility was assessed based on difficulty of reaching the intervention population (the capacity of the healthcare system to deliver an intervention to the targeted population), technical complexity (the level of medical technologies or expertise needed for implementing an intervention), capital intensity (the amount of capital required for an intervention), and cultural acceptability (appropriateness of an intervention in terms of social norms and/or religious beliefs). ++++ indicates feasible for all four aspects, +++ indicates feasible for three of the four, ++ indicates feasible for two of the four, and + indicates feasible for one of the four.

^b Implementing priority was assessed by combining the cost-effectiveness of an intervention and its implementation feasibility; 1 represents the highest priority and 3 represents the lowest priority.

ACE, angiotensin-converting enzyme; QALY, quality-adjusted life-year.

treatment, which was associated with a ~40% reduction in risk of diabetes in a meta-analysis [291]. In addition, several clinical trials indicated that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers may reduce incident diabetes in high-risk people with hypertension [292–296]. A large randomized clinical trial compared the ACE inhibitor ramipril with placebo in people with impaired glucose tolerance or impaired fasting glycaemia. It did not show a significant reduction in incident diabetes after a median follow-up of three years, although ramipril was associated with increased regression to normoglycaemia [297]. In a recent pooled analysis of individual participant data from two phase 3, randomized, double-blind clinical trials, treatment with the sodium-glucose cotransporter 2 (SGLT-2) inhibitor dapagliflozin was associated with a 33% reduction in the development of type 2 diabetes over a median follow-up of 21.2 months [298].

Many pharmacological agents are currently in development or undergoing clinical trials for the treatment of type 2 diabetes or obesity, which should provide a constant supply of promising agents for evaluation in their effectiveness for preventing type 2

diabetes. At present, however, lifestyle intervention remains more cost-effective as a strategy for diabetes prevention. Recent prevention studies have also demonstrated the effectiveness of using mobile phone messaging or other aids to deliver support for lifestyle modification or person empowerment [299]. Among those who have morbid obesity, bariatric surgery has a significant impact on glycaemic levels and >60% of individuals with diabetes and severe obesity experience remission after gastric bypass surgery [300]. In the three-year follow-up of people with severe obesity who underwent bariatric surgery in the USA, the incidence of diabetes was 0.9% after Roux-en-Y gastric bypass and 3.2% after laparoscopic gastric banding [301].

Given the increased appreciation of the important role of the intrauterine environment and early development in modifying the risk of non-communicable diseases, it is increasingly recognized that pregnancy represents a critical period that requires optimal maternal nutrition [302], and also has long-term consequences for the health of the offspring. Therefore, diabetes and non-communicable disease prevention efforts now include

considerations of primordial prevention, whereby measures to avoid the establishment of different environmental, social, behavioural, and physical exposures that may impair long-term health start early, including pre-conception and the pregnancy period [1, 303].

Remission of type 2 diabetes

While type 2 diabetes is traditionally considered to be an irreversible and progressive disease, the twin cycle hypothesis from Taylor in 2008 posited that type 2 diabetes arises as a result of long-term excessive energy intake, accompanied by accumulation of liver fat, hepatic insulin resistance, hyperinsulinemia, ectopic pancreatic fat accumulation, and impaired β -cell function [304]. It was therefore postulated that weight loss sufficient to reverse this may lead to durable remission of hyperglycaemia [305]. In a landmark proof of concept, 11 individuals with type 2 diabetes were started on a 600 kcal/d diet for eight weeks, during which they lost a mean 15 kg, and achieved normalization of hepatic insulin sensitivity, β -cell function, and blood glucose, accompanied by decreased liver and pancreas triacylglycerol stores [306]. In a subsequent open-label, cluster randomized trial in a primary care setting involving 306 participants with short duration of type 2 diabetes and BMI of 27–45 kg/m², of those who were recruited into a weight management programme involving caloric restriction and total diet replacement, withdrawal of diabetes and blood pressure medications, and structured support for long-term weight loss maintenance, 24% of participants in the intervention arm achieved a weight loss of ≥ 15 kg, while 46% of those in the intervention arm achieved diabetes remission [307]. A consensus report has now

defined remission as HbA_{1c} < 6.5% (48 mmol/mol) measured at least three months after cessation of glucose-lowering pharmacotherapy as the diagnostic criterion [308]. As there is an increasing number of programmes to implement caloric restriction and weight loss, as well as population-based studies on diabetes remission based on these criteria, future epidemiological studies would need to consider the impact of diabetes remission in consideration of diabetes prevalence.

More detailed discussion on epidemiological aspects of diabetes can be found elsewhere [309].

Conclusion

The interaction between genetic predisposition, the popularization of fast food, and a sedentary lifestyle, in addition to ageing of the general population, plays a major role in the increase in the prevalence of impaired glucose tolerance and type 2 diabetes globally. Countries in the Asia-Pacific and Africa regions with a growing economy will bear the major burden in the increase in number of people with diabetes. The significant increase in macro- and microvascular complications of diabetes places a heavy burden on healthcare resources. Studies have confirmed the benefit of intensive multifactorial risk management in reducing all-cause mortality and cardiovascular adverse events. Measures such as weight reduction and exercise are effective in preventing the progression of impaired glucose tolerance to diabetes. Hence, despite being one of the commonest chronic diseases, diabetes can be prevented or managed effectively with interventions that are relatively cost-effective compared with the cost of treating the micro- and macrovascular complications.

Overview of Glucose Metabolism

Richard I.G. Holt

Professor in Diabetes & Endocrinology, Human Development and Health, University of Southampton, Faculty of Medicine, Southampton, UK

Honorary Consultant Physician, Southampton National Institute for Health Research Biomedical Research Centre, University Hospital Southampton NHS Foundation Trust, Southampton, UK

Key points

- Under normal physiological conditions, blood glucose levels are maintained within narrow limits.
- The tight regulation of glucose is necessary because some tissues, particularly the brain, are highly dependent on glucose as an energy source.
- Insulin, produced by the β cells of the pancreatic islet, is the key hormone involved in the regulation of cellular energy supply and macronutrient balance derived from food. Insulin increases the uptake and storage of glucose in liver, adipose tissue, and skeletal muscle.
- Several hormones including glucagon, catecholamines, corticosteroids, and growth hormone antagonize the actions of insulin and are collectively known as the counter-regulatory hormones.
- The key insulin-sensitive tissues are the liver, skeletal muscle, and adipose tissue.
- The liver is the principal organ of glucose homeostasis; in the post-absorptive state, the liver stores glucose as glycogen, a large highly branched glucose polymer. The liver also possesses the ability to produce glucose for utilization by other tissues by breaking down glycogen (glycogenolysis) or *de novo* glucose synthesis (gluconeogenesis).
- Muscle glycogen synthesis accounts for ~90% of insulin-stimulated whole-body glucose disposal and for virtually all the non-oxidative glucose disposal in healthy humans.
- The incretin hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), act as β -cell sensitizers potentiating glucose-induced insulin secretion when glucose concentrations are above 4–5 mmol/l and suppressing glucagon secretion in a similarly glucose-dependent manner.
- The gastrointestinal system influences glucose metabolism through the microbiome, a diverse collection of over 1000 bacterial species that live within the gut, through as yet poorly defined mechanisms.
- The brain plays an important role in coordinating the multiple responses from pancreas, liver, and other tissues to regulate glucose levels.
- The kidney makes a unique contribution to glucose homeostasis by controlling glucose reabsorption from renal tubules following glomerular filtration and, apart from the liver, is the only organ with sufficient gluconeogenic enzyme activity to contribute to gluconeogenesis.

Under normal physiological conditions, blood glucose levels are maintained within narrow limits and in health rarely stray outside the range of 3.5–8.0 mmol/l (63–144 mg/dl). This is despite wide variations in glucose supply during eating and demand during fasting and exercise. The tight regulation of glucose is necessary because some tissues, particularly the brain, are highly dependent on glucose as an energy source. The brain relies on glucose as its primary fuel source and utilizes ~20% of whole-body glucose supplies, despite constituting only ~2% of total body weight (Chapter 10) [1]. Its requirement is 1 mg/kg body weight per minute, or ~100 g daily in a 70 kg person. The brain requires a continuous supply of glucose from the circulation for normal function because it can neither synthesize glucose nor store more than a few minutes' supply as glycogen. Furthermore, it is unable to use alternative fuel sources such as amino acids, ketones, and lactate effectively at physiological concentrations. Glucose uptake by the brain is not dependent on insulin, but is obligatory depending on an adequate glucose concentration to cross into the brain.

By contrast, the body cannot tolerate high glucose concentrations, because these irreversibly damage cellular proteins and cause irreversible tissue damage, as is seen in people with diabetes-related microvascular complications (Chapter 42). The body has developed a highly complex feedback system involving multiple organs including the brain, pancreatic islets, liver, and other tissues that coordinate the regulation of glucose homeostasis (Figure 6.1).

The following chapters in this section describe how individual tissues and hormones regulate glucose. Rather than repeat what follows, this chapter is short by design, but its purpose is to provide an overview of glucose metabolism.

Pancreatic islets of Langerhans

Mammalian pancreatic islets typically contain ~1000 endocrine cells; these cells include the β cells (~60% of adult human islet cells) that produce insulin, α cells (20–30%) that produce glucagon,

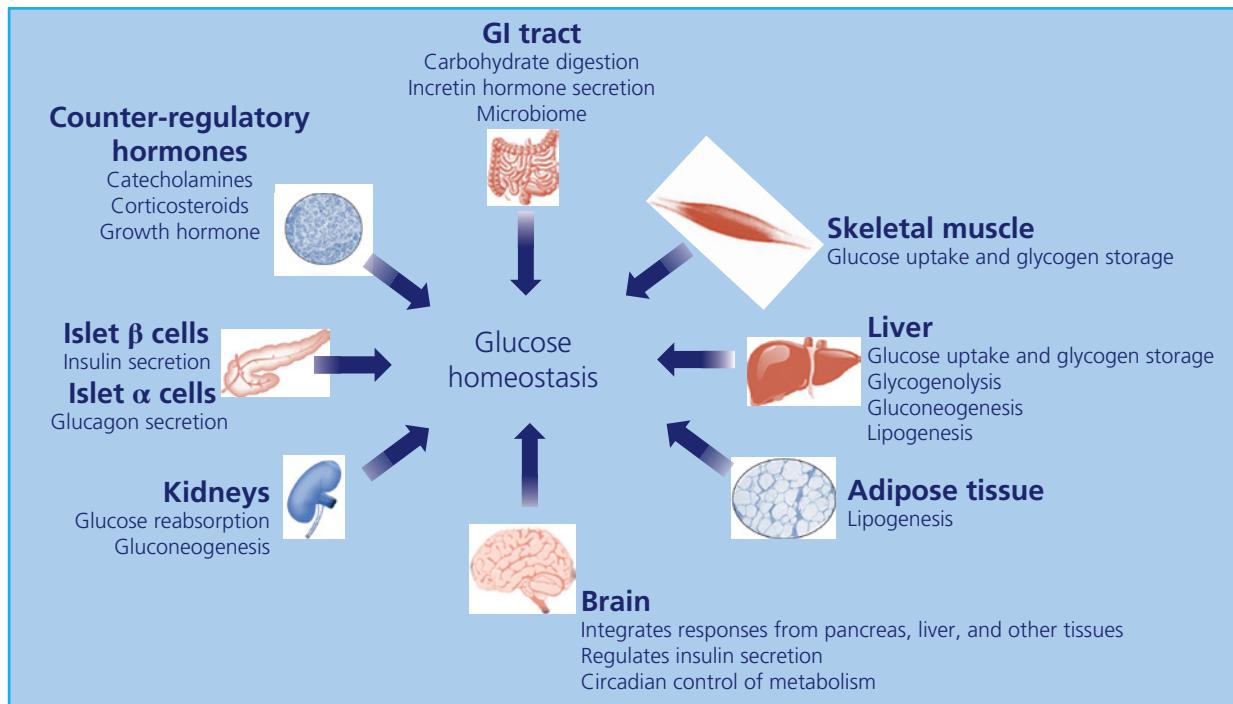

Figure 6.1 Tissues involved in glucose homeostasis. GI, gastrointestinal.

somatostatin-expressing δ cells (~10%), and cells expressing pancreatic polypeptide (<5%), ghrelin, and peptide YY (<1%) (see Figure 7.1). Islets are highly vascularized, receiving up to 15% of the pancreatic blood supply despite accounting for only 2–3% of the total pancreatic mass and are well supplied by autonomic nerve fibres [2].

Insulin

Insulin is the key hormone involved in the regulation of cellular energy supply and macronutrient balance derived from food and may be considered as the hormone that signals the *post-meal* fed state. Insulin secretion is influenced by many factors (Table 6.1), but food ingestion is the most important. After a meal, once glucose concentrations rise above 5 mmol/l, insulin is secreted in a coordinated pulsatile fashion into the portal vein in a characteristic biphasic pattern; first there is an acute rapid *first-phase* release of insulin, lasting for a few minutes, followed by a less intense but more sustained *second phase* (Chapter 7). Insulin is also produced during the fasting state; although at a low level, this background secretion accounts for ~50% of total daily insulin production.

Insulin exerts its biological actions by binding to the insulin receptor, which is a heterotetrameric transmembrane protein comprising two α - and two β -glycoprotein subunits linked by disulfide bonds (Chapter 9). Following binding to the α subunits, insulin induces a conformational change in the β subunits, resulting in activation of tyrosine kinase and initiation of a cascade response involving a host of other intracellular substrates. The insulin-receptor complex is then internalized by the cell, insulin is degraded, and the receptor is recycled to the cell surface.

Effect on glucose metabolism

Insulin is involved in the regulation of carbohydrate metabolism at many steps (Table 6.2), but predominantly acts to increase the uptake and storage of glucose in liver, adipose tissue, and skeletal

Table 6.1 Factors regulating insulin release from the β cells of the pancreatic islets.

Factor	Insulin secretion increased by	Insulin secretion decreased by
Nutrients	Raised glucose Amino acids Fatty acids	Low glucose
Islet products	Glucagon Adenine nucleotides Divalent cations	Somatostatin Ghrelin PPY
Neurotransmitters	Acetylcholine through parasympathetic stimulation Norepinephrine via sympathetic α -receptors VIP PACAP GRP	Norepinephrine via sympathetic β receptors Dopamine NPY Galanin
Gastrointestinal hormones	Cholecystokinin GIP GLP-1	Somatostatin Ghrelin
Adipokines	Adiponectin	Leptin Resistin
Stress		Exercise Hypoxia Hypothermia Surgery Severe burns

GIP, glucose-dependent insulinotropic peptide (previously known as gastric inhibitory peptide); GLP-1, glucagon-like peptide 1; GRP, gastrin-releasing polypeptide; NPY, neuropeptide Y; PACAP, pituitary adenylate cyclase activating polypeptide; PYY, peptide tyrosine tyrosine; VIP, vasoactive intestinal polypeptide.

Table 6.2 Insulin actions on carbohydrate metabolism.

Action	Mechanism
Increases glucose uptake into cells	Translocation of glucose transporter (GLUT) 4 to the cell surface
Increases glycogen synthesis	Activates glycogen synthase by dephosphorylation
Inhibits glycogen breakdown	Inactivates glycogen phosphorylase and its activating kinase by dephosphorylation
Inhibits gluconeogenesis	Dephosphorylation of pyruvate kinase and 2,6-biphosphate kinase
Increases glycolysis	Dephosphorylation of pyruvate kinase and 2,6-biphosphate kinase
Converts pyruvate to acetyl co-enzyme A	Activates the intramitochondrial enzyme complex pyruvate dehydrogenase

muscle. Cell membranes are not inherently permeable to glucose and require a family of specialized glucose-transporter (GLUT) proteins to carry glucose through the membrane into cells [3]. The function of GLUT1 to 3 is insulin independent, but insulin stimulates glucose uptake into muscle and adipose tissue through GLUT4. GLUT4 is normally present in the cytoplasm, but after insulin binds to its receptor, GLUT4 moves to the cell surface where it creates a pore for glucose entry.

Effect on lipid metabolism

Insulin promotes fat storage within adipose tissue and the liver by increasing the rate of lipogenesis and controlling the formation and storage of triglyceride [4]. The critical step in lipogenesis is the activation of the insulin-sensitive lipoprotein lipase in the capillaries. This enzyme acts to release fatty acids from circulating chylomicrons or very low-density lipoproteins, which are taken up into the adipose tissue. Lipogenesis is also facilitated by glucose uptake, because its metabolism by the pentose phosphate pathway provides nicotinamide adenine dinucleotide phosphate (NADPH), which is needed for fatty acid synthesis.

Insulin increases triglyceride synthesis by activating acetyl co-enzyme A (CoA) carboxylase, while at the same time suppressing fat oxidation through the inhibition of carnitine acyltransferase

Table 6.3 Insulin actions on fatty acid metabolism.

Action	Mechanism
Releases fatty acids from circulating chylomicrons or very low-density lipoproteins	Activates lipoprotein lipase
Increases fatty acid synthesis	Activates acetyl CoA carboxylase
Suppresses fatty acid oxidation	Inhibits carnitine acyltransferase
Increases triglyceride synthesis	Stimulates esterification of glycerol phosphate
Inhibits triglyceride breakdown	Dephosphorylates hormone-sensitive lipase
Increases cholesterol synthesis	Activates and dephosphorylates HMGCoA reductase
Inhibits cholesterol ester breakdown	Dephosphorylates cholesterol esterase

CoA, co-enzyme A; HMGCoA, hydroxymethylglutaryl co-enzyme A.

(Table 6.3). Insulin also stimulates triglyceride synthesis through the esterification of glycerol phosphate. By contrast, triglyceride breakdown is suppressed by insulin by inhibiting hormone-sensitive lipase. Within the liver, insulin reduces ketogenesis (Chapter 41). Cholesterol synthesis is increased by insulin through activation and dephosphorylation of hydroxymethylglutaryl co-enzyme A (HMGCoA) reductase, while cholesterol ester breakdown appears to be inhibited by dephosphorylation of cholesterol esterase.

Effect on protein metabolism

Insulin stimulates amino acid uptake into cells and promotes protein synthesis in a range of tissues by increasing transcription of specific mRNA and translation into proteins on the ribosomes [5]. Examples of enhanced mRNA transcription include glucokinase and fatty acid synthase. By contrast, insulin decreases mRNA-encoding liver enzymes such as carbamoyl phosphate synthetase, which is a key enzyme in the urea cycle. However, the major action of insulin on protein metabolism is to inhibit protein breakdown. In this way, it acts synergistically with growth hormone and insulin-like growth factor I (IGF-I) to increase protein anabolism.

Glucagon

Glucagon is made predominantly in islet α cells and regulates glycaemia through actions in the liver and islet β cell (Chapter 8). Its secretion is stimulated by a fall in blood glucose and by amino acids. Release of glucagon is also under neural control; sympathetic adrenergic activation increases glucagon release while the parasympathetic nervous system inhibits its release. Local control within the islet and signals from the gastrointestinal tract are also important; insulin and somatostatin inhibit glucagon release while glucagon stimulates its own release in an autocrine manner. The gastrointestinal incretin hormones, glucose-dependent insulinotropic peptide (GIP) stimulates and glucagon-like peptide-1 (GLP-1) inhibit glucagon secretion.

Glucagon has direct actions on hepatocytes to promote glucose production, and lipid and amino acid metabolism. It plays an important role in preventing significant hypoglycaemia during fasting, stress, and exercise by antagonizing the actions of insulin. Following binding to specific glucagon receptors in the liver, glucagon mobilizes glycogen and enhances glucose production from non-carbohydrate precursors by gluconeogenesis. At the same time, glucagon promotes lipid oxidation within the liver. Glucagon has central effects where it inhibits food intake and increases resting energy expenditure.

Liver

The liver is the principal organ of glucose homeostasis and receives absorbed monosaccharides directly from the intestine via the portal vein [6]. In the post-absorptive state, the liver stores glucose as glycogen, a large highly branched glucose polymer. Initially glucose enters the hepatocyte and is phosphorylated to glucose 6-phosphate, which may subsequently follow a number of metabolic pathways, including glycogen synthesis, the hexosamine pathway, the pentose phosphate pathway, and oxidative routes (Figure 6.2). Approximately 50% of ingested glucose is stored as glycogen during the post-prandial period in healthy people. The capacity to store glycogen is limited and so excess dietary glucose is converted into fat by hepatic *de novo* lipogenesis [7].

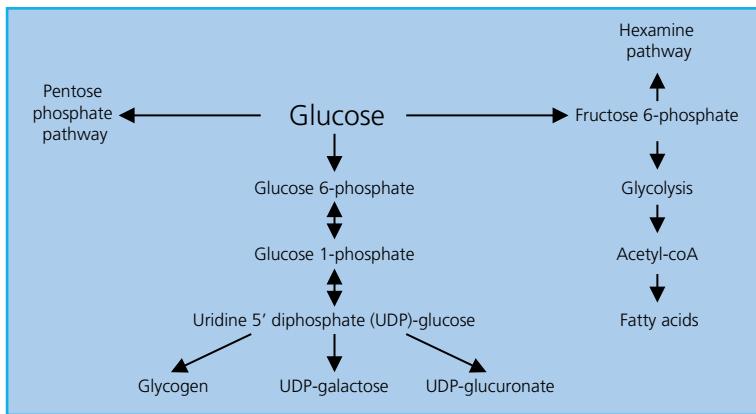

Figure 6.2 Glucose metabolic pathways. coA, co-enzyme A.

The liver possesses the ability to produce and release glucose into the systemic circulation for utilization by other tissues, particularly during periods of fasting. The formation of glycogen is a reversible process and glycogen can be easily metabolized to glucose when needed through a process known as glycogenolysis. Although glucose is mainly derived from the diet, the body can also synthesize glucose *de novo* from non-carbohydrate sources, through a process known as gluconeogenesis. The liver is responsible for the production of more than 90% of the glucose derived from gluconeogenesis. The principal gluconeogenic precursors are pyruvate and lactate, certain gluconeogenic amino acids, and glycerol from fat metabolism. During short-term periods of fasting, glycogenolysis is the predominant component of hepatic glucose output. However, during prolonged periods of fasting, the glycogen reserve and glycogenolysis gradually diminish while gluconeogenesis becomes increasingly important.

Skeletal muscle and adipose tissue

Tissues such as muscle and fat have insulin-responsive glucose transporters and absorb glucose in response to post-prandial peaks in glucose and insulin. Glucose taken up by muscle is stored as glycogen or metabolized to lactate or carbon dioxide and water. Muscle glycogen synthesis accounts for ~90% of insulin-stimulated whole-body glucose disposal and for virtually all the non-oxidative glucose disposal in healthy insulin-sensitive humans [8]. Glycogen storage is a reversible process and glycogen can be easily metabolized to glucose when needed (glycogenolysis). Glucose is metabolized through glycolysis and the Krebs cycle to produce adenosine triphosphate (ATP) to supply the cell with energy. Insulin stimulates glycolysis and enhances the irreversible conversion of pyruvate to acetyl CoA, which may then be directly oxidized via the tricarboxylic acid (Krebs') cycle, or used for fatty acid synthesis. Although the contribution of adipose cells to glucose disposal is smaller than that of

skeletal muscle, adipose tissue is a highly dynamic organ that nevertheless plays an important role in glucose and lipid homeostasis.

Gastrointestinal tract

Glucose is derived mainly from foods in the diet containing carbohydrates or sugars. The process of digestion begins in the mouth by both mechanical processes, such as chewing, and chemical breakdown by the action of specific enzymes, such as α -amylase and α -glucosidase. Sugars within food may be polysaccharides, such as starch or glucagon, disaccharides (sucrose, lactose, and maltose), or monosaccharides (glucose, fructose, and galactose) (Figure 6.3). The end products of digestion are monosaccharides, which are absorbed across the membrane of the small intestine into the circulation and transported for storage or use as energy.

Several factors affect the rate of carbohydrate digestion and absorption, such as the food composition and other foods eaten at the same time [9]. The glycaemic index (GI) is a scale that ranks carbohydrate-rich foods as *high GI*, *medium GI*, and *low GI* based on the rate at which glucose-containing carbohydrates are digested and absorbed and consequently increase blood glucose concentrations [10]. High GI foods are digested and absorbed more quickly and lead to a larger increase in post-prandial blood glucose level than low GI foods. Other food factors affecting the rate of carbohydrate absorption are shown in Table 6.4.

Incretin hormones

Nearly 100 years ago, injected extracts of the small intestinal mucosa were shown to exert a hypoglycaemic effect, leading to speculation that the gastrointestinal tract produced hormones that could regulate glucose homeostasis (Chapter 36). Further evidence for this

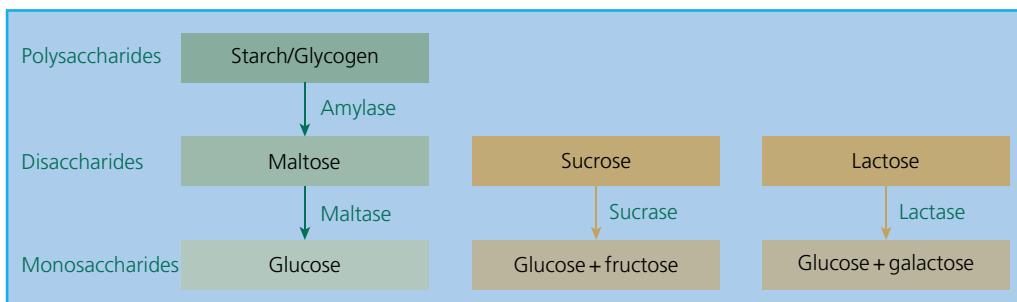

Figure 6.3 Carbohydrate digestion.

Table 6.4 Food factors affect the rate of carbohydrate absorption.

Factors that increase the rate of absorption	Factors that reduce the rate of absorption
Cooking	Food processing
Simultaneous consumption of fat and protein

Food containing acid	

hypothesis came from the observation that orally administered glucose evoked a greater insulin response than intravenously administered glucose, the so-called *incretin effect* [11]. Although other hormones may contribute, two incretin hormones, GIP and GLP-1, are mainly responsible for this effect.

GLP-1 is produced following meal ingestion by the enteroendocrine L cells. Within 5–15 minutes of eating, plasma GLP-1 concentrations start to rise, and peak after 45–60 minutes. GLP-1 is rapidly degraded within minutes by the enzyme dipeptidyl peptidase-4, which is widely expressed and is highly active in the liver, the intestinal and renal brush border membranes, and the lungs. The main way in which GLP-1 contributes to glucose homeostasis is through its actions on pancreatic islet cell function. GLP-1 acts as a β -cell sensitizer, potentiating glucose-induced insulin secretion when glucose concentrations are above 4–5 mmol/l [12]. GLP-1 also suppresses glucagon secretion in a similarly glucose-dependent manner [13]. Beyond its actions on the β cell, GLP-1 slows gastric emptying, to limit delivery of nutrients to the small intestines from the stomach, reducing post-prandial plasma glucose excursions [14]. GLP-1 has a further indirect effect on glucose metabolism by its action in the hypothalamus to signal satiety and reduce appetite and food intake [15].

GIP is synthesized by K cells of the duodenum and jejunum [16]. Like GLP-1, it is stimulated by food ingestion, is broken down by DPP-4 and stimulates insulin secretion in a glucose-dependent manner. In contrast to GLP-1, however, it stimulates glucagon secretion. GIP also regulates appetite and satiety.

Microbiome

A further way in which the gastrointestinal system influences glucose metabolism is through the microbiome, which comprises a diverse collection of over 1000 bacterial species that live within the gut (Chapter 19). The microbiome differs between individuals and its composition may be influenced by numerous factors, including diet, medication, and hygiene. The precise mechanisms by which the microbiome influences glucose homeostasis are yet to be elucidated, but the microbiome has the potential to activate immune pathways, which interact with insulin signalling pathways and glucose homeostasis as well as regulating enteroendocrine cell function, incretin signalling, and the composition of the bile acid pool and downstream signalling pathways [17].

Brain

Given the brain's reliance on glucose for fuel, it is unsurprising that the brain has evolved mechanisms that ensure a continuous supply of glucose (Chapter 10). The brain plays an important role in

coordinating the multiple responses from pancreas, liver, and other tissues that occur following the ingestion of a meal, limiting plasma glucose excursion in the post-prandial state. The brain, which is capable of sensing changes in glucose, modifies insulin secretion through alterations of autonomic tone to pancreatic islets [18]. Connections between the brain and islet cells involve both the sympathetic nervous system and parasympathetic nervous system [19] (see Figure 10.2) and can rapidly influence both insulin and glucagon secretion in response to changes in the level of circulating nutrients and other stimuli under physiological conditions [20]. The *cephalic phase* of insulin release, whereby insulin is secreted in anticipation of a meal, provides an example of how the brain controls insulin secretion. In addition to the direct effects on the pancreas, the brain also activates insulin-independent mechanisms that lower blood glucose levels, including both suppression of endogenous glucose production and increased hepatic glucose uptake [21].

Glucose metabolism is affected by the circadian rhythm under the influence of the brain. A system of *clock* genes within the suprachiasmatic nucleus is entrained to the light–dark cycle that aligns many behaviours and metabolic functions to the circadian clock. One example is hepatic insulin sensitivity, which decreases during sleep but increases upon waking and the expectation of breakfast [22].

Kidney

The kidney performs an important and distinctive role in glucose homeostasis, through both glucose utilization and production [23]. Apart from the liver, the kidney is the only organ with sufficient gluconeogenic enzyme activity to contribute significant amounts of glucose to the circulation via gluconeogenesis. The kidney may be responsible for up to 20% of all glucose production and 40% of gluconeogenesis, although 10% is more usual. Renal gluconeogenesis adapts to various nutritional and hormonal stimuli. Compared with the liver, renal gluconeogenesis is more sensitive to insulin and catecholamines, whereas glucagon has little to no effect. In contrast to the liver, the kidney increases glucose release after glucose ingestion.

The kidney also makes a unique contribution to glucose homeostasis by controlling glucose reabsorption from renal tubules following glomerular filtration (Chapter 35). Plasma glucose is neither protein bound nor complexed with macromolecules and is therefore freely filtered by the glomerulus, with up to 180 g/d filtered under normal physiological conditions [24]. This would lead to an excessive and unsustainable urinary loss of glucose if not recovered, and so an important adaptive response conserves glucose in normal situations by reabsorbing almost all of the filtered glucose in the proximal tubule through an insulin-independent process. The amount of glucose reabsorbed is dependent on the amount filtered, but the maximal reabsorptive capacity, the renal threshold for glucose, is reached once the circulating glucose concentration is ~11 mmol/l. The renal threshold varies between individuals and is affected by renal function, age, pregnancy, insulin resistance, and glycaemic levels, among others.

Glucose is reabsorbed in the proximal tubules by the sodium-glucose co-transporter 2 (SGLT2), with ~10% being reabsorbed by SGLT1 (Figure 6.4) [25]. The SGLTs belong to a broader group of solute carriers called SLC5, which currently has six SGLT members [26]. SGLT1 and SGLT2 are the best characterized and are differentiated from other SGLTs by their high capacity to transport glucose. SGLT1 has a relatively higher affinity for glucose [27], but

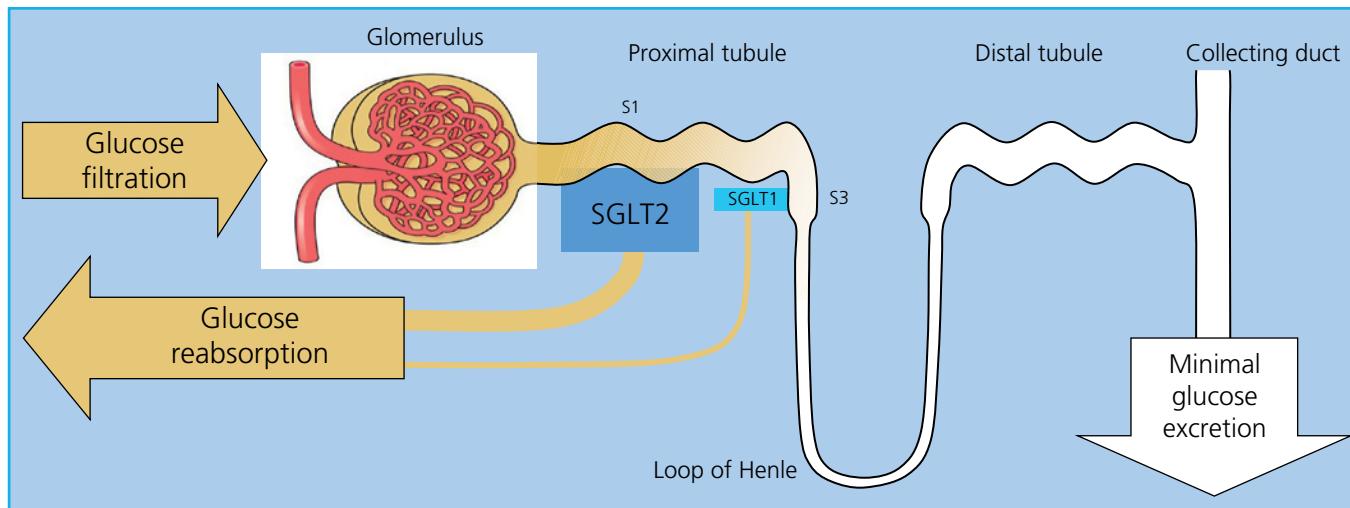

Figure 6.4 Normal physiology of renal glucose filtration and reabsorption. SGLT, sodium–glucose co-transporter.

transports less glucose than SGLT2 because it is only expressed in the third segment of the proximal tubule, whereas SGLT2 is abundantly expressed in the first two segments as well [26]. SGLT-2 transfers one sodium ion with one glucose molecule down an electrochemical gradient for sodium, generated by, for example, the activity of an $\text{Na}^+ - \text{K}^+$ ATPase pump [28]. SGLTs are expressed in other tissues in the body: SGLT1 is the main intestinal glucose transporter and is also found in the heart and trachea, whereas SGLT2 is primarily found in renal tissues but has also been isolated in the ileum, brain, and liver [24].

Other hormones involved in glucose metabolism

In addition to glucagon, several hormones including growth hormone, cortisol, and catecholamines antagonize the effects of insulin. These hormones are released in response to falling glucose concentrations as part of the *counter-regulatory response to defend the body against hypoglycaemia* [1]. As plasma glucose declines, there is a decrease in insulin secretion followed by release of glucagon and adrenaline and then cortisol and growth hormone. The combined action of the counter-regulatory response is to increase glucose concentrations by stimulating gluconeogenesis and glycogenolysis while reducing peripheral glucose utilization. The symptoms associated with the release of these hormones prompt a behavioural response to ingest food.

Catecholamines

Adrenaline influences glucose homeostasis through two main mechanisms to inhibit insulin secretion and increase hepatic glucose output (Chapter 22). In pancreatic β cells, adrenaline acts via stimulation of α_2 adrenoceptors [29]. In the liver, the actions of adrenaline are mediated by β_2 adrenoceptors. There is a transient increase in glycogenolysis and a more sustained effect on gluconeogenesis [30–32]. As well as a direct effect on the liver, adrenaline also drives hepatic gluconeogenesis by increasing adipose tissue lipolysis, providing the precursors lactate, alanine, and glycerol needed for gluconeogenesis. Adipose tissue lipolysis is stimulated via the β_1 - and β_3 -adrenoceptors. Impaired glucose utilization in muscle is mediated through direct β_2 -adrenergic

effects, which may explain why adrenaline is more potent in producing hyperglycaemia than noradrenaline, because the former has a higher affinity for β_2 -receptors [30–32].

Corticosteroids

The effect of glucocorticoids on glucose metabolism results from multiple pathways including β -cell function and insulin resistance [33]. Acutely glucocorticoids impair β -cell function, although this can recover somewhat with prolonged exposure [34]. Glucocorticoids directly impair insulin-mediated glucose uptake by interfering with components of the insulin signalling cascade, including glycogen synthase kinase-3, glycogen synthase, and GLUT4 translocation [35]. Furthermore, glucocorticoids increase glucose level indirectly through their actions on fat metabolism. Phosphoenolpyruvate carboxykinase (PEPCK) is a key enzyme that regulates fatty acid release from adipose tissue and synthesis of triacylglycerol from fatty acids and glycerol 3-phosphate [36]. Glucocorticoids inhibit PEPCK in adipose, but increase its action in the liver; this leads to an increase in circulating free fatty acids in the blood, which in turn interferes with glucose utilization and results in insulin resistance, especially in skeletal muscle.

Growth hormones and insulin-like growth factor I

The effect of growth hormone on glucose metabolism is complicated by its interplay with insulin-like growth factor (IGF-I) [37]. Growth hormone increases fasting hepatic glucose output, by increasing hepatic gluconeogenesis and glycogenolysis, and decreases peripheral glucose utilization through the inhibition of glycogen synthesis and glucose oxidation [38]. Furthermore, growth hormone stimulates lipolysis with the release of glycerol and free fatty acids. However, growth hormone also increases the production of IGF-I, which has insulin-like actions that are, in the case of glucose metabolism, opposite to those of growth hormone. The precise role of growth hormone and IGF-I and their interactions with insulin in regulating normal glucose homeostasis remain unknown, but glucose metabolism is frequently deranged in situations where growth hormone is either deficient or in excess. The IGF-binding proteins (IGFBPs) have a further modifying role on glucose homeostasis, particularly IGFBP-1, which is inversely related to insulin concentration and has a diurnal variation, with the highest concentrations being overnight when insulin levels are lowest [39].

Islet Function and Insulin Secretion

Peter M. Jones and Shanta J. Persaud

Department of Diabetes, King's College London, London, UK

Key points

- Regulation of fuel homeostasis in mammals is dependent on numerous small endocrine organs known as islets of Langerhans, which are located in the pancreas.
- Islets contain β cells, which are the only source of the polypeptide hormone insulin.
- Islet β cells are equipped to detect changes in circulating nutrients.
- Elevated levels of nutrients initiate an insulin secretory response from β cells that results in the storage of circulating nutrients in liver, muscle, and adipose tissue.
- A wide range of other signals, including hormones, neurotransmitters, and neuropeptides, can modify the insulin secretory response to circulating nutrients.
- Complex interactions between islet cells, the autonomic nervous system, and gastrointestinal incretin hormones allow precise integration between metabolic fuel intake, usage, and storage.

The German anatomy student Paul Langerhans first described in 1869 the ‘islands of clear cells’ distributed throughout the pancreas [1], but he did not realize the physiological significance of these cell clusters, which are today known as islets of Langerhans. We now know that islets are the endocrine compartment of the pancreas, comprising ~2–3% of the total pancreatic volume. Islets are approximately spherical (Figure 7.1a), with an average diameter of 100–200 μm , and a healthy human pancreas may contain up to a million individual islets, each having its own complex anatomy, blood supply, and innervation.

Islet structure and function

Islet anatomy

A typical mammalian islet comprises ~1000 endocrine cells including the insulin-expressing β cells (~60% of adult human islet cells), glucagon-expressing α cells (20–30%), somatostatin-expressing δ cells (~10%), and cells expressing pancreatic polypeptide (<5%), ghrelin, and peptide YY (<1%). The anatomical arrangement of islet cells varies between species. In rodents, the majority β -cell population forms a central core surrounded by a mantle of α and δ cells (Figure 7.1a), but human islets show less well-defined organization, with α and δ cells also being located throughout the islet (Figure 7.1b) [2,3]. Advances in high-throughput functional and molecular phenotyping have demonstrated that human islets show considerable molecular, anatomical, and functional heterogeneity, which may be important in the islet dysfunction associated with the development of type 2 diabetes [4].

Islets are highly vascularized and receive up to 15% of the pancreatic blood supply, despite accounting for only 2–3% of the total pancreatic mass. Each islet is served by an arteriolar blood supply that penetrates the mantle to form a capillary bed in the islet core. Earlier studies using vascular casts of rodent islets suggested that the major route of blood flow through an islet was from the inner β cells to the outer α and δ cells [5], but later studies using optical imaging of fluorescent markers to follow islet blood flow *in vivo* [6] revealed more complex patterns of both inner-to-outer and top-to-bottom blood flow through the rodent islet. Imaging studies in human islets suggest that most β cells are in direct contact with capillaries and are structurally polarized to target insulin secretion towards the capillary bed [3].

Islets are well supplied by autonomic nerve fibres and terminals containing the classic neurotransmitters acetylcholine and norepinephrine, along with a variety of biologically active neuropeptides [7, 8]. Vasoactive intestinal polypeptide (VIP) and pituitary adenylate cyclase-activating polypeptide (PACAP) are localized with acetylcholine to parasympathetic nerves, where they may be involved in mediating prandial insulin secretion and the α -cell response to hypoglycaemia [9]. Other neuropeptides, such as galanin and neuropeptide Y (NPY), are found with norepinephrine in sympathetic nerves, where they may have a role in the sympathetic inhibition of insulin secretion, although there are marked inter-species differences in the expression of these neuropeptides [7].

Intra-islet interactions

The anatomical organization of the islet has a profound influence on the ability of the β cells to recognize and respond to physiological signals [10–12], and numerous studies have demonstrated important

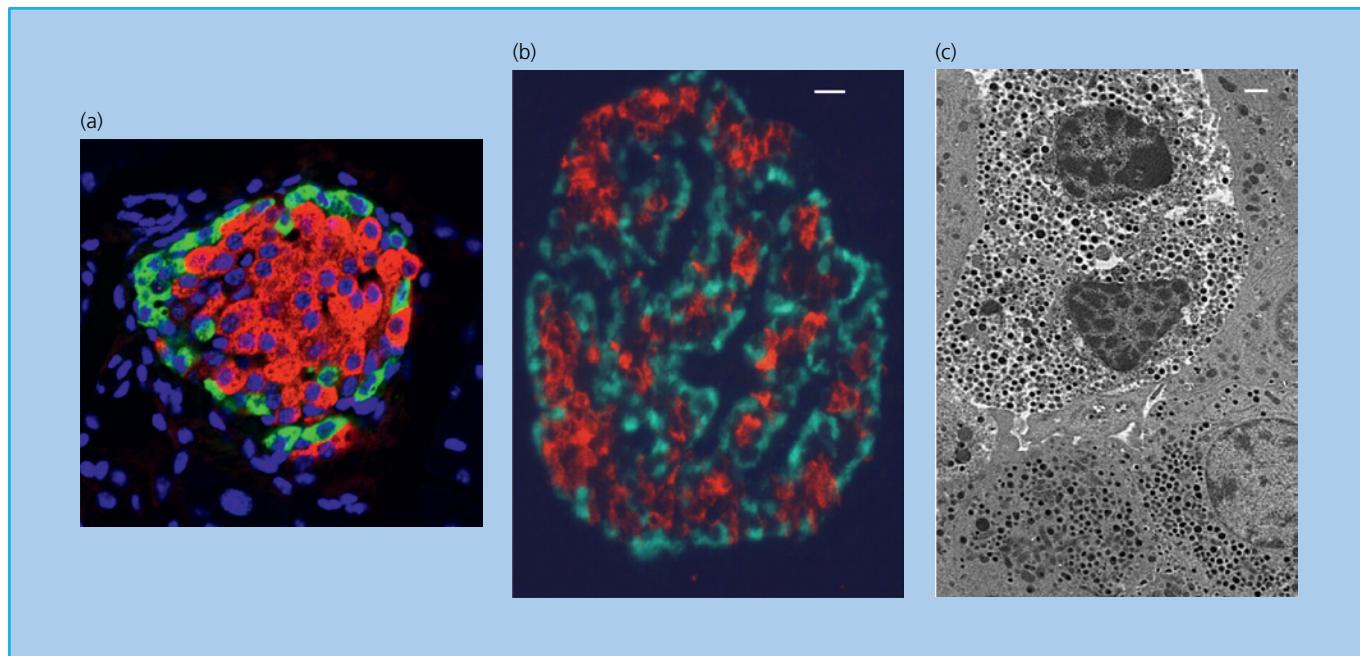

Figure 7.1 Anatomy of the islet of Langerhans. (a) Mouse islet. The image shows a section through a mouse pancreas in which insulin and glucagon are identified by red and green immunofluorescence, respectively, demonstrating the typical β -cell core surrounded by a thin mantle of α cells. In mouse islets, β cells comprise ~80% of the endocrine cell mass. Scale bar is 10 μm . (b) Human islet. The image shows a section through a human pancreas in which insulin and glucagon are identified by red and green immunofluorescence, respectively, demonstrating the less organized

structure of the human islet when compared with mouse islets. In human islets, β cells comprise ~50–60% of the endocrine cell mass. Scale bar is 10 μm . (c) Transmission electron micrograph of human islet cells. The image shows a transmission electron micrograph of several cells within a human islet. The two cells at the top with the electron-dense secretory granules surrounded by a clear halo are β cells. The cells in the lower part of the micrograph are α cells. Scale bar is 2 μm . Source: Authors' unpublished data.

roles for islet α cells and δ cells in the regulation of human β -cell function. Islet cells have the potential to communicate through several mechanisms, although their relative importance is still uncertain [13]. Islet cells are functionally coupled through a network of gap junctions, and gene deletion studies in mice have highlighted the importance of gap-junctional coupling via connexin 36 in the regulation of insulin secretory responses [14, 15]. Cell-to-cell contact through cell-surface adhesion molecules in localized micro-domains offers an alternative communication mechanism [16], and interactions mediated by E-cadherin [16–18] or ephrins [19] have been implicated in the regulation of β -cell function. Components of the intra-islet extracellular matrix, which is predominantly synthesized by islet endothelial cells and pericytes [20], influence β -cell gene expression [20], proliferation, survival, and function via interactions with integrins on the β -cell surface [21]. A further important level of control is exerted via numerous intra-islet paracrine and autocrine effects in which a biologically active substance released by one islet cell can influence the functional status of a neighbouring cell (paracrine), or of itself (autocrine) [22]. Figure 7.2 shows some of the molecules that have been implicated in this type of intra-islet cell-cell communication. Thus, islet cells can interact with each other via the classic islet hormones: insulin, glucagon, and somatostatin [23–28]; via other products secreted by the endocrine cells, including neurotransmitters [29], peptides such as kisspeptin [30], glucagon-like peptide 1 (GLP-1) [29, 31], and urocortin3 (Ucn3) [32], and adenine nucleotides and divalent cations that are co-released with insulin [33–36]; and via other less well-known mechanisms, including the generation of gaseous signals such as nitric oxide and carbon monoxide [37–39]. This plethora of potential intra-islet interactions may reflect the requirement for coordi-

nating the secretory responses of many individual islet cells to generate the rate and pattern of hormone secretion appropriate to the prevailing physiological conditions. However, much of the experimental evidence is derived from isolated islets *in vitro*, which, lacking a microcirculation, may not be an appropriate model for the *in vivo* situation [40].

Insulin biosynthesis and storage

The ability to release insulin rapidly in response to metabolic demand, coupled with the relatively slow process of producing polypeptide hormones, means that β cells are highly specialized for the production and storage of insulin, to the extent that insulin comprises ~10% (~10 pg/cell) of the total β -cell protein.

Biosynthesis of insulin

In humans, the gene encoding pre-proinsulin, the precursor of insulin, is located on the short arm of chromosome 11 [41]. It is 1355 base pairs in length and its coding region comprises three exons: the first encodes the signal peptide at the N-terminus of pre-proinsulin, the second the B-chain and part of the C-(connecting)-peptide, and the third the rest of the C-peptide and the A-chain (Figure 7.3). Transcription and splicing to remove the sequences encoded by the introns yield a messenger RNA of 600 nucleotides, translation of which gives rise to pre-proinsulin, an 11.5-kDa polypeptide. The cellular processes and approximate timescales involved in insulin biosynthesis, processing, and storage are summarized in Figure 7.4.

Pre-proinsulin is rapidly (<1 minute) discharged into the cisternal space of the rough endoplasmic reticulum, where proteolytic enzymes immediately cleave the signal peptide, generating

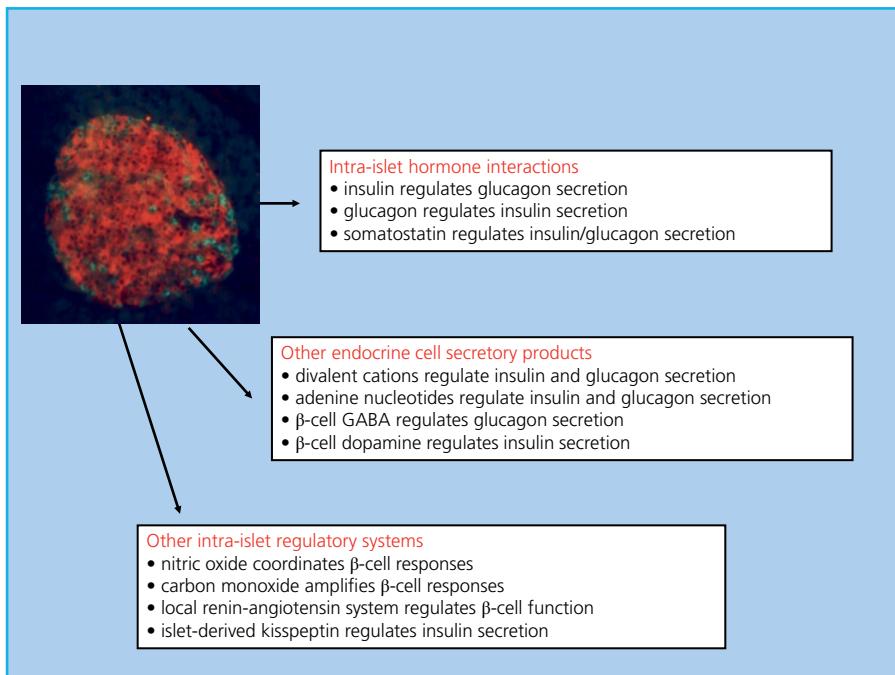

Figure 7.2 Intra-islet autocrine–paracrine interactions. The heterogeneous nature and complex anatomy of the islet permit numerous interactions between islet cells that are mediated by the release of biologically active molecules.

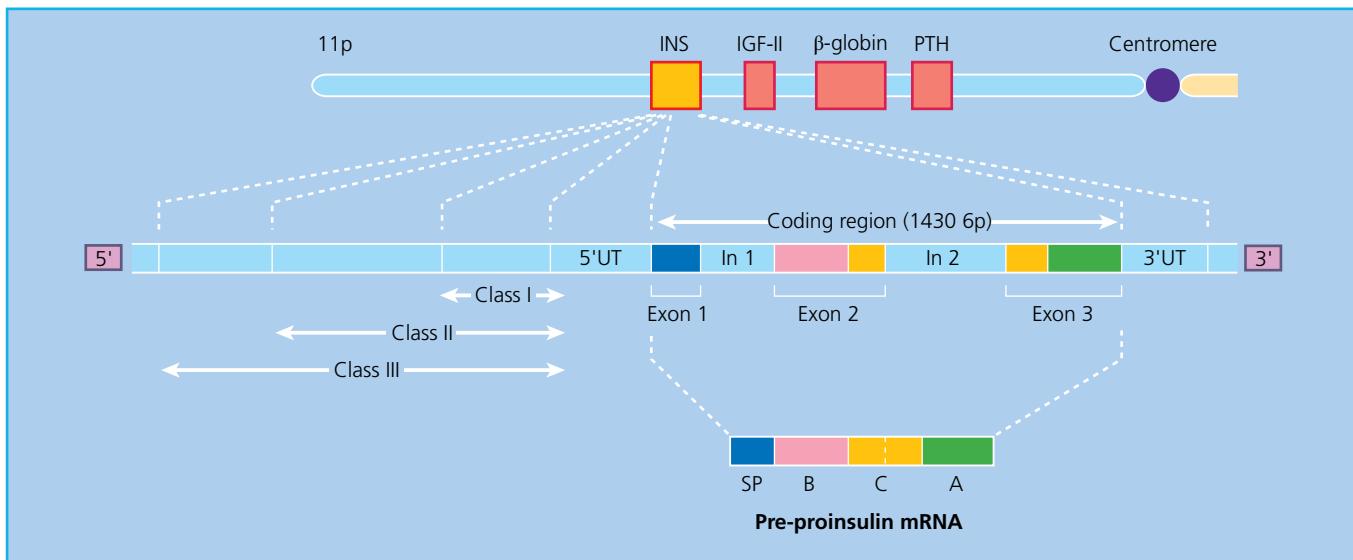

Figure 7.3 Structure of the human insulin gene. The coding region of the human insulin (INS) gene comprises three exons, which encode the signal peptide (SP), B-chain, C-peptide, and A-chain. The exons are separated by two introns (ln1 and ln2). Beyond the 5' untranslated region (5'UT), upstream of the coding sequence, lies a hypervariable region in which three alleles (classes I, II, and III) can be distinguished by their size. IGF-II, insulin-like growth factor II; PTH, parathyroid hormone.

proinsulin. Proinsulin is a 9-kDa peptide, containing the A- and B-chains of insulin (21 and 30 amino acid residues, respectively) joined by the C-peptide (30–35 amino acids). The structural conformations of proinsulin and insulin are very similar, and a major function of the C-peptide is to align the disulfide bridges that link the A- and B-chains so that the molecule is correctly folded for cleavage (Figure 7.5). Proinsulin is transported in microvesicles to the Golgi apparatus, where it is packaged into membrane-bound vesicles known as secretory granules. The conversion of proinsulin

to insulin is initiated in the Golgi complex and continues within the maturing secretory granule through the sequential action of two endopeptidases (prohormone convertases 2 and 3) and carboxypeptidase H [42], which remove the C-peptide chain, liberating two cleavage dipeptides and finally yielding insulin (Figure 7.5). Insulin and C-peptide are stored together in the secretory granules and are ultimately released in equimolar amounts by a process of regulated exocytosis. Under normal conditions, >95% of the secreted product is insulin (and C-peptide) and <5% is released as proinsulin.

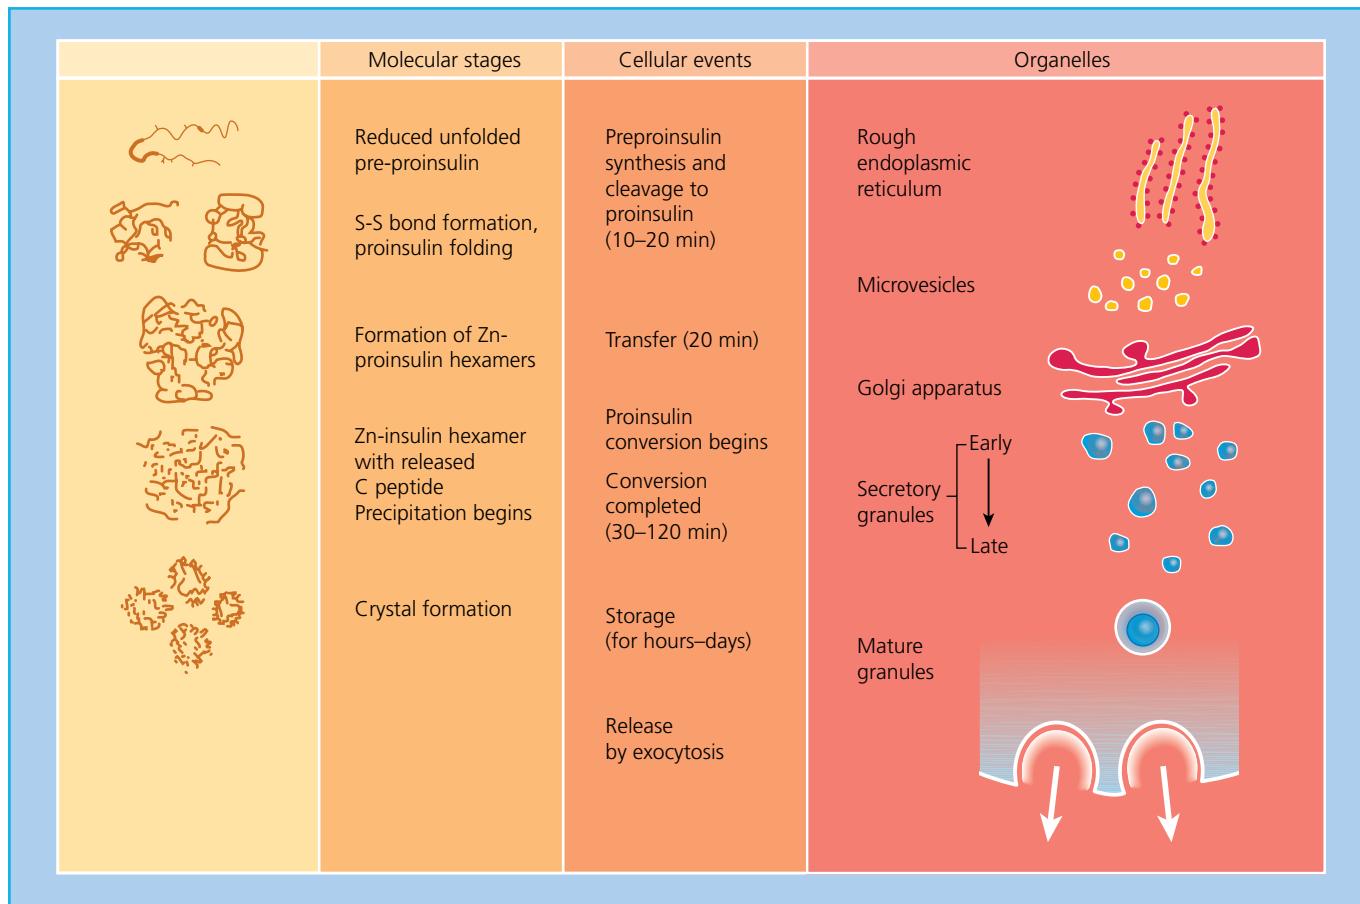

Figure 7.4 The intracellular pathways of proinsulin biosynthesis, processing, and storage. The molecular folding of the proinsulin molecule, its conversion to insulin, and the subsequent arrangement of the insulin hexamers into a regular pattern are shown on the left. The time course of the various processes and the organelles involved are also shown.

However, the secretion of incompletely processed insulin precursors (proinsulin and its *split* products; Figure 7.5) is increased in some individuals with type 2 diabetes.

The β cell responds to increases in the circulating concentrations of nutrients by increasing insulin production in addition to increasing insulin secretion, thus maintaining insulin stores [42]. Acute (<2 hours) increases in the extracellular concentration of glucose and other nutrients result in a rapid and dramatic increase in the transcription of pre-proinsulin mRNA and in the rate of proinsulin synthesis [43]. There is a sigmoidal relationship between glucose concentrations and biosynthetic activity, with a threshold glucose level of 2–4 mmol/l. This is slightly lower than the threshold for the stimulation of insulin secretion (~5 mmol/l), which ensures an adequate reserve of insulin within β cells.

Storage and release of insulin

The insulin secretory granule has a typical appearance in electron micrographs, with a wide space between the crystalline electron-opaque core and its limiting membrane (Figure 7.1c). The major protein constituents of the granules are insulin and C-peptide, which account for ~80% of granule protein [44], with numerous minor components including peptidases, peptide hormones, and a variety of (potentially) biologically active peptides of uncertain function [44, 45]. Insulin secretory granules also contain high concentrations of divalent cations, such as zinc (~20 mmol/l), which is

important in the crystallization and stabilization of insulin within the granule [46]. Zinc is transported into the insulin secretory granules by the islet-specific zinc transporter ZnT8, where it binds to insulin to form a crystalline lattice of insoluble hexamers. Polymorphisms in the *SLC30A8* gene encoding ZnT8, in which a single nucleotide polymorphism (SNP) generates a ZnT8 variant with lower Zn^{2+} transporting activity, are associated with increased risk of type 2 diabetes [47]. However, deletion of *SLC30A8* in a number of transgenic mouse models produces only modest effects on insulin storage and secretion, and on whole-body glucose homeostasis, so the mechanistic link between *SLC30A8* polymorphisms and type 2 diabetes risk remains unclear [47]. The intragranular functions of calcium (~120 mmol/l) and magnesium (~70 mmol/l) are uncertain, but they are co-released with insulin on exocytosis of the secretory granule contents, so they may have extracellular signalling roles via the cell-surface calcium-sensing receptor [33]. Similarly, the adenine nucleotides found in insulin secretory granules (~10 mmol/l) may have a signalling role when they are released into the extracellular space [34].

The generation of physiologically appropriate insulin secretory responses requires complex mechanisms for moving secretory granules from their storage sites within the cell to the specialized sites for exocytosis on the inner surface of the plasma membrane, and the role of cytoskeletal elements, notably microtubules and microfilaments, in the intracellular translocation of insulin storage

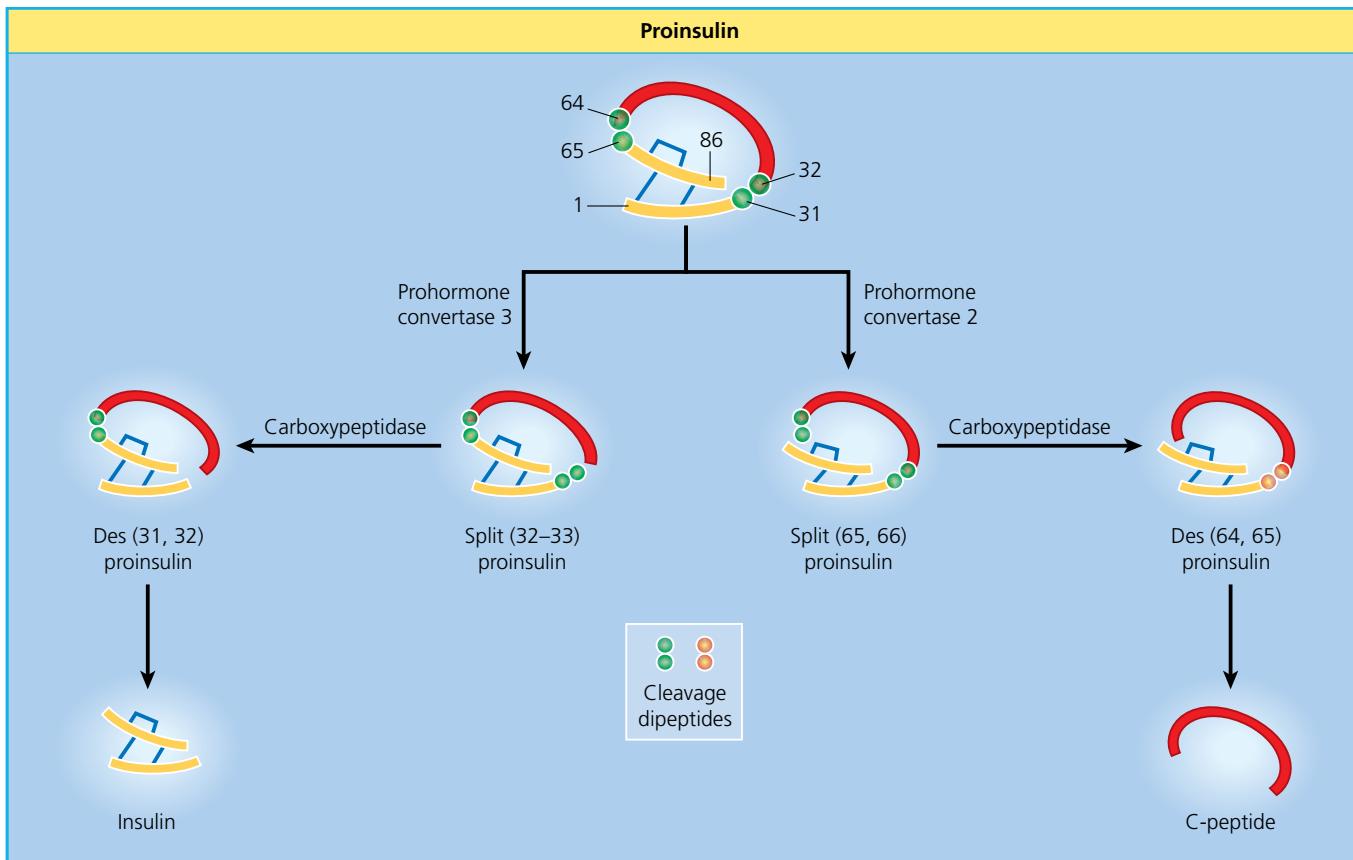

Figure 7.5 Insulin biosynthesis and processing. Proinsulin is cleaved on the C-terminal side of two dipeptides, namely Arg³¹-Arg³² (by prohormone convertase 3) and Lys⁶⁴-Arg⁶⁵ (prohormone convertase 2). The cleavage dipeptides are liberated, so yielding the 'split' proinsulin products and ultimately insulin and C-peptide.

granules has been studied extensively [48, 49]. Microtubules are formed by the polymerization of tubulin subunits and normally form a network radiating outwards from the perinuclear region [50]. The microtubular network is in a process of continual remodelling and the dynamic turnover of tubulin, rather than the total number of microtubules, is an important regulator of insulin secretion. Recent studies have implicated the microtubule-associated protein tau as a key player in the glucose-induced remodelling of β -cell microtubules, and hence insulin secretion [51].

The microtubule framework may provide the pathway for the secretory granules, but microtubules do not provide the motive force so other contractile proteins are likely to be involved. Actin is the constituent protein of microfilaments and exists in cells as a globular form of 43 kDa and as a filamentous form (F-actin), which associates to form microfilaments. F-actin remodelling in β cells is regulated by agents that alter rates of insulin secretion, and the pharmacological disruption of microfilament formation inhibits insulin secretion [52]. Myosin light and heavy chains are expressed at high concentrations in β cells, suggesting that actin and myosin may interact to propel granules along the microtubular network, and a myosin- and Rab-interacting protein (MyRIP) has been implicated in cyclic adenosine monophosphate (cAMP)-dependent insulin secretion through interaction with the motor protein MyoVa [53]. It is likely that other molecular motors, including myosin 5a, kinesins, and dynein [51, 54–56], are also involved in the movement of secretory granules, and perhaps other organelles, in β cells.

Insulin is released from secretory granules by exocytosis, a process in which the granule membrane and plasma membrane fuse together, releasing the granule contents into the interstitial space. Much of our knowledge of the molecular mechanisms of exocytosis is derived from studies of neurotransmitter release from nerve cells, and similar mechanisms operate in β cells, although some proteins implicated in synaptic vesicle exocytosis are not required for release of β -cell secretory granules [57]. The docking of the granules at the inner surface of the plasma membrane is via the formation of a multimeric complex of proteins known as the SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor) complex, which comprises proteins associated with secretory granules and the plasma membrane, and soluble fusion proteins [52, 58, 59]. The docked granules will fuse with the membrane and release their contents only in the presence of elevated intracellular calcium levels, which are sensed by synaptotagmins, a class of calcium-binding granule proteins [58, 60]. Secretory granules are distributed throughout the β -cell cytoplasm (Figure 7.1c), and it is likely that the transport of granules from distant sites to the plasma membrane is regulated independently from the final secretory process, with a reservoir of pre-docked granules available at the inner surface of the plasma membrane. Fusion of this readily releasable pool of granules may account for the rapid first-phase release of insulin in response to glucose stimulation, and direct electrophysiological measurements have demonstrated that the β -cell exocytotic response comprises a short-lived first phase with a very rapid rate of granule exocytosis from the

readily releasable pool, followed by a sustained second phase with a slower rate of exocytosis, from a reserve pool [61]. A key role for the regulatory protein Munc18c in the β -cell secretory granule fusion complex was identified in experiments where its knockdown in human β cells led to significant reductions in exocytosis of granules of both the readily releasable and reserve pools [62].

Regulation of insulin secretion

To ensure that circulating levels of insulin are appropriate for the prevailing metabolic status, β cells are equipped with mechanisms to detect changes in circulating nutrients and hormone levels, and in the activity of the autonomic nervous system [63]. Moreover, β cells have fail-safe mechanisms for coordinating this afferent information and responding with an appropriate secretion of insulin. The major physiological determinant of insulin secretion in humans is the circulating concentration of glucose and other nutrients, including amino acids and fatty acids. These nutrients possess the ability to initiate an insulin secretory response: when nutrients are absorbed from the gastrointestinal system, the β cell detects the changes in circulating nutrients and releases insulin to enable their uptake and metabolism or storage by the target tissues. The consequent decrease in circulating nutrients is detected by the β cells, which switch off insulin secretion to prevent hypoglycaemia. The β -cell responses to nutrient initiators of insulin secretion can be modified by various hormones and neurotransmitters, which act to amplify, or occasionally inhibit, the nutrient-induced responses (Table 7.1). Under normoglycaemic conditions, these agents have little or no effect on insulin secretion, a mechanism that prevents inappropriate secretion of insulin, which would result in potentially harmful hypoglycaemia. These agents are often referred to as potentiators of insulin secretion to distinguish them from nutrients that initiate the secretory response. The overall insulin output

Table 7.1 Key non-nutrient regulators of insulin secretion.

Stimulators	Inhibitors
<i>Islet products</i>	
Glucagon/GLP-1	SST-14
Adenine nucleotides	Ghrelin
Divalent cations	PPY
<i>Neurotransmitters</i>	
Acetylcholine	Norepinephrine
VIP	Dopamine
PACAP	NPY

CCK, cholecystokinin; GIP, glucose-dependent insulinotropic peptide; GLP-1, glucagon-like peptide-1; GRP, gastrin-releasing polypeptide; NPY, neuropeptide Y; PACAP, pituitary adenylate cyclase-activating polypeptide; PYY, peptide YY; SST, somatostatin; VIP, vasoactive intestinal polypeptide.

depends on the relative input from initiators and potentiators at the level of individual β cells, on the synchronization of secretory activity between β cells in individual islets, and on the coordination of secretion between the hundreds of thousands of islets in a human pancreas. This section considers the mechanisms employed by β cells to recognize and respond to nutrient initiators and non-nutrient potentiators of insulin secretion.

Nutrient-induced insulin secretion

Nutrient metabolism

Islet β cells respond to small changes in extracellular glucose concentrations within a narrow physiological range and the mechanisms through which β cells couple changes in nutrient metabolism to regulated exocytosis of insulin are becoming increasingly well understood. Glucose is transported into β cells via high-capacity glucose transporters (GLUT; GLUT2 in rodents, GLUT1, 2, and 3 in humans [64, 65]), enabling rapid equilibration of extracellular and intracellular glucose concentrations. Once inside the β cell, glucose is phosphorylated by glucokinase, which acts as the *glucose sensor*, coupling insulin secretion to the prevailing glucose level [66], although evidence is accumulating of other metabolic amplifiers of insulin secretion, notably the anaplerotic flux of pyruvate to oxaloacetate and beyond [63]. The dose-response curve of glucose-induced insulin secretion from isolated islets is sigmoidal (Figure 7.6) and is determined primarily by the activity of glucokinase. Glucose concentrations below 5 mmol/l do not affect rates of insulin release, and the rate of secretion increases progressively at extracellular glucose levels between 5 and \sim 15 mmol/l, with half-maximal stimulation at \sim 8 mmol/l. The time course of the insulin secretory response to elevated glucose is characterized by a rapidly rising but transient first phase, followed by a maintained and prolonged second phase, as shown in Figure 7.7. This profile of insulin secretion is obtained whether insulin levels are measured following a glucose load *in vivo*, or whether the secretory output from the perfused pancreas or isolated islets is assessed, suggesting that the characteristic biphasic secretion pattern is an intrinsic property of the islets.

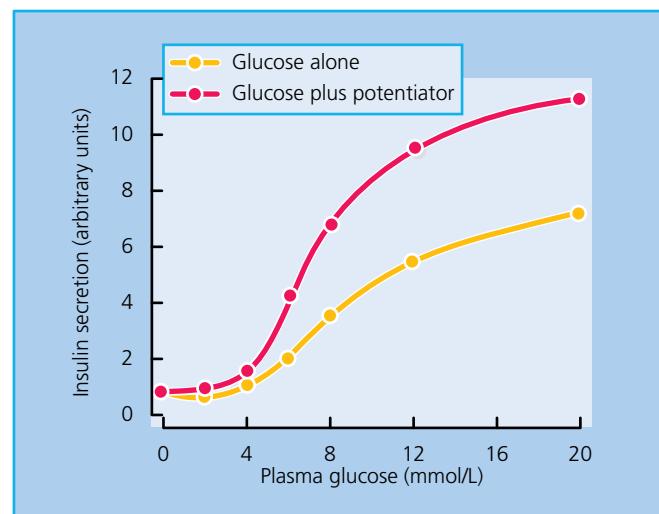

Figure 7.6 Glucose-induced insulin secretion from islets of Langerhans. No stimulation is seen below a threshold value of \sim 5 mmol/l glucose. Potentiators amplify insulin secretion at stimulatory concentrations of glucose, but are ineffective at subthreshold glucose levels.

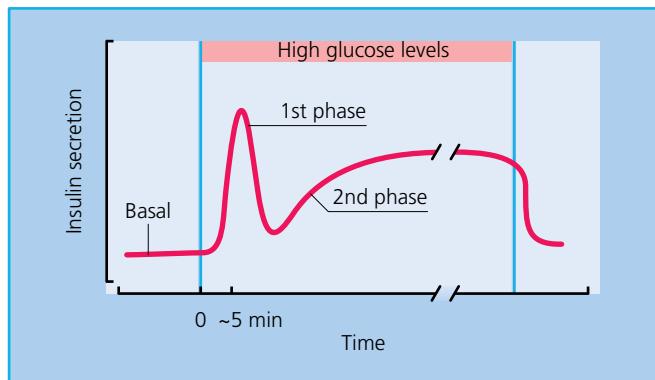

Figure 7.7 Glucose-induced insulin release *in vitro*. The image shows the pattern of glucose-induced insulin secretion from perfused pancreas, in response to an increase in the glucose concentration. An acute first phase, lasting a few minutes, is followed by a sustained second phase of secretion that persists for the duration of the high-glucose stimulus. A similar biphasic pattern of glucose-induced insulin secretion is seen in isolated rodent and human islets, suggesting that this characteristic pattern of insulin secretion is an intrinsic property of the islets.

ATP-sensitive potassium channels and membrane depolarization

In the absence of extracellular glucose, the β -cell membrane potential is maintained close to the potassium equilibrium potential by the efflux of potassium ions through inwardly rectifying potassium channels. These channels were called ATP-sensitive potassium (K_{ATP}) channels, because application of adenosine triphosphate (ATP) to the cytosolic surface of β -cell membrane patches resulted in rapid, reversible inhibition of resting membrane permeability to potassium ions [67]. This property of the K_{ATP} channel is pivotal in linking glucose metabolism to insulin secretion. Thus, ATP generation following glucose metabolism, in conjunction with concomitant lowering of adenosine diphosphate (ADP) levels, leads to closure of β -cell K_{ATP} channels. Channel closure and the subsequent reduction in potassium efflux promote depolarization of the β -cell membrane and influx of calcium ions through voltage-dependent L-type calcium channels. The resultant increase in cytosolic Ca^{2+} triggers the exocytosis of insulin secretory granules, thus initiating the insulin secretory response (Figure 7.8).

At around the time that the K_{ATP} channels were established as the link between the metabolic and electrophysiological effects of

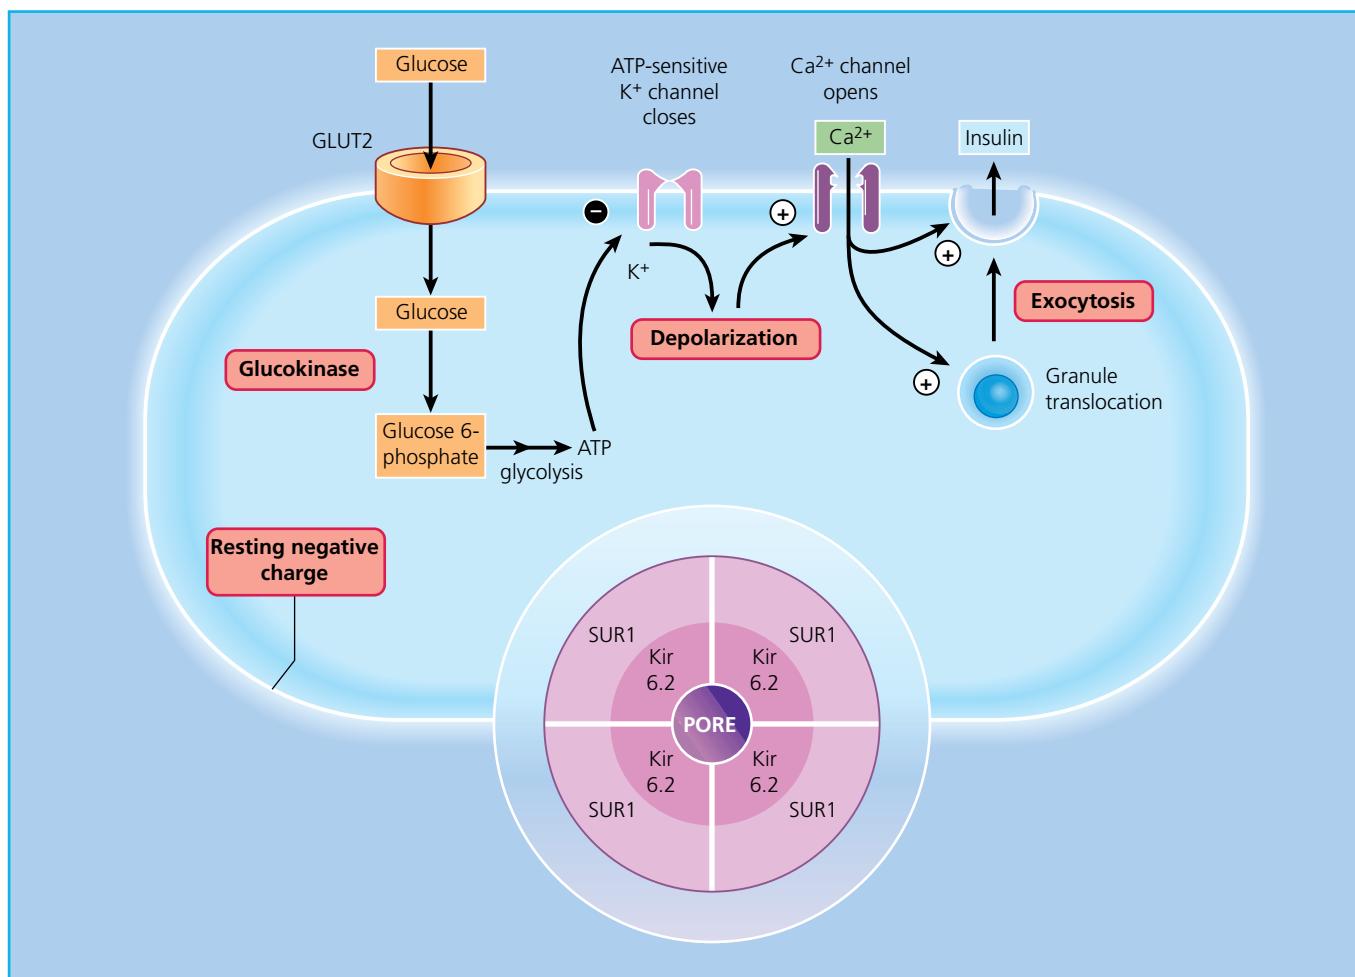

Figure 7.8 Intracellular mechanisms through which glucose stimulates insulin secretion. Glucose is metabolized within the β cell to generate adenosine triphosphate (ATP), which closes ATP-sensitive potassium channels in the cell membrane. This prevents potassium ions from leaving the cell, causing membrane depolarization, which in turn opens voltage-gated calcium channels in the membrane and allows calcium ions to enter the cell. The increase in cytosolic calcium initiates granule exocytosis. Sulfonylureas act downstream of glucose metabolism, by binding to the SUR1 component of the K_{ATP} channel (inset). GLUT, glucose transporter.

glucose, they were also identified as the cellular target for sulfonylureas. The capacity of sulfonylureas to close K_{ATP} channels explains their effectiveness in type 2 diabetes where the β cells no longer respond adequately to glucose, as the usual pathway for coupling glucose metabolism to insulin secretion is bypassed. The β-cell K_{ATP} channel is a hetero-octamer formed from four potassium channel subunits (termed Kir6.2) and four sulfonylurea receptor subunits (SUR1) [68]. The Kir6.2 subunits form the pore through which potassium ions flow and these are surrounded by the SUR1 subunits, which have a regulatory role (Figure 7.8). ATP and sulfonylureas induce channel closure by binding to Kir6.2 and SUR1 subunits, respectively, while ADP activates the channels by binding to a nucleotide-binding domain on the SUR1 subunit. Diazoxide, an inhibitor of insulin secretion, also binds to the SUR1 subunit to open the channels. The central role of K_{ATP} channels in β-cell glucose recognition makes them obvious candidates for β-cell dysfunction in type 2 diabetes. Early studies in people with type 2 diabetes, maturity-onset diabetes of the young (MODY), or gestational diabetes failed to detect any *Kir6.2* gene mutations that compromised channel function [69, 70]. Since then, larger-scale studies of variants in genes encoding *Kir6.2* and *SUR1* have demonstrated polymorphisms associated with increased risk of type 2 diabetes [71]. Similarly, activating mutations in the *Kir6.2* gene are causal for cases of permanent neonatal diabetes (PNDM) [72], which has enabled individuals with insulin-dependent PNDM to achieve normal glucose levels with sulfonylurea treatment alone. In contrast, loss of β-cell functional K_{ATP} channel activity has been implicated in the pathogenesis of congenital hyperinsulinism [73], a condition characterized by hypersecretion of insulin. Numerous mutations in both the *Kir6.2* and *SUR1* subunits have been identified in people with congenital hyperinsulinism and these are responsible for the severe impairment in glucose homeostasis in these individuals [74, 75].

Calcium and other intracellular effectors

Intracellular calcium is a principal effector of the nutrient-induced insulin secretory response, linking depolarization with exocytosis of insulin secretory granules (Figure 7.8). A large electrochemical concentration gradient (~10 000-fold) of calcium is maintained across the β-cell plasma membrane by a combination of membrane-associated calcium extruding systems and active calcium sequestration within intracellular organelles. The major route through which calcium is elevated in β cells is by influx of extracellular calcium through voltage-dependent L-type calcium channels that open in response to β-cell depolarization, and it has been estimated that each β cell contains about 500 L-type channels [76].

Studies with permeabilized β cells have demonstrated that elevations in intracellular calcium are alone sufficient to initiate insulin secretion [77], and conditions that elevate intracellular calcium usually stimulate insulin release. An increase in cytosolic calcium is essential for the initiation of insulin secretion by glucose and other nutrients: preventing calcium influx by removal of extracellular calcium or by pharmacological blockade of voltage-dependent calcium channels abolishes nutrient-induced insulin secretion. Glucose and other nutrients also induce a calcium-dependent activation of β-cell phospholipase C (PLC) [78], leading to the generation of inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG), both of which serve second-messenger functions in β cells [79]. The generation of IP₃ leads to the rapid mobilization of intracellular calcium, but the significance of this in secretory responses to nutrients is uncertain, and it is likely to have little more

than a modulatory role, amplifying the elevations in cytosolic calcium concentration induced by the influx of extracellular calcium.

The elevations in intracellular calcium are transduced into the regulated secretion of insulin by intracellular calcium-sensing systems within β cells. Important among these are the calcium-dependent protein kinases, which include myosin light-chain kinases, the calcium/phospholipid-dependent kinases, and the calcium/calmodulin-dependent kinases (CaMKs). CaMKs are protein kinases that are activated in the presence of calcium and the calcium-binding protein calmodulin, and several studies have implicated CaMK II in insulin secretory responses [79]. It has been proposed that CaMK II activation is responsible for the initiation of insulin secretion in response to glucose and other nutrients, and for enhancing nutrient-induced secretion in response to receptor agonists that elevate intracellular calcium [79]. Cytosolic PLA₂ (cPLA₂) is another β-cell calcium-sensitive enzyme. It is activated by concentrations of calcium that are achieved in stimulated β cells, and it generates arachidonic acid by the hydrolysis of membrane phosphatidylcholine. Arachidonic acid is capable of stimulating insulin secretion in a glucose- and calcium-independent manner, and it is further metabolized in islets by the cyclooxygenase (COX) pathways to produce prostaglandins and thromboxanes, and by the lipoxygenase (LOX) pathways to generate hydroperoxyeicosatetraenoic acids (HPETES), hydroxyeicosatetraenoic acids (HETES), and leukotrienes.

The precise roles of arachidonic acid derivatives in islet function remain uncertain because experimental investigations have relied on COX and LOX inhibitors of poor specificity, and although prostaglandin E₂ is largely inhibitory in rodent islets [80], it has stimulatory effects on insulin secretion from human islets [81]. Calcium sensors are also important at the later stages of the secretory pathway, where the calcium-sensitive synaptotagmin proteins are involved in the formation of the exocytic SNARE complex, to confer calcium sensitivity on the initiation and rate of exocytic release of insulin secretory granules [58].

The elevations in intracellular calcium induced by nutrients activate other effector systems in β cells, including PLC and cPLA₂, and calcium-sensitive adenylate cyclase isoforms, which generate cAMP from ATP. Although these signalling systems are of undoubtedly importance in the regulation of β cells by non-nutrients, their role in nutrient-induced insulin secretion is still uncertain. Thus, DAG generated by glucose-induced PLC activation has the potential to activate some protein kinase C (PKC) isoforms. PKC was first identified as a calcium- and phospholipid-sensitive, DAG-activated protein kinase, but some isoforms of PKC require neither calcium nor DAG for activation. The isoforms are classified into three groups:

- Calcium and DAG sensitive (conventional).
- Calcium independent, DAG sensitive (novel).
- Calcium and DAG independent (atypical).

β cells contain conventional, atypical, and novel PKC isoforms [79, 82]. The early literature on the role of PKC in nutrient-induced insulin secretion is confusing, but several studies have shown that glucose-induced insulin secretion is maintained under conditions where DAG-sensitive PKC isoforms are depleted, suggesting that conventional and novel PKC isoforms are not required for insulin secretion in response to glucose [79, 83].

The role of cAMP in the insulin secretory response to nutrients is similarly unclear. cAMP has the potential to influence insulin secretion by the activation of cAMP-dependent protein kinase A (PKA), or via the cAMP-regulated guanine nucleotide exchange factors

known as exchange proteins activated by cAMP (EPACs) [84]. However, elevations in β -cell cyclic AMP do not stimulate insulin secretion at substimulatory glucose concentrations, and the secretagogue effects of glucose can be maintained in the presence of competitive antagonists of cAMP binding to PKA or EPACs [85]. These observations suggest that cAMP does not act as a primary trigger of nutrient-stimulated β -cell secretory function, but observations linking glucose-induced oscillations in β -cell cAMP to oscillations in insulin secretion [86] suggest that a role for this messenger system in nutrient-induced insulin secretion cannot be ruled out.

K_{ATP} channel-independent pathways

Since the early reports linking K_{ATP} channel closure to the exocytotic release of insulin, it has become apparent that β cells also possess a K_{ATP} channel-independent stimulus–secretion coupling pathway: this is termed the amplifying pathway to distinguish it from the triggering pathway that is activated by K_{ATP} channel closure [87]. Studies in which β -cell calcium is elevated by depolarization and K_{ATP} channels are maintained in the open state by diazoxide have indicated that glucose, at concentrations as low as 1–6 mmol/l, is still capable of stimulating insulin secretion [88]. The triggering and amplifying pathways are both physiologically relevant for the first and second phases of glucose-induced insulin secretion [63, 89], but the mechanisms by which glucose stimulates insulin secretion in a K_{ATP} channel-independent manner remain debated, although adenine nucleotides have been implicated [89, 90]. However, it is clear that glucose must be metabolized and various potential metabolic amplifiers of glucose-induced insulin secretion have been identified in experimental studies, with the suggestion that perturbations in these pathways may be involved in β -cell failure in type 2 diabetes [63, 87].

Amino acids

Several amino acids stimulate insulin secretion *in vivo* and *in vitro*. Most require stimulatory concentrations of glucose, but some, such as leucine, lysine, and arginine, can stimulate insulin secretion in the absence of glucose, and therefore qualify as initiators of secretion. Leucine enters islets by a sodium-independent transport system and stimulates a biphasic increase in insulin release. The effects of leucine on β -cell membrane potential, ion fluxes, and insulin secretion are similar to, but smaller than, those of glucose [91]. Thus, metabolism of leucine within β cells decreases the potassium permeability, causing depolarization and activation of L-type calcium channels through which calcium enters the β cells and initiates insulin secretion. Leucine also activates the amplifying pathway of insulin secretion in a K_{ATP} channel-independent manner, as described already for glucose. The charged amino acids lysine and arginine cross the β -cell plasma membrane via a transport system specific for cationic amino acids. It is generally believed that the accumulation of these positively charged molecules directly depolarizes the β -cell membrane, leading to calcium influx.

Regulation of insulin secretion by non-nutrients

The complex mechanisms that have evolved to enable changes in extracellular nutrients to initiate an exocytotic secretory response are confined to islet β cells, and perhaps to a subset of hypothalamic neurons [92]. However, the mechanisms that β cells use to recognize and respond to non-nutrient potentiators of secretion are ubiquitous in mammalian cells, and so are covered only briefly in this section, followed by a review of the physiologically relevant non-nutrient regulators of β -cell function.

Most, if not all, non-nutrient modulators of insulin secretion influence β cells by binding to and activating specific receptors on the extracellular surface. Because of their central role in coordinating whole-body fuel homeostasis, β cells express receptors for a wide range of biologically active peptides, glycoproteins, and neurotransmitters (Table 7.1), and quantitative reverse transcriptase polymerase chain reaction (RT-PCR) analysis has indicated that human islets express 293 different G-protein-coupled receptors [93]. However, receptor occupancy generally results in the activation of a limited number of intracellular effector systems, which were introduced in the section ‘Nutrient-Induced Insulin Secretion’ (Figures 7.9 and 7.10).

Islet hormones

There is convincing evidence for complex intra-islet interactions via molecules released from islet endocrine cells (Figure 7.2). The physiological relevance of some of these interactions is still debated [40], but some of the intra-islet factors that influence insulin secretion are discussed briefly in this section.

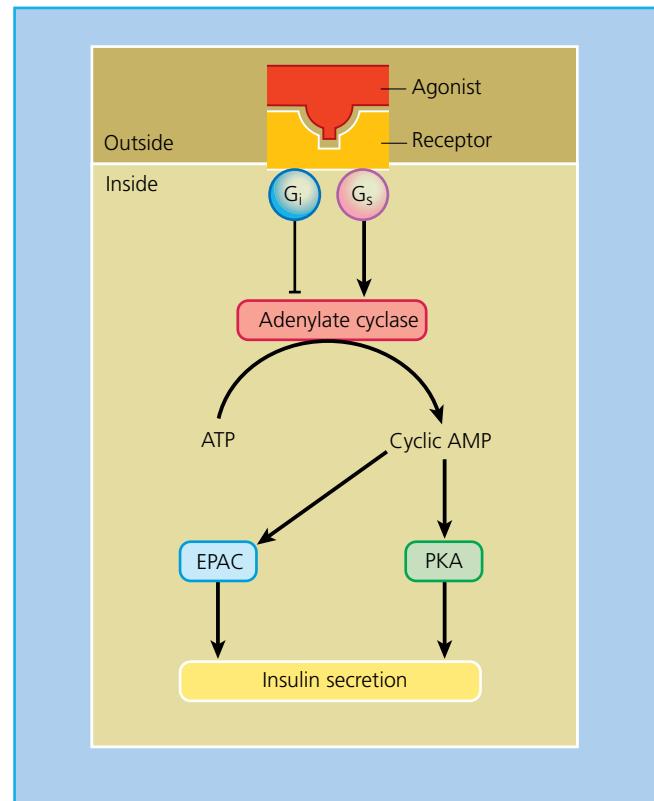

Figure 7.9 Adenylate cyclase and the regulation of insulin secretion. Some receptor agonists (e.g. glucagon, glucagon-like peptide-1, pituitary adenylate cyclase-activating polypeptide) bind to cell-surface receptors that are coupled to adenylate cyclase (AC) via the heterotrimeric GTP-binding protein Gs. Adenylate cyclase hydrolyses adenosine triphosphate (ATP) to generate adenosine 5' cyclic monophosphate (cAMP), which activates protein kinase A (PKA) and exchange proteins activated by cAMP (EPACs). Both of these pathways potentiate glucose-stimulated insulin secretion. Glucose also activates adenylate cyclase, but increases in intracellular cyclic AMP levels in response to glucose are generally smaller than those obtained with receptor agonists. Some inhibitory agonists (e.g. norepinephrine, somatostatin) bind to receptors that are coupled to adenylate cyclase via the inhibitory GTP-binding protein Gi, resulting in reduced adenylate cyclase activity and a decrease in intracellular cAMP.

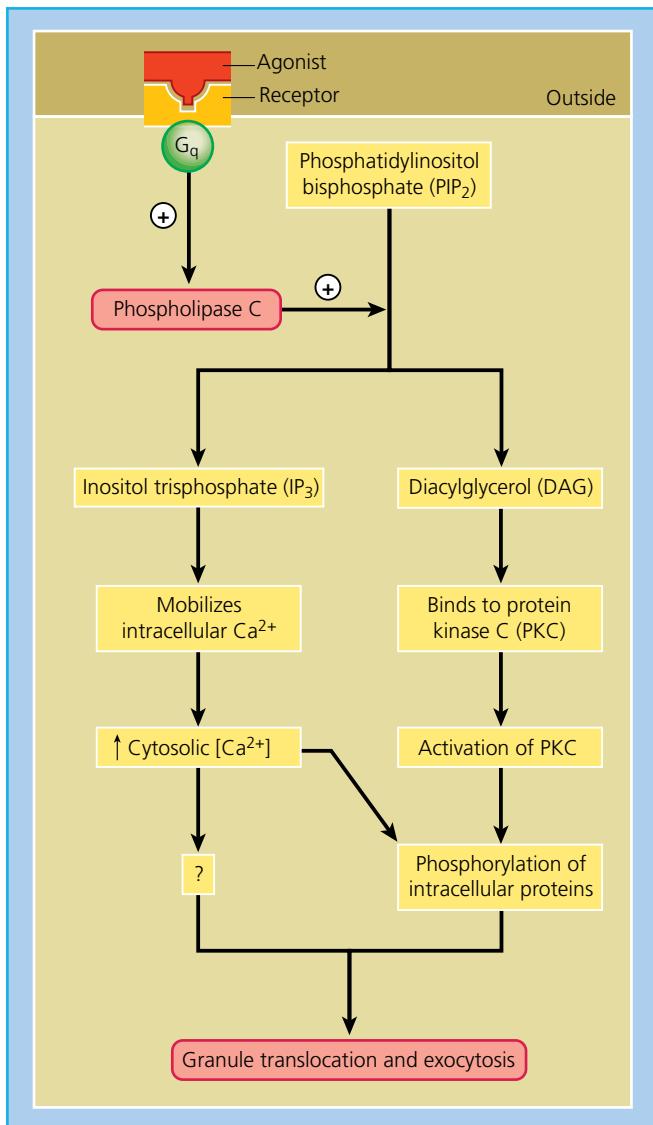

Figure 7.10 Phospholipase C and the regulation of insulin secretion. Some receptor agonists (e.g. acetylcholine, cholecystokinin) bind to cell-surface receptors that are coupled to phospholipase C (PLC) via the heterotrimeric GTP-binding protein G_q. Phospholipase C hydrolyses phosphatidylinositol bisphosphate (PIP₂), an integral component of the membrane, to generate inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG). IP₃ mobilizes calcium from the endoplasmic reticulum and DAG activates protein kinase C (PKC), both of which enhance insulin secretion. Nutrients also activate PLC in a calcium-dependent manner, but the importance of IP₃ and DAG in nutrient-induced insulin secretion is uncertain.

It is clear that β cells express insulin receptors and the associated intracellular signalling elements, suggesting the existence of auto-crime and/or paracrine feedback regulation of β -cell function [26, 94]. Earlier suggestions that secreted insulin regulates insulin secretion [95] have not been confirmed [26, 96], and the physiological rationale of a positive feedback loop for insulin to promote further insulin release is questionable [97]. The main auto-crime function of insulin on β cells is to regulate β -cell gene expression [98, 99] and β -cell mass through effects on proliferation and apoptosis [26, 99].

Glucagon is a 29 amino acid peptide secreted by islet α cells. The precursor, proglucagon, undergoes differential post-translational processing in the gut to produce entirely different peptides with

different receptors and biological activities. These include GLP-1 (7–36) amide, an *incretin* hormone, and GLP-2, which promotes growth of the intestinal mucosa. Although glucagon is the major proglucagon product in islet α cells, a subpopulation of human α cells also synthesizes and secretes GLP-1, presumably to exert local effects within islets [36, 38, 73]. Glucagon secretion is regulated by nutrients, islet and gastrointestinal hormones, and the autonomic nervous system, with hypoglycaemia and sympathetic nervous input being important stimulators of glucagon secretion [100]. Glucagon enhances insulin secretion through the stimulatory G-protein (G_s)-coupled activation of adenylate cyclase and the consequent increase in intracellular cAMP (Figure 7.9).

Somatostatin (SST) is expressed by islet δ cells and in numerous other sites, including the central nervous system (CNS) and D cells of the gastrointestinal tract, where it acts predominantly as an inhibitor of endocrine and exocrine secretion [101]. The precursor, pro-somatostatin, is processed by alternative pathways: in islets and the CNS SST-14 is generated, while SST-28, the major circulating form of somatostatin in humans, is produced in the gastrointestinal tract [102]. Somatostatin secretion is regulated by numerous nutrients and endocrine and neural factors [24, 101, 103, 104]. Islets express five different somatostatin receptor (SSTR) subtypes, and SST-14 released from islet δ cells has a tonic inhibitory effect on insulin and glucagon secretion [24], via activation of SSTR5 and SSTR2, respectively [105, 106]. Somatostatin receptors are coupled via an inhibitory G-protein (G_i) to the inhibition of adenylate cyclase and decreased formation of cAMP [107] (Figure 7.9), and to ion channels that cause hyperpolarization of the β -cell membrane and reductions in intracellular calcium [108]. Live cell imaging studies in rodent and human islets have shown that δ cells possess motile, neural-like processes that enable individual δ cells to reach, and potentially regulate, a large number of β cells within an islet [109].

Pancreatic polypeptide (PP) is a 36 amino acid peptide produced by PP cells that are found in the mantle of islets, predominantly those located in the head of the pancreas. PP secretion is mainly regulated via cholinergic parasympathetic stimulation [110], but the physiological function of PP as a circulating hormone, or as an intra-islet signal, is uncertain [110]. Peptide YY (PYY), which is structurally related to PP, is also expressed in islets, mainly by subpopulations of PP- and δ cells [111]. PYY inhibits insulin secretion via the NPY family of receptors, the most abundant of which is Y1 in both mouse and human islets [93, 112]. Ablation of PYY-expressing cells *in vivo* causes β -cell destruction and induction of diabetes, suggesting a role for islet PYY in maintaining β -cell mass [112].

Ghrelin is a 23 amino acid peptide first identified in the gastrointestinal system, but now known to be expressed in islet ϵ cells that are localized to the islet mantle in rodents, and appear to be developmentally distinct from the classic islet endocrine cells [113, 114]. The physiological function of ϵ -cell-derived ghrelin has not been fully established, but most experimental evidence suggests an inhibitory role in the regulation of insulin secretion [115], analogous to that of δ -cell somatostatin [24]. The inhibitory mode of action of ghrelin has been identified as being via GHSR1a receptors, leading to indirect opening of K_{ATP} channels and β -cell membrane hyperpolarization [116]. The recent observations that the ghrelin receptor GHSR shows high co-expression with PP in islets and that its inhibition *in vivo* results in increased circulating PP add another layer of complexity to islet paracrine signalling [117].

Neural control of insulin secretion

The association of nerve fibres with islets was shown over 100 years ago by silver staining techniques [118]. Since that time it has become well established that both mouse and human islets are innervated by cholinergic, adrenergic, and peptidergic autonomic nerves and that the central and autonomic nervous systems are important regulators of islet hormone secretion [8]. Coordination between the brain and the islets is required for normal glucose homeostasis, such that defects in this cooperative system may be associated with the development of type 2 diabetes [8].

The neural pathways regulating autonomic outflow to the islets have been mapped in detail. Parasympathetic (cholinergic) fibres originate in the dorsal motor nucleus of the vagus, while sympathetic nervous system motor neurons (adrenergic) are located in the intermediolateral column of the spinal cord. The activity of both parasympathetic and sympathetic input to islets is regulated by neural input from multiple regions of the hindbrain, midbrain, and forebrain [8].

Neurotransmitters: acetylcholine and norepinephrine

Acetylcholine is the major post-ganglionic parasympathetic neurotransmitter, and it stimulates the release of insulin and glucagon in many mammalian species [7, 93, 119]. Acetylcholine is also synthesized in and secreted from α cells in human islets, where it primes the β cells to respond optimally to increases in glucose [29, 120]. Acetylcholine acts predominantly via M₃ receptors in β cells [119, 121] to activate PLC (Figure 7.10), generating IP₃ and DAG, which act to amplify the effects of glucose by elevating cytosolic calcium and activating PKC [77]. Activation of β -cell muscarinic receptors can also lead to PLA₂ activation, with the subsequent generation of arachidonic acid and lysophosphatidylcholine, which can further enhance nutrient-induced insulin secretion. Acetylcholine also depolarizes the plasma membrane by affecting Na⁺ conductivity, and this additional depolarization induces sustained increases in cytosolic calcium [119].

The major sympathetic neurotransmitter norepinephrine (noradrenaline) can exert positive and negative influences on hormone secretion. Thus, norepinephrine can exert direct stimulatory effects on β cells via β_2 -adrenoreceptors [122], or inhibitory effects via α_2 -adrenoreceptors [123], and the net effect of norepinephrine may depend on the relative levels of expression of these receptor subtypes. Differences between species in the expression levels of adrenoreceptor subtypes probably account for the differential effects of β -adrenergic agonists on human islets, where they are stimulatory, and rodent islets, where they are ineffective [124]. The stimulatory effects mediated by β_2 -receptors occur by activation of adenylate cyclase and an increase in intracellular cAMP (Figure 7.9), while the inhibitory effect of α_2 -receptor activation involves reductions in cAMP and of cytosolic calcium [107, 123], and an unidentified inhibitory action at a more distal point in the stimulus–secretion coupling mechanism [125]. Increased expression of α_2A adrenoreceptors and decreased insulin secretion are a consequence of a SNP in the human α_2A receptor gene [126], and an α_2A receptor antagonist has been used to improve the insulin secretion deficiency in individuals with type 2 diabetes [127]. In contrast to the inhibitory effects of norepinephrine on insulin release, it has direct stimulatory effects on glucagon secretion from α cells mediated by both β_2 - and α_2 -receptor subtypes [7]. Circulating catecholamines secreted by the adrenal medulla (mainly epinephrine) also have the potential to influence islet hormone

secretion through interactions with the adrenoreceptors expressed on the α and β cells.

Neuropeptides

Parasympathetic nerve fibres in islets contain biologically active neuropeptides, including VIP, PACAP, and gastrin-releasing peptide (GRP), all of which are released by vagal activation and stimulate the release of insulin and glucagon.

VIP (28 amino acids) and PACAP (27 or 38 amino acids) are abundantly expressed neuropeptides that are widely distributed in parasympathetic nerves that supply the islets and gastrointestinal tract [9]. VIP and PACAP have similar structures, and VIP₁ and VIP₂ receptors also have an affinity for PACAP. The stimulatory effects of VIP and PACAP on insulin secretion *in vitro* and *in vivo* are through β -cell VIP₂ and PAC₁ receptors, respectively, and involve increases in intracellular cAMP (Figure 7.9) and cytosolic calcium [9, 128, 129]. GRP is a 27 amino acid peptide that also stimulates the secretion of insulin, glucagon, somatostatin, and PP [7]. These effects of GRP are mediated through specific receptors, and involve the activation of PLC and the generation of IP₃ and DAG (Figure 7.10).

Sympathetic nerves contain different neuropeptides to parasympathetic nerves, including NPY and galanin, both of which have inhibitory actions within islets. NPY (36 amino acids) and galanin (29 amino acids) are expressed in fibres innervating both the endocrine and exocrine pancreas [7, 130]. Both neuropeptides inhibit basal and glucose-stimulated insulin secretion [107, 130, 131], although differences between species have been reported. Both NPY and galanin act through specific G_i-coupled receptors to inhibit adenylate cyclase [93, 132, 133], and galanin may have additional inhibitory effects at an undefined late stage of exocytosis [107].

Regulation of insulin secretion by gut- and adipose-derived factors

Incretins

It has been known for over 50 years that insulin secretion from islets is greater following oral rather than intravenous administration of glucose [134] and it is now known that this enhanced insulin secretory output is a consequence of the release of gastrointestinal-derived *incretin* hormones [135]. The main incretins that have been implicated in an elevated insulin response to absorbed nutrients after food intake are GLP-1, glucose-dependent insulinotropic peptide (GIP), and cholecystokinin (CCK), all of which are hormones secreted by specialized endocrine cells in the gastrointestinal tract in response to nutrient absorption [135, 136]. These hormones are carried to the islets in the blood and they interact with specific receptors on the β -cell surface to stimulate insulin secretion.

Glucagon-like peptide 1

After food intake, L cells of the distal gastrointestinal tract secrete GLP-1 in response to elevated levels of nutrients derived from carbohydrates, lipids, and proteins in the intestinal lumen [135, 136]. GLP-1 is generated by prohormone convertase 1–3 cleavage of proglucagon in the L cells and it is highly conserved in mammals, with identical amino acid sequences in humans and mice [102, 135]. GLP-1 is degraded by dipeptidyl protease 4 (DPP-4), which cleaves two amino acids from its N-terminus. Full-length GLP-1 (1–37) does not show biological activity, but the truncated peptides GLP-1 (7–36) amide and GLP-1 (7–37) are potent stimulators of insulin secretion *in vitro* and *in vivo* [135]. Observations that infusion of the

peptide into individuals with type 2 diabetes before food intake improved insulin output and reduced the post-prandial increase in circulating glucose led to studies to determine whether GLP-1 or related peptides may be useful as therapies for type 2 diabetes. Reports of other beneficial effects of GLP-1, including its capacity to inhibit glucagon secretion, delay gastric emptying, and decrease food intake, indicated its positive effects on normalizing post-prandial glycaemia, but its half-life of less than 2 minutes precludes its use as a diabetes therapy. Nonetheless, exenatide, which is present in the saliva of the Gila monster lizard and has ~50% amino acid homology with GLP-1, has been developed for clinical use for type 2 diabetes [137]. Exenatide exerts the same effects on islets as native GLP-1, but its resistance to degradation by DPP-4 increases its half-life to ~2 hours *in vivo*, which ensures effective regulation of blood glucose levels. Another GLP-1 receptor agonist, liraglutide, has a greatly extended half-life (>12 hours) as a result of incorporation of the fatty acid palmitate into the GLP-1 sequence, allowing it to bind to plasma albumin and reducing its exposure to DPP-4. More recently, an oral GLP-1 receptor agonist formulation (oral semaglutide) has been approved for clinical use [138] and this provides a major advantage over other GLP-1 receptor agonists, which are administered by subcutaneous injection. Selective DPP-4 inhibitors, such as sitagliptin, are used clinically to treat type 2 diabetes by extending the half-life of endogenous GLP-1. GLP-1 and GLP-1 receptor agonists act at islet GLP-1 receptors [93, 135] that are linked, via G_s , to adenylate cyclase activation (Figure 7.9). Elevations in cAMP following GLP-1 receptor activation potentiate glucose-induced insulin secretion via activation of both PKA and EPACs [139]. Improved glucose homeostasis following bariatric gastric bypass surgery results, at least in part, from more rapid delivery of food to the L cells through a shorter gastrointestinal tract, which leads to enhanced post-prandial GLP-1 secretion [140, 141].

Glucose-dependent insulinotropic peptide

GIP, a 42 amino acid peptide, is released from K cells in the duodenum and jejunum in response to the absorption of glucose, other actively transported sugars, amino acids, and long-chain fatty acids [136]. It was originally called *gastric inhibitory polypeptide* because of its inhibitory effects on acid secretion in the stomach, but its main physiological effect is now known to be stimulation of insulin secretion in a glucose-dependent manner [135]. GIP receptors, like those activated by GLP-1, are coupled to G_s , with essentially the same downstream cascades leading to stimulation of insulin secretion (Figure 7.9). Although GLP-1 and GIP both enhance insulin output following their release in response to food intake, development of GIP-related peptide monotherapies for type 2 diabetes is unlikely because GIP stimulates glucagon secretion and inhibits GLP-1 release, and its infusion in individuals with type 2 diabetes worsens post-prandial hyperglycaemia [142]. However, a GLP-1/GIP receptor co-agonist is more effective in normalizing glycaemia and stimulating weight loss in people with type 2 diabetes than a GLP-1 analogue [143], most likely as a consequence of stimulation of GIP receptor signalling pathways in the CNS [144].

Cholecystokinin

CCK is another gastrointestinal hormone that is released from I cells in response to elevated fat and protein levels [136]. It was originally isolated from porcine intestine as a 33 amino acid peptide and the truncated CCK-8 form stimulates insulin secretion *in vitro* and *in vivo* [145]. CCK-8 acts at specific G_q -coupled receptors on β cells to activate PLC (Figure 7.10), and its potentiation of insulin

secretion is completely dependent on PKC activation [146]. However, the physiological role of CCK as an incretin has not been established because high concentrations are required for its effects on insulin secretion, and it is possible that its major function in humans is in digestion in the duodenum.

Bile acids

Bile acids act as endocrine factors to enable signalling between the gut and other tissues involved in metabolic homeostasis, including islet cells. They signal via the nuclear receptor farnesoid-X receptor (FXR) and the G-protein-coupled receptor TGR5, both of which are expressed in islets [93, 147]. TGR5 activation stimulates insulin secretion from mouse and human islets *in vitro* [148], but *in vivo* studies using transgenic mice suggest that FXR mediates most, if not all, of the effects of bile acids to enhance insulin secretion [147]. The composition and plasma concentrations of bile acids are altered by gastric bypass surgery, perhaps as a consequence of changes in the gut microbiome, and these changes have been linked to improved β -cell function and metabolic regulation [149]. However, a recent study in which an FXR- and TGR5-activating bile acid and a bile acid sequestrant were delivered to individuals after gastric bypass surgery reported only a limited role for bile acids in acute glucose regulation [150].

Decretins

Starvation studies in humans and other mammals suggest the existence of gut-derived factors that are released post-prandially to suppress insulin secretion and thus prevent post-prandial hyperinsulinaemic hypoglycaemia [151], these factors being referred to as *decretins* [152, 153] or *anti-incretins* [154]. Studies in baboons first identified gut-derived SST-28 as a putative decretin by demonstrating that immunoneutralization of SST-28 caused elevations in post-prandial plasma insulin concentrations [152]. Foregut-derived dopamine has also been proposed as a physiological decretin that is released post-prandially to inhibit glucose- and GLP-1-stimulated insulin secretion [155]. In *Drosophila* the neuropeptide limostatin acts as a decretin by suppressing the activity of insulin-producing cells and reducing the secretion of *Drosophila* insulin-like peptides [153]. The mammalian homologue of limostatin is neuromedin U (NMU), a neuropeptide that is expressed in foregut enteroendocrine cells, and is proposed to act as a decretin by suppressing glucose-induced insulin secretion from human islets through a specific β -cell receptor, NMUR1 [153]. However, intravenous delivery of neuromedin to rats does not affect insulin secretion or blood glucose levels [156]. The same study reported that neuromedin receptors are not expressed by rat or human islets, raising doubts about the decretin status of neuromedin, but NMUR1 has been identified in human islets in another study [93]. While decretins may be important in the pathophysiology of type 2 diabetes [154], most studies have been carried out in rodent models and it is clear that full understanding requires further research, including human clinical studies [157].

Adipokines

Obesity is a risk factor for diabetes, and hormones (adipokines) released from fat depots have been implicated in insulin resistance associated with obesity and type 2 diabetes [158]. Some adipokines, such as leptin, resistin, and adiponectin, are also reported to influence islet function. Thus, β cells express Ob-Rb leptin receptors, which, when activated by leptin, lead to inhibition of insulin secretion [159], and specific deletion of β -cell Ob-Rb receptors is associated with

enhanced insulin secretion [160]. The inhibitory effects of leptin on glucose-stimulated insulin secretion have been attributed to activation of β -cell K_{ATP} channels [161] or of c-Jun N-terminal kinases (JNKs) [162]. Leptin may also further impair β -cell function through reductions in β -cell mass [142, 144]. Resistin, another adipocyte polypeptide, also inhibits glucose-stimulated insulin release [163] and stimulates apoptosis of rat β cells [164], suggesting that it has similar functions to leptin. However, resistin is not considered to be a true adipokine because, although it is secreted at high levels from mouse adipocytes, it is not produced by human adipocytes, and high plasma resistin levels do not correlate with reduced insulin sensitivity [165]. Nevertheless, it is possible that resistin has paracrine effects on β -cell function in humans as it has been identified in human islets [166]. Unlike leptin and resistin, adiponectin has protective effects by improving insulin sensitivity, and decreased plasma adiponectin levels may contribute to the development of type 2 diabetes [167]. Human and rat β cells express AdipoR1 and AdipoR2 adiponectin receptors [168, 169], and adiponectin is reported to stimulate insulin secretion [168, 169], protect against β -cell apoptosis [170], and stimulate β -cell regeneration [171]. The signalling cascades that couple adiponectin receptors to downstream effects in β cells have not been fully defined, but adiponectin is reported to activate the kinases Erk and Akt in islets [172], and it also stimulates expression of genes that regulate lipid transport and metabolism [173]. Other less well-known adipokines, such as adipsin, apelin and chemerin, have also been implicated in improved insulin secretion, via activation of β -cell G-protein-coupled receptors [174].

Conclusions

Islets of Langerhans are complex micro-organs containing different types of endocrine cells, with extensive vasculature and autonomic nerve supply. Interactions between the islet cells, the autonomic and central nervous systems, and hormones secreted by the gastrointestinal system and adipose tissue permit the appropriate release of islet hormones to regulate metabolic fuel usage and storage.

The insulin-secreting β cells within islets respond to changes in circulating nutrients by linking changes in nutrient metabolism to β -cell depolarization and the calcium-dependent exocytotic release of stored insulin. Islet β cells can also respond to a wide range of hormones and neurotransmitters through conventional cell-surface receptors that are linked to intracellular effector systems regulating the release of insulin. The ability to detect nutrient, hormonal, and neural signals allows β cells to integrate information about the prevailing metabolic status, and to secrete insulin as required for glucose homeostasis.

This detailed understanding of islet cell biology has informed the development of new treatments for type 2 diabetes, such as GLP-1 receptor agonists and DPP-4 inhibitors. It is now acknowledged that β -cell dysregulation is a key factor in the development of type 2 diabetes. Advances in our understanding of normal β -cell function may therefore assist in identifying the β -cell pathologies in type 2 diabetes, and in developing new therapeutic approaches.

Glucagon in Islet and Metabolic Regulation

Jonathan E. Campbell and David A. D'Alessio

Department of Medicine, Division of Endocrinology, Duke University, Durham, NC, USA

Key points

- Glucagon is made predominantly in islet α cells and regulates systemic glycaemia through actions in the liver and islet β cell.
- Glucagon has direct actions on hepatocytes to promote glucose production, lipid metabolism, and amino acid metabolism.
- Hepatic glucagon signalling is essential for normal amino acid metabolism and increased circulating amino acids stimulate α -cell glucagon production.
- Excess glucagon contributes to dysglycaemia in some people with diabetes and may contribute to diabetic ketoacidosis in those with type 1 diabetes.
- Compounds that both stimulate and antagonize the glucagon receptor are under investigation for treatment of metabolic disorders.

Glucagon is a regulatory peptide made almost exclusively in the α cells of the pancreatic islet and has a notable history in basic research, clinical physiology, and therapeutics. Discovered initially as a contaminant in the process of insulin extraction from the pancreas [1], the demonstration of specific actions to raise blood glucose led to a physiological model in which glucagon acted as a counterbalance to insulin, providing glucose under circumstances of need [2]. The fundamental aspects of glucagon signalling at the cellular level formed much of the basis for the discovery of cyclic adenosine monophosphate (cAMP) and G-proteins [3]. Glucagon was one of the first hormones that could be measured in the circulation and tissues of humans and experimental animals. Early work demonstrated dramatic increases in circulating levels with hypoglycaemia and extreme physical exertion [2], and smaller but consistent elevations during starvation [4]. Especially important was the observation that glucagon levels were elevated in many people with diabetes, dramatically so during diabetic ketoacidosis [5, 6]. These findings raised the possibility that both islet hormones, insulin and glucagon, had a role in the pathogenesis of diabetes [7], a hypothesis that was supported by human experiments using somatostatin to inhibit α -cell secretion [8]. Interest in glucagon as a central factor in diabetes pathophysiology waned for several decades as the focus of metabolic research and treatment of diabetes focused on insulin resistance and defects in β -cell function. However, recently glucagon has regained its status as a topic of great interest in diabetes investigation, and renewed attention to glucagon physiology has been bolstered by the advent of new drugs that suppress glucagon as part of their glucose-lowering activity.

This chapter will review basic concepts in α -cell biology and glucagon physiology with an emphasis on how these processes are altered in disease states, particularly diabetes. Relatively new findings that implicate glucagon in intra-islet signalling, hepatic protein

metabolism, and energy balance, as well as descriptions of new uses for glucagon activity in drug development, will be discussed. The role of glucagon in hypoglycaemic counter-regulation is addressed in detail in Chapter 40 and will not be considered in depth here. The pharmacology of available diabetes drugs that affect glucagon secretion, such as dipeptidyl-peptidase inhibitors and glucagon-like peptide 1 (GLP-1) receptor agonists, is covered in Chapter 36. There are several recent reviews that cover the molecular and systemic physiology of glucose in more detail than the current chapter [9–12].

Anatomy and development of α cells

The function of glucagon and other α -cell products is based in great part on the anatomy of the pancreatic islet. New research implicates the α cell in paracrine regulation of the endocrine pancreas, and islet structure has an important bearing on this function. Recent studies demonstrating key differences in islet architecture between rodents and humans have provided new insights into pancreatic endocrine function. These differences include heterogeneity of islet size and organization within species [13, 14]. In mice and rats the organization of the islet includes a mantle of α and δ cells on the periphery of the islet, surrounding a core of β cells (Figure 8.1). Estimates of the relative endocrine cell composition in rodent islets are ~75–80% β and 20–15% α cells, and most β cells have contact with other β cells [15–17]. In humans, the major endocrine cell types are spread more diffusely throughout the islet, most β cells have contact with either α or δ cells, and the percentage of β cells per islet is 40–60% (Figure 8.1) [13–15]. Based on recent analyses of large numbers of human pancreata, the frequency of contacts between α and β cells appears to be much greater than previously estimated, as is the

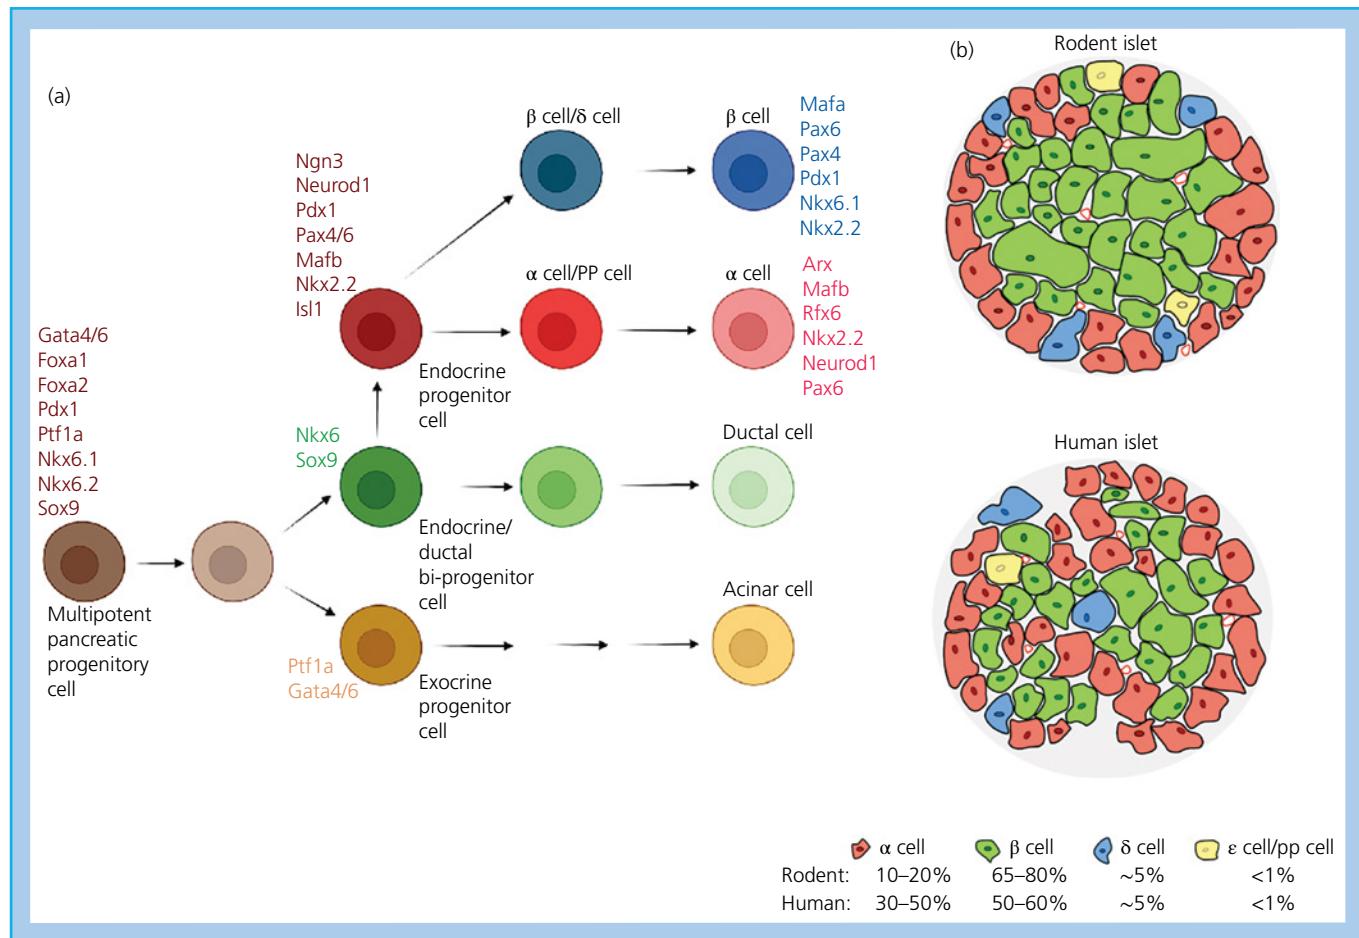

Figure 8.1 Islet development and composition. (a) Cellular markers for pancreatic exocrine and endocrine cell types through development. (b) Cell populations of endocrine cells in pancreatic islets from rodents versus humans. Human islets contain a higher percentage of α cells, with more α cells in the centre of the islet. Rodent islets have fewer α cells that are primarily found on the outside of the islet.

location of islet endocrine cells in close proximity to the microvasculature [13]. In humans, smaller islets have cellular architecture that resembles rodents – that is, a ring of α cells surrounding a β-cell core with a higher percentage of β cells than larger islets; smaller islets also have greater relative insulin secretion [13,14]. These recent studies on the organization of islet anatomy, particularly in humans, have shifted the focus from interactions mediated through the microcirculation to control through direct cell-to-cell contacts.

Neural regulation of islet function is well established, although the nature and magnitude of effects are still under debate. In general, sympathetic nervous system activity is thought to be important in settings where there is enhanced demand for glucose – that is, hypoglycaemia and physical activity – and parasympathetic activity is important before and during meal ingestion [18–20]. Recent data suggest a difference between the density of autonomic innervation of rodent and human α and β cells, with rats and mice having greater density of neural fibres in islets [21]. While this has led to the hypothesis that neural regulation of islet secretion is more important in rodents and paracrine control in humans, this has not been formally tested, and not all studies have demonstrated reduced innervation of human islet cells [22].

The formation of α cells is within the general process of pancreatic development in early embryonic life, directed by the sequential and interacting effects of specific transcription factors (Figure 8.1).

Most of the current knowledge on endocrine pancreatic development comes from studies in mice, and while there are general similarities with human islet development, some key differences exist [23–25]. In both mice and humans, pancreatic duodenal homeobox 1 (Pdx1) directs the differentiation of pancreatic epithelial cells, which will become the exocrine and endocrine pancreas, from the foregut endoderm [26]. Subsequent expression of neurogenin 3 (Ngn3) initiates the primary differentiation of endocrine precursors and their initial association into discrete cellular aggregates. The transcription factor aristaless-related homeobox (Arx) is critical for determining a definitive α-cell fate for developing endocrine progenitors, and in its absence normal α cells do not develop [27]. Both mice and humans also have a secondary transition of endocrine development where the various hormone-producing cells start to express the gene profiles that mark mature endocrine cells [26,27]. In mice, glucagon-producing cells are the first detectable endocrine cell type, while insulin-containing cells are the earliest form in humans [25]. Once the secondary transition has occurred, the formation of islets in the distinct murine and human forms progresses throughout the remainder of the prenatal period [24]. The molecular physiology of islet development has assumed particular importance as efforts progress to generate β cells for potential use in therapeutics. There is evidence that mature α cells can be reprogrammed to insulin-producing cells in

states of severe β -cell loss [28], and that diabetes induces dedifferentiation of β cells into α cells [29]. The plasticity of islet cells is only beginning to be understood, but holds promise for understanding the mechanisms of various forms of diabetes.

Proglucagon gene transcription, translation, and peptide processing

Pre-proglucagon (*Gcg*), the gene that encodes glucagon, is expressed in pancreatic islet α cells but also within the hindbrain, specifically in a subset of neurons in the nucleus of the solitary tract, and within the enteroendocrine L-cell of the intestinal mucosa [30, 31]. Regulation of *Gcg* expression is complex, but initiating signals include elevations of cAMP and/or amino acids, and the effects of several specific transcription factors [32–34]. *Gcg* expression is differentially regulated in the pancreas and intestine. The most relevant example of this is related to nutritional state, with fasting increasing islet *Gcg* expression, while feeding promotes transcription in L cells [35]. As an extension of this level of regulation, insulin inhibits *Gcg* transcription in islet α cells [33, 36], but increases *Gcg* expression in intestinal endocrine cells [37, 38]. The latter effect is mediated in part by signalling related to transcription factor 7 like 2 (TCF7L2), a gene product linked to type 2 diabetes in genetic epidemiological studies [39], which seems to be specific for control of L-cell *Gcg* transcription [37]. Bowel resection or injury causes a large increase in intestinal *Gcg* expression [40]. Differential regulation of *Gcg* transcription in intestinal and islet endocrine cells is in keeping with their distinct patterns of prohormone processing and the predominant secretion of glucagon from the pancreas and GLP-1 and GLP-2 by the gut.

The differential synthesis and release of *Gcg* peptides from α cells compared to intestinal and neural cells expressing *Gcg* is the result of tissue-specific post-translational modification by prohormone convertases (PC). In the α cell, PC2 is the major convertase and it cleaves specific sites along proglucagon to release glucagon, but not the glucagon-related peptides [41]. In contrast, intestinal L cells have significantly more PC1/3 than PC2 activity, and process proglucagon into GLP-1, oxyntomodulin, and GLP-2 as physiologically relevant products [42–44]. There is PC1/3 expression in α cells, albeit at lower levels than PC2, and increasing evidence for islet production of GLP-1; similarly, there have been reports of glucagon produced from enteroendocrine cells in individuals after bariatric surgery [45]. While PC2 is expressed by some central nervous system (CNS) neurons, it is not co-localized with *Gcg*, and only trace amounts of glucagon have been detected in the CNS [42]. In addition to glucagon and the glucagon-like peptides, other proglucagon-derived peptides are measurable in tissue extracts and the circulation and may have signalling properties. These include oxyntomodulin, glicentin, glicentin-related pancreatic polypeptide (GRPP), major proglucagon fragment (MPGF), and mini-glucagon [12].

Regulation of α -cell secretion

Glucagon is the chief secretory product of α cells and glucagon concentrations have been used as the principal measure of α -cell function *in vivo* and *in vitro*. With the possible exception of individuals treated with bariatric surgery [45], there is no evidence that tissues besides the islet α cell release glucagon into the circulation.

Glucagon secreted from islets in the pancreas collects in the portal vein, where concentrations are higher than other major vascular systems, and the liver is the primary target of glucagon signalling. Circulating glucagon is cleared by the liver and kidney, with roughly equal contributions by each organ, and 20–40% hepatic clearance of portal venous content [46–48]. Glucagon secretion is regulated by a complex interplay of nutrient, endocrine, paracrine, and neural factors (Figure 8.2). While there is convincing evidence to support this diverse control of α -cell secretion, how the system is integrated varies under different physiological states, and is altered by disease in ways that are still not well understood.

Like the β -cell secretion of insulin, ambient glucose concentrations also regulate α -cell release of glucagon. Low glucose levels increase and high concentrations inhibit glucagon secretion, in part through changes in α -cell electrical activity involving K_{ATP} channels [49–51]. It remains a curiosity that α and β cells have similarities in key aspects of glucose transport, metabolism, and K_{ATP} channel activity, yet opposite secretory responses to changes in ambient glucose. Differences in resting electrical characteristics and ion channel function downstream of K_{ATP} channel closure can explain much of the reciprocal pattern of glucagon and insulin secretion at relative hypo- and hyperglycaemia [51–53]. Moreover, new findings suggest that α cells, but not β cells, express sodium glucose transporters (SGLTs) 1 and 2 [54], and that reduced flux through SGLT-2 increases glucagon secretion. It is unclear how SGLT function is integrated with other aspects of α -cell glucose metabolism, but observations that humans treated with SGLT-2 inhibitors have increased plasma glucagon suggests that this is an active physiological mechanism [55, 56]. Beyond glucose, amino acids are another nutrient source that stimulates α cells. Protein meals or infusions of amino acids stimulate glucagon release, and arginine is commonly used to stimulate glucagon secretion in research studies. Among the amino acids alanine, glutamine, proline, and glycine are also potent α -cell secretagogues [57, 58].

Substantial differences exist between glucagon release from isolated α cells and intact islets [10, 59, 60], suggesting that other islet cells have important roles in α -cell regulation. Endocrine cells in islets are exposed to high concentrations of local products and both insulin and somatostatin inhibit glucagon release [10], acting either through the microvasculature or by local cell-to-cell contact. Insulin contributes measurably to the suppression of glucagon after meals [61] and during progressive hyperglycaemia [62]. Other compounds released from β cells inhibit glucagon release, including zinc [59], γ -amino-butrylic acid [63], and glutamate [10], but the physiological relevance of these compounds is unclear. Exogenous somatostatin is a potent inhibitor of glucagon secretion [64], and somatostatin secreted from islet δ cells restrains α -cell secretion during exposure to circulating nutrients after meals. A final mechanism of intra-islet regulation of glucagon is autocrine, as recent work suggests that other α -cell products may regulate the α cells. The α cells from both primates and mice secrete glutamate and express ionotropic glutamate receptors (iGluR) [65]. Glutamate stimulates glucagon release, and this seems to be important for the normal response to low plasma glucose, since inhibition of iGluR impairs hypoglycaemic counter-regulation in mice [65].

The autonomic nervous system is critical for the regulation of glucagon secretion, particularly in the setting of hypoglycaemic counter-regulation. Activation of both the parasympathetic and sympathetic limbs of the autonomic nervous system increases glucagon release [19], and adrenal epinephrine has a similar effect that may be especially important when blood glucose is very low.

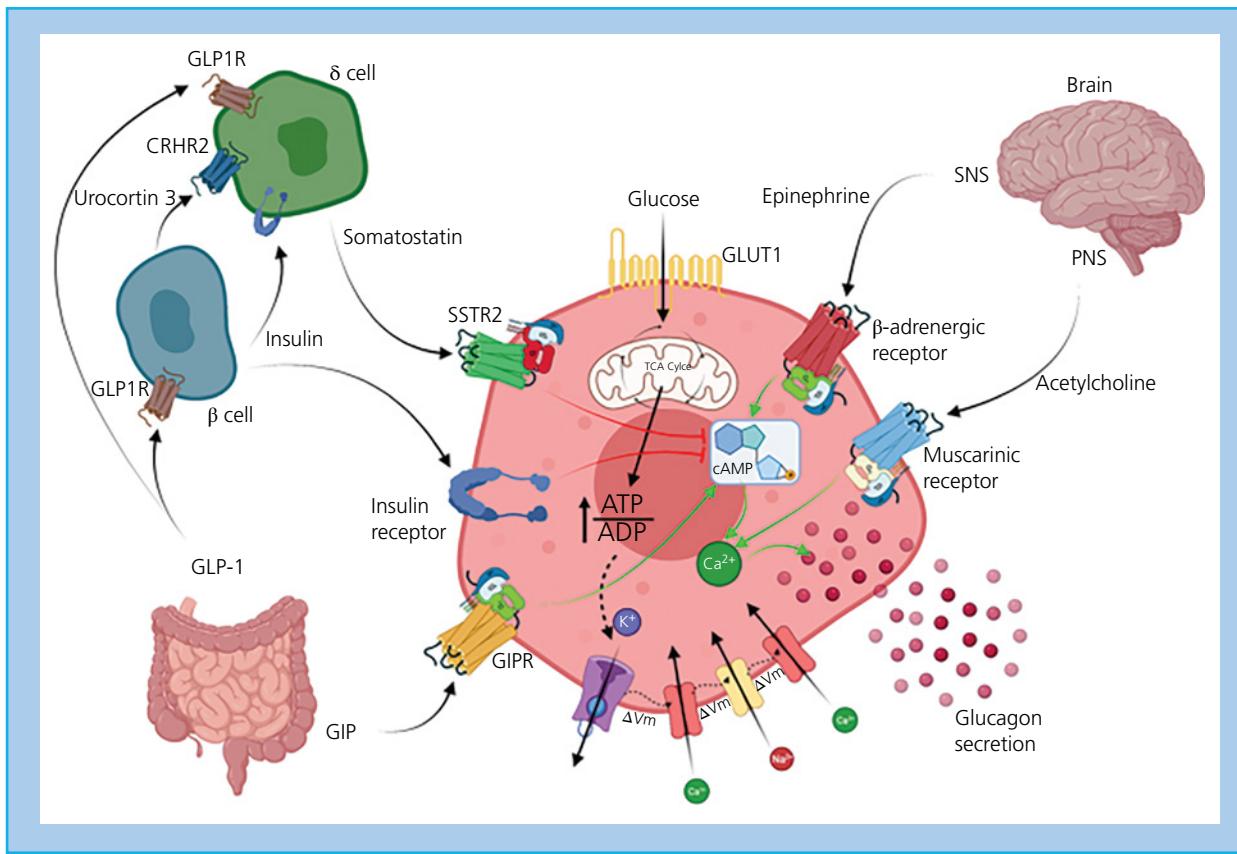

Figure 8.2 Signals that integrate to regulate α -cell secretion of glucagon. The α cell receives input from multiple sources including neuronal, endocrine, and paracrine signals. The incretins are endocrine signals that regulate α -cell function both directly (GIP) and indirectly (GLP-1). Paracrine signals within the islet originate from both the β cell and the δ cell. Activation of the β cell enhances these paracrine signals, directly inhibiting the α cell through factors such as insulin, γ -aminobutyric acid, or Zn^{2+} , and

indirectly by increase δ -cell activity through the urocortin 3 system. Increased activity of the δ cell inhibits glucagon secretion through somatostatin. The α cell also receives neuronal input through the sympathetic (SNS) and parasympathetic nervous systems (PNS), both of which increase glucagon secretion. CRHR2, corticotropin-releasing hormone receptor 2; GIP, glucose-dependent insulinotropic polypeptide; GLP-1, glucagon-like peptide 1; SSTR2, somatostatin receptor 2.

Importantly, catecholaminergic signalling synergizes with low blood glucose to stimulate glucagon release [53], and genetic disruption of autonomic neurons in the islet predisposes mice to hypoglycaemia [66]. The key regions in the CNS for sensing circulating blood glucose and initiating counter-regulation are located in the hypothalamus and hindbrain [67, 68].

Similar to insulin, glucagon release is also affected by the actions of enteric peptides [10, 69]. Glucose-dependent insulinotropic polypeptide (GIP) stimulates glucagon release through direct actions on the GIP receptor expressed on α cells [70]. It is of great importance that the other major G_{cg} peptide, GLP-1, inhibits glucagon secretion, although there is debate over the mechanism whereby this occurs, since the majority of α cells do not express the GLP-1 receptor [71]. GLP-1 increases the secretion of hormones from both β and δ cells, and so could act indirectly to reduce glucagon release [10, 69], and this is currently considered to be the primary means by which GLP-1 acts on the α cell. In addition, GLP-1 affects electrical activity and secretion of α cells, even in the absence of changes in somatostatin or insulin [72].

Overall α -cell regulation is a complex, multilayered process with dense integration of control by nutrients and neural, endocrine, paracrine, and autocrine inputs to secretion. Because glucagon has a key role across a range of physiological settings, during fasting, exercise, hypoglycaemia, and following mixed-nutrient meals, α cells are subject to a diversity of controlling factors. While there

appears to be some overlap in α -cell control, it seems likely that some regulatory factors also have specific roles as well. Further understanding the regulation of glucagon secretion, and adaptation of therapeutic approaches to control this process, has great potential for the treatment of metabolic disease.

Glucagon actions in the liver: glucose and lipid metabolism

Glucagon action is mediated by the glucagon receptor (GCGR), a family B G-protein-coupled receptor that is highly conserved across mammalian species [73]. Binding of glucagon to the GCGR activates adenylyl cyclase through the G_s subtype G-protein generating cAMP and activating protein kinase A (PKA) as one major mode of intracellular signalling [74]. However, the GCGR also couples to G_q , suggesting access to a wider range of downstream signalling pathways [75, 76]. The richest source of glucagon binding is in the liver and kidney; lesser binding occurs in heart, adipose tissue, the CNS, adrenal gland, and spleen [73]. Consistent with the relative receptor expression, the liver and kidney play the major role in glucagon clearance, accounting for ~70% of the removal from the circulation [46, 48, 73]. The half-life of glucagon in circulating plasma is relatively short: 2, 5, and 7 minutes in rats, dogs, and humans, respectively [73, 77].

The first known action of glucagon, to increase hepatic glucose production, was recognized nearly 100 years ago [3]. Subsequent work demonstrated effects of glucagon to counter hypoglycaemia and led to the general principle that it has a role opposing that of insulin to maintain plasma glucose in times of stress, fasting, or exercise [3]. The endocrine mechanism of glucagon action is based on the effects of exogenous glucagon to increase hepatic glucose output in animals, humans, and several *in vitro* systems, as well as the observation that removal of circulating glucagon with a neutralizing antibody reduces blood glucose [77,78].

The cAMP/PKA signalling pathway is critical for the ability of glucagon to regulate hepatic glucose production [77,79]. The downstream activation of phosphorylase kinase and its target glycogen phosphorylase activates glycogenolysis and inhibits glycogenesis [80,81]. However, insulin also regulates these pathways. Thus, a long-held view is that the balance between glycogen breakdown and synthesis results from the relative insulin and glucagon effects on hepatocytes, the degree of cAMP signalling, and the level of glycogen stores [81]. Strategies that increase glycogen synthesis relative to glycogenolysis promote glucose tolerance [80,82] and are potential therapeutic targets for hyperglycaemia. GCGR signalling also regulates the flux between glucose-6-phosphate and fructose bisphosphate via action on fructose 2,6 bisphosphatase and its inhibition of pyruvate kinase activity [77]. The result of cAMP signalling is rapid inhibition of hepatic glucose metabolism and mobilization of stored glucose to deliver glucose to peripheral tissues.

However, another critical aspect of glucagon-induced regulation of hepatic glucose production is through enhancement of the gluconeogenic pathway, an action mediated by PKA activation of CREB and Forkhead box (FOXO1). Glucagon upregulates phosphoenolpyruvate carboxykinase (*Pepck*) gene transcription, which varies with the metabolic state, increasing during fasting and decreasing in response to insulin [77]. PEPCK catalyses a key step in gluconeogenesis by converting oxaloacetate, a product of the tricarboxylic acid (TCA) cycle, into phosphoenolpyruvate. In animal models, gluconeogenesis is increased by overexpression of *Pepck* [83] and conversely decreased by deletion of *Pepck* [84,85]. Other key genes involved in glucose production, including peroxisome proliferator-activated receptor- γ coactivator 1 (*PGC-1*) and glucose-6-phosphatase (*G6P*), are also activated by glucagon signalling. Overall, glucagon regulates several processes within the gluconeogenic pathway that enable sustained glucose production, an effect that is enhanced in the face of limited glycogen supply. Gluconeogenesis is an energy-demanding process, requiring six moles of high-energy phosphate bonds for each mole of glucose produced, and is tightly linked to TCA cycle activity and lipid oxidation for sources of ATP [84]. Indeed, glucagon contributes to hepatic fatty acid oxidation and ketogenesis at several metabolic steps [86,87], and elimination of glucagon action increases liver triglyceride content during fasting. A recent study has shown the centrality of the inositol triphosphate receptor 1 to mediate fatty acid mobilization and oxidation downstream of the GCGR [88]. Taken with previous work, these new findings support a model whereby glucagon has broad effects on hepatic fuel metabolism, generating energy from lipids to support glucose production.

The effects of glucagon on hepatic glucose and lipid metabolism may also lead to pathological consequences if they are not counterbalanced by appropriate levels of insulin action. Increased glucagon during extended periods of fasting or uncontrolled type 1 diabetes stimulates fatty acid oxidation and contributes to ketogenesis [9].

The transcription factor FOXA2 may play a central role in this process. FOXA2 controls the expression of genes involved in fatty acid oxidation and ketogenesis [89,90] and is activated by both fasting and glucagon. Insulin has opposing effects on FOXA2 [91], presenting yet another example of coordinated and inverse regulation by insulin and glucagon on glucose and lipid metabolism, with glucagon more active in the fasted state and insulin predominating during and after feeding.

Studies in humans using somatostatin to inhibit insulin and glucagon secretion, with selective replacement of one or both hormones, are consistent with the knowledge gained from pre-clinical animal studies. Glucagon is necessary to support normal fasting glucose levels [92,93] and basal insulin replacement without glucagon results in hypoglycaemia. However, physiological regulation of hepatic glucose production by glucagon occurs against a backdrop of constant but variable hepatic insulin action [94]. At glucose levels of 4.5–5.5 mmol/l, plasma glucagon levels are relatively low and unchanging, while changes in glycaemia within this range can affect insulin secretion. This suggests that the effect of glucagon to promote glycogenolysis and initiate gluconeogenesis during fasting occurs tonically, with the absolute level of fasting blood glucose determined by variations of hepatic insulin action. At a cellular level, this can be conceived as glucagon maintaining a threshold of cAMP, or other signalling mediators, that can be modulated by changes in hepatic insulin signalling.

Although glucagon-driven hepatic glucose production includes both glycogenolysis and gluconeogenesis, these two processes follow different temporal patterns. As fasting progresses, the contribution of glycogenolysis to total hepatic glucose output wanes such that glycogenolysis contributes ~50% of liver glucose output in the postabsorptive state but less than 10% after 36 hours of fasting [95,96]. In acute experiments, where glucagon action can be selectively increased, glycogenolytic effects predominate [97]. This is because activation of gluconeogenesis by glucagon requires a supply of glucose precursors, primarily lactate, alanine, and glycerol. Increased delivery of these compounds to the liver is not directly regulated by glucagon and requires a longer period of fasting to reduce plasma insulin and disinhibit lipolysis and proteolysis. With extended periods of starvation, gluconeogenesis becomes even more tightly controlled by precursor supply as preservation of protein stores becomes essential [98].

The hallmark of glucagon action in homeostasis is to increase hepatic glucose production during hypoglycaemic counter-regulation (Figure 8.3) [99]. Glycogenolysis provides the most rapid source of glucose. However, the rise in catecholamines that also occurs with hypoglycaemia provides a supply of glucose precursors for gluconeogenesis as well as direct stimulation of hepatic glucose production through hepatic adrenergic receptors [100]. Thus, there is an integrated, synergistic effect of catecholamines and hypoglycaemia to stimulate glucagon release and glucagon action to return glucose levels to normal.

Glucagon also contributes to the maintenance of blood glucose during exercise, another metabolic stressor [101,102]. Similar to hypoglycaemia, increasing catecholamines and glucagon in response to exercise, combined with the usually low circulating levels of insulin, enhance glucagon action and ensure adequate glucose output to maintain glucose supply to peripheral working muscles. With prolonged exercise, the impact of glucagon to promote lipid oxidation becomes increasingly important to preserve limited glucose and provide energy [103].

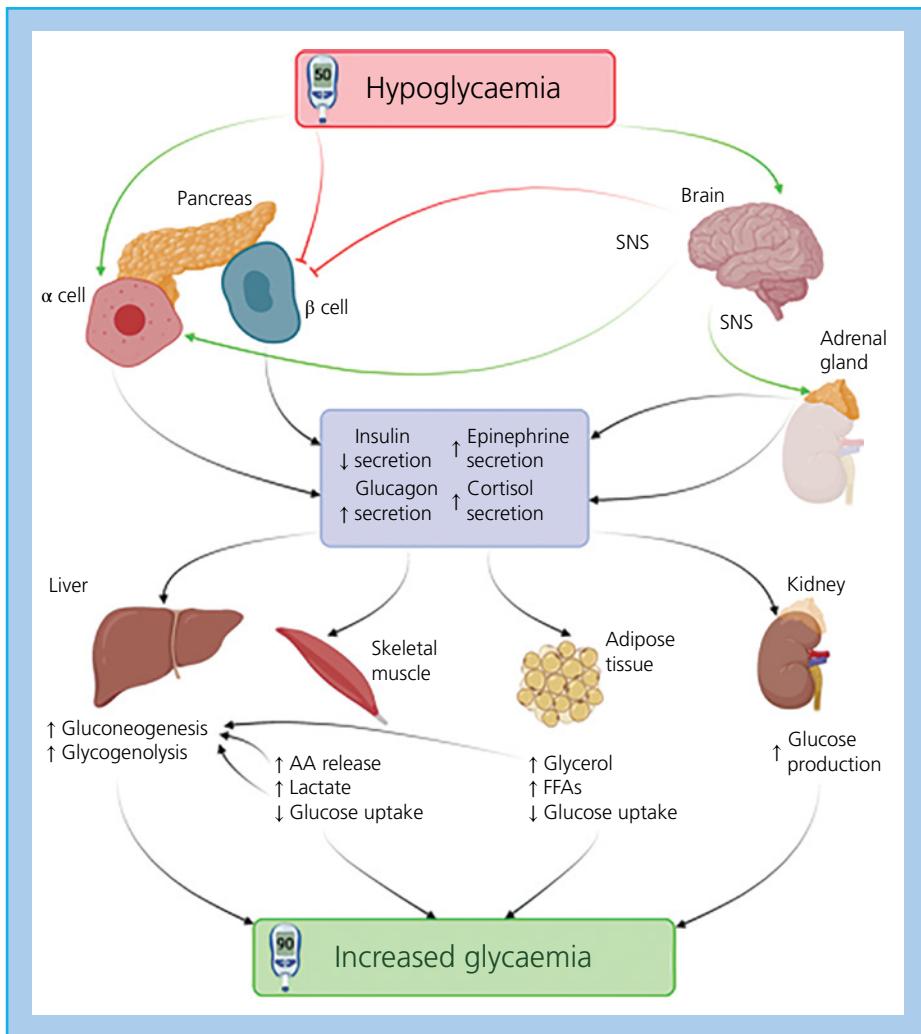

Figure 8.3 Counter-regulatory actions in response to hypoglycaemia. A decrease in glycaemia initiates multiple events in order to restore euglycaemia. In the islet, a low blood glucose decreases insulin secretion from β cells and increases glucagon secretion from α cells. Hypoglycaemia also initiates neuronal sympathetic tone, which increases glucagon, cortisol, and epinephrine secretion. The changes in hormone concentrations in response to hypoglycaemia are summarized in the middle

of the figure. These hormonal changes increase glycaemia by enhancement of glucose production by the liver and kidney, reduction of glucose uptake into peripheral tissues, and efflux of amino acids (AAs) and lipid products from skeletal muscle and adipose tissue, respectively. The increased concentrations of AAs, lactate, and glycerol facilitate gluconeogenesis to further increase hepatic glucose output. AA, amino acid; FFA, free fatty acid; SNS, sympathetic nervous system.

Although the physiology of glucagon to regulate hepatic glucose and lipid metabolism is based on a large base of experimental evidence accumulated over many years, several recent reports have raised questions about the fundamental aspects of the consensus model. The pre-eminence of G_s/cAMP signalling as the basis for driving hepatic glucose production has been challenged by pre-clinical studies that implicate signalling through G_i as increasing glycogenolysis and gluconeogenesis [104]. A similar challenge to traditional thinking is based on studies in mice showing that glucagon is dispensable for the ketosis induced by starvation or SGLT-2 inhibitor treatment [105]. Finally, an effect of hepatic glucagon receptor signalling to improve insulin-stimulated glucose uptake in skeletal muscle and brown fat has been described in mice [106], suggesting a broader role for glucagon on glucose disposition through indirect mechanisms. These findings suggest that there remain significant gaps in understanding glucagon action, and that further study could provide insights into disease and potential for therapeutic development.

Glucagon actions in the liver: amino acid metabolism and the hepatic- α -cell axis

Glucagon plays an important role in amino acid metabolism, and experimental variation of circulating glucagon across the physiological range causes inverse changes of plasma concentrations of amino acids in humans [107,108]. This effect is most pronounced for glucogenic amino acids [108], and is associated with increased urinary excretion of nitrogen [107] and enhanced glucose production [107,108], supporting a link between glucagon-induced amino acid catabolism and gluconeogenesis. In mice, genetic deletion of the GCGR, or its antagonism with a blocking antibody, causes downregulation of genes encoding proteins involved in amino acid catabolism and the urea cycle, and an increase in circulating amino acids [109]. Acute blockade of the GCGR caused an almost immediate increase in circulating glucagon, and induced α -cell hyperplasia within several days. A profound increase in islet α cells along

with hyperaminoacidaemia and hyperglucagonaemia are cardinal features of mice with genetic deletion of GCGR; each of these abnormalities is at least partially corrected with liver-specific re-expression of GCGR [109]. Considered together, findings from studies of humans and mice suggest a physiological connection between the liver and α cell mediated by amino acids.

Understanding of the liver– α -cell axis has become an area of active investigation. Recently two groups independently reported the importance of the amino acid transporter Slc38a5 for mediating amino acid-induced hyperplasia of α cells [110, 111]. This specific transporter actively transports several amino acids into α cells, including glutamine, alanine, and glycine, three prevalent species that increase markedly with interruption of glucagon signalling to the liver. Expression of Slc38a5 is increased with GCGR blockade or deletion and is necessary for the full manifestation of α -cell hyperplasia in these settings. L-glutamine seems to be the key amino acid driving α -cell hyperplasia [110], a process that is dependent on mechanistic target of rapamycin (mTOR) signalling [109–111], a fundamental pathway connecting energy and amino acid availability with cell growth.

The liver– α -cell axis may be involved in the pathogenesis of metabolic liver disease and type 2 diabetes. Individuals with obesity and greater hepatic steatosis than lean individuals had hyperaminoacidaemia, hyperglucagonaemia, and downregulation of hepatic expression of genes involved in amino acid transport and metabolism [112]. When given infusions of exogenous glucagon, circulating amino acids were reduced in lean individuals but not those with obesity. Based on these results, as well as supporting findings that people with non-alcoholic fatty liver disease (NAFLD) have increased plasma levels of glucagon and amino acids, it has been proposed that impairment of the liver– α -cell axis may link hepatic steatosis and dysregulated glucose metabolism [113].

Glucagon intra-islet communication and insulin secretion

The GCGR is expressed by islet β cells and supraphysiological amounts of glucagon stimulate insulin release *in vitro* and *in vivo* [114–116]. In isolated human and rat islets studied in culture, antagonism of the GCGR impairs insulin secretion in response to increased media glucose, suggesting a physiological role for islet glucagon action to maintain normal β -cell stimulus–secretion coupling [77, 80, 81]. Consistent with local control of insulin secretion mediated by α -cell products, dispersed β cells are more responsive to glucose when attached to an α cell [117]. Thus, paracrine regulation mediated by α -to- β -cell communication (Figure 8.4) is increasingly accepted and has gained additional support from recent studies. Several groups, using complementary approaches, have shown that glucagon acts through both glucagon and GLP-1 receptors on β cells to stimulate insulin release [116, 118, 119], an effect that is apparent in both mouse and human islets [57]. One proposed effect of α -cell products on systemic homeostasis is regulation of the glycaemic set-point – that is, the normal basal concentration of blood glucose – through effects on β -cell tone and responsiveness to glucose [21, 57, 120]. However, a recent demonstration that stimulation of α -cell secretion by gastric inhibitory polypeptide (GIP), a hormone released episodically after meals, promotes glucose tolerance through α -to- β -cell communication [70] suggests that proglucagon peptides are also a component of prandial insulin responses.

Effects of glucagon on energy intake and energy expenditure

The GCGR is expressed by neurons throughout the CNS, including regions in the brain that are central to metabolic regulation [121]. Glucagon moves into the brain from the circulation and administration of glucagon into the cerebroventricular system of rats suppresses food intake. It is unknown whether the discrete population of hindbrain neurons that are the sole source of proglucagon peptides in the brain [122] produce glucagon as well as GLP-1, or whether direct actions of glucagon on CNS neurons is part of physiological regulation. A stronger case can be made that glucagon suppresses appetite through activation of peripheral signals in the liver [121]. Stimulation of hepatic FGF-21 release by glucagon contributes to negative energy balance [123, 124]. This model has been developed in rodents, and is based on the relatively higher hepatic portal glucagon concentrations and a connection to the satiety centres of the hindbrain through vagal afferent fibres. While plausible, this remains hypothetical, with as yet no translation to humans.

While glucagon may reduce energy intake, it may also promote energy expenditure. In pre-clinical studies, glucagon increases both core body temperature [125] and brown adipose tissue mass and heat generation [125–128]. Brown adipose tissue is highly activated during cold exposure to maintain body temperature, and cold exposure increases both plasma glucagon levels and brown adipose tissue glucagon content in rats [129]. However, recent work in mice [130] and humans [131] has demonstrated that glucagon increases energy expenditure independently of brown adipose tissue activation. Moreover, while there are several studies showing that infusion of glucagon to humans for several hours causes a 10–20% increase in energy expenditure, this effect is not maintained over 24 hours [132]. Mice with deletion of the *Gcg* gene and an absence of proglucagon peptides were leaner than control mice, but did not differ in total body weight [133], suggesting that glucagon may have a minor role in determining adiposity. Thus, while there are both mechanistic and clinical data supporting glucagon action as a means to reduce energy balance, the magnitude of the effect does not appear to be large.

Production of glucagon-like peptide 1 by α cells

Glucagon is not the only important *Gcg* peptide with a role in intra-islet regulation, with recent studies suggesting that α -cell production of GLP-1 may also have a role in the regulation of islet function (Figure 8.4). Rodent islets studied in culture have demonstrable expression of PC1/3, and release fully processed, bioactive GLP-1 in culture [134, 135]. Moreover, intact GLP-1[7–36]-amide is secreted from isolated rat islets [134, 136], and from isolated human islets and α cells [137]. Interruption of GLP-1 receptor (GLP-1R) signalling in isolated rodent islets or pancreata, using receptor antagonists or gene knockout techniques, reduces basal [134] and glucose-stimulated insulin secretion [138]. These findings have recently been corroborated in a mouse model with β -cell-specific deletion of the GLP-1R [139]. Finally, infusion of a GLP-1R antagonist to fasting humans, with fixed, low circulating GLP-1 levels, decreases glucose-stimulated insulin secretion [140, 141]. These findings can be taken as support for the action of local islet GLP-1. Overall, there has been an accumulation of evidence to support a role for local production of GLP-1 in α -to- β -cell communication and the regulation of insulin secretion.

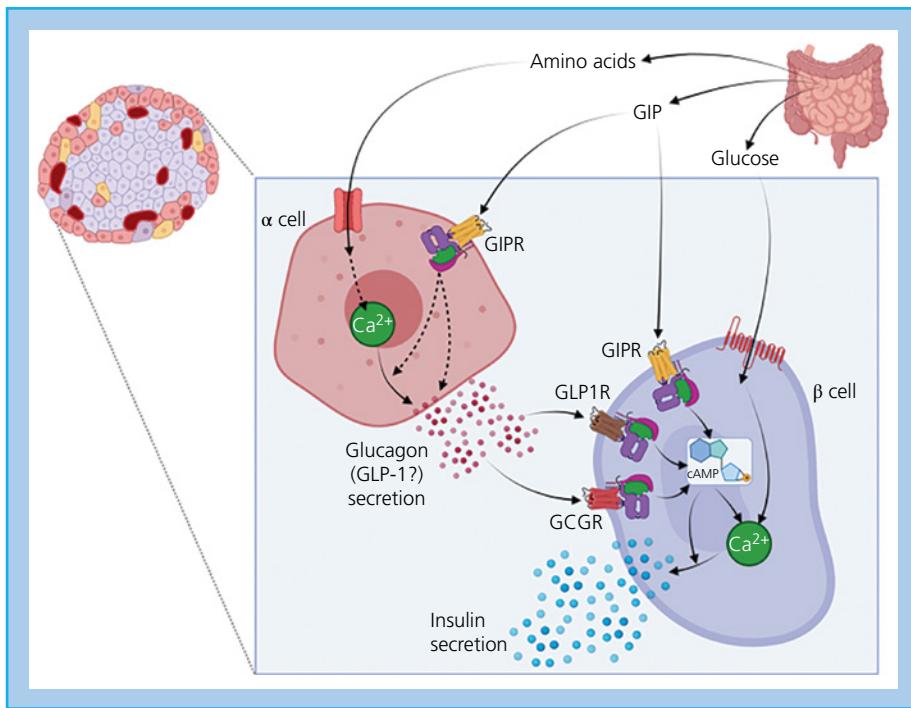

Figure 8.4 The integration of the incretin system and nutrient sensing in α and β cells in the post-prandial state. Feeding increases the plasma concentrations of glucose, amino acids, and glucose-dependent insulinotropic polypeptide (GIP). GIP potentiates glucose-stimulated insulin secretion in β cells and amino acid-stimulated glucagon secretion in α cells. The rise in glucagon, and potentially glucagon-like peptide 1 (GLP-1), secretion in α cells enhances α -to- β -cell communication, which is mediated by both the GLP-1 receptor (GLP-1R) and glucagon receptor (GCGR). The combined activation of GLP-1R, GCGR, and GIP in β cells produces maximal insulin secretion and glucose homeostasis.

Beyond a role in normal islet function, α -cell GLP-1 seems to be involved in response to stress and illness as well. In rats treated with the β -cell toxin streptozotocin, islet PC 1/3 and ProG expression, and processing of the pro-peptide to GLP-1, were increased [142]. Moreover, increased GLP-1 signalling in the islet was implicated in the recovery from injury. Islet GLP-1 production and action are also mediated by the cytokine interleukin (IL)-6, which is released in response to exercise, obesity, diabetes, and critical illness [143–145]. Expression of the IL-6 receptor is relatively high in α cells, and IL-6 signalling increases Gcg transcription and GLP-1 production in mice. Overall, the findings from these and other studies suggest that a paracrine system of islet GLP-1 signalling plays a role in several adaptations to metabolic stress. Understanding the control of the relative production of α -cell GLP-1 and glucagon would seem to hold promise for therapeutic development.

Abnormalities of glucagon secretion and action in diabetes

The potent effects of glucagon to promote fasting hepatic glucose production can be amplified in the setting of diabetes, where insulin secretion is impaired and insufficient for normal opposition of glucagon effects [146–148]. The secretion of both principal islet hormones, insulin and glucagon, is abnormal in people with diabetes. Plasma glucagon levels tend to be substantially elevated in suboptimally managed diabetes with severe insulin deficiency or ketoacidosis [9]. In a classic study using somatostatin to inhibit α -cell secretion, individuals with type 1 diabetes had substantial improvements in hyperglycaemia and ketogenesis when plasma glucagon was reduced [5]. Among groups with type 2 diabetes, some individuals will have modest fasting hyperglucagonaemia even without metabolic decompensation, and clinical studies sug-

gest that this increase is sufficient to contribute to the elevated hepatic glucose production in individuals with diabetes [146, 149]. Moreover, in a group of individuals with type 2 diabetes who had suppression of islet hormone secretion by somatostatin, there was a significant reduction of basal hepatic glucose production, and this effect was enhanced when insulin was given at basal levels [9]. Together these findings exemplify the basis for concluding that glucagon action contributes to pathogenic elevations of fasting glucose in at least a subset of those with type 2 diabetes.

Similar to the β cell in individuals with diabetes, the α cell has abnormal sensitivity to glucose and is less suppressed during hyperglycaemia. As a result, plasma glucagon levels after mixed-nutrient meals are generally higher with type 2 diabetes [69, 150, 151]. In contrast, glucagon responses to hypoglycaemia are also reduced [69, 152]. The mechanism for this is not clear, but the functional result suggests another form of α -cell glucose insensitivity. There is emerging evidence that α -cell dysfunction in diabetes has a genetic origin. Specifically, a common polymorphism in the KCNJ11 gene, which encodes the KIR6.2 component of the K_{ATP} channel, predisposes individuals to type 2 diabetes and is related to blunted glucose-induced suppression of glucagon [153, 154].

In addition to the effects of hyperglucagonaemia on fasting glucose levels, abnormal α -cell regulation also contributes to glucose intolerance. Following meals, glucagon levels remain abnormally elevated in individuals with diabetes, rather than undergoing the abrupt post-prandial decline typical of individuals without diabetes [155]. In normal physiological regulation, the post-prandial suppression of glucagon is a key factor in shifting hepatic metabolism from glucose production to glucose clearance [156], and failure to make this shift disrupts normal glycaemic regulation after meals. For example, individuals without diabetes have significantly greater glycaemic excursions after a test meal when glucagon levels are maintained at fasting concentrations compared to when they are allowed to follow the normal post-prandial decline [157]. Similar results can also be demonstrated in

individuals with type 2 diabetes [158]. Thus, failure to suppress fasting glucagon levels after a meal contributes to glucose intolerance, and this effect is magnified in the setting of diabetes where insulin secretion and action are reduced.

Pharmacology based on glucagon action

Exogenous glucagon has been used by individuals with diabetes for the acute treatment of hypoglycaemia for nearly 50 years. However, approaches to block glucagon action as a means of lowering blood glucose in individuals with diabetes go back nearly as far. Mouse models with interruption of glucagon receptor function [159,160] or absence of α -cell secretion [161,162] have lower fasting glucose and significantly improved glucose tolerance than control mice and provide proof of principle that long-lasting blockade of glucagon signalling could be an effective means of reducing diabetic hyperglycaemia. Despite these compelling findings, there is no approved drug that selectively blocks the effects of glucagon as a diabetes treatment. This is primarily due to findings in pre-clinical models and safety concerns with compounds tested in humans. Animal models with GCGR or Gcg deletion develop α -cell hyperplasia and/or profound elevations of circulating proglucagon-related peptides occur in mice with GCGR or Gcg deletion [163]; this has also been reported in humans with GCGR mutations [164]. In addition to the expansion of endocrine cells, animals deficient in glucagon signalling also have increased total pancreatic weight, reflecting expansion of the exocrine compartment. Moreover, lack of glucagon action is associated with reductions in hepatic lipid oxidation [165] and increased hepatic susceptibility to toxic injury [166]. Blockade of

glucagon action in humans has been possible with several small-molecule GCGR antagonists. One of these compounds was demonstrated to block the actions of exogenous glucagon in individuals without diabetes [167], but was not further developed and no information on treatment of individuals with diabetes with fasting hyperglycaemia or endogenous hyperglucagonaemia was published. Other GCGR antagonists have been reported to lower fasting [168], and post-prandial [169], glucose in individuals with diabetes in a dose-responsive manner. As the pharmacological approach most analogous to genetic models of reduced GCGR signalling, antagonists have obvious potential as drugs to lower glucose and treat diabetes. However, the data from pre-clinical studies, and the failure of products tested in humans to progress from the trial stage, raise concerns that adverse effects such as α -cell hyperplasia, hepatic steatosis, or susceptibility to hepatic toxicity could occur in treated individuals (Figure 8.5). Moreover, the effects of these agents on glucose counter-regulation would need to be carefully assessed.

Importantly, there are now diabetes drugs available that work at least in part by inhibiting glucagon secretion. GLP-1 receptor agonists and DPP-4 inhibitors mimic the effect of endogenous GLP-1 to inhibit glucagon secretion and hepatic glucose production, and this contributes to their effect on improving glucose regulation in type 2 diabetes [170]. These compounds have achieved common usage in clinical practice. Administration of pharmacological amounts of GLP-1 to hyperglycaemic individuals with type 1 diabetes with minimal β -cell function reduced blood glucose by ~4 mmol/l, and this was associated with a 40–50% decrease in plasma glucagon [171].

A novel and exciting recent approach to treat type 2 diabetes has been the development of hybrid peptides that activate more than one receptor to generate an effect [172]. These agents are touted as

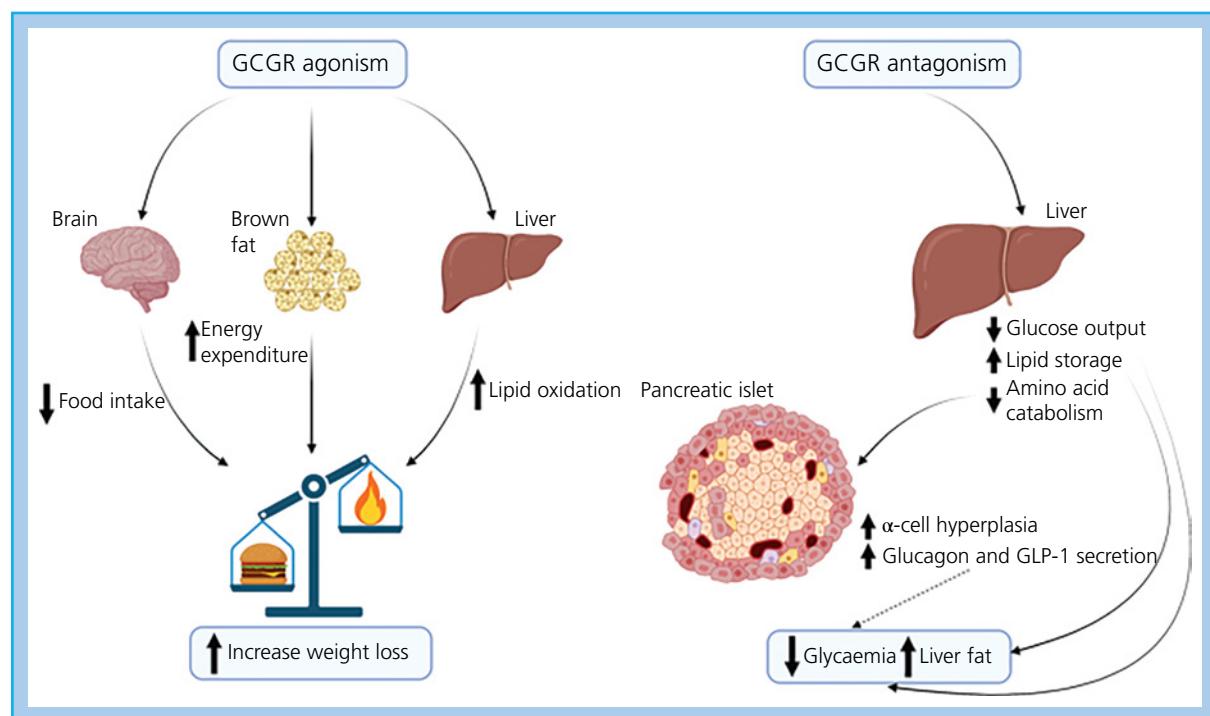

Figure 8.5 Glucagon receptor (GCGR) agonism vs antagonism. Glucagon receptor agonists enhance catabolic events including thermogenesis in brown adipose tissue and lipid oxidation in hepatocytes. This results in increase energy expenditure. Glucagon receptor agonism also reduces food intake. The overall effect is negative energy balance and potentially weight loss. Glucagon receptor

antagonism reduces hepatic glucose output, lowering glycaemia. Glucagon receptor antagonism also prevents lipid oxidation and amino acid catabolism in hepatocytes. The rise in plasma amino acids provides a signal for α -cell hyperplasia, resulting in elevated concentrations of both glucagon and glucagon-like peptide 1 (GLP-1).

mimicking the broad range of hormonal changes associated with bariatric surgery, and the need to utilize more than one ligand-receptor system to achieve significant weight loss. Some of the first compounds developed using this strategy were targeted to the glucagon and GLP-1 receptors, peptides engineered to activate the cognate receptors of both peptides in different relative potencies [173, 174]. The rationale for this was that activating both glucagon and GLP-1, which bind to specific and distinct receptor populations in the brain to cause satiety [175, 176], might have synergistic results. Two different initial reports suggest that hybrid peptides with balanced GCGR and GLP-1R potency reduced body weight and fat, increased energy expenditure, and dramatically improved glucose tolerance in obese mice and rats [174, 177] (Figure 8.5). The effects on weight loss were significantly greater than that of a GLP-1R-only agonist, and this additive response

supports differential activation of different neural pathways for glucagon and GLP-1 to cause weight loss. In humans, while GLP-1 infusion alone had no effect on energy expenditure, and glucagon infusion alone raised both blood glucose levels and energy expenditure, co-administration of both peptides increased energy expenditure but did not raise glucose levels [178]. The potential for a GLP-1R/GCGR co-agonist to raise blood glucose has also been demonstrated with oxyntomodulin [179], a Gcg product that activates both receptors. Thus, the coupling of GLP-1 activity has promise to provide greater weight loss effects than either compound administered alone, with hyperglycaemic actions of glucagon mitigated by GLP-1 signalling. Given the technology to engineer peptides with multireceptor effects and the dramatic responses in pre-clinical models, this is likely to be an area of active diabetes drug development in the future.

Mechanism of Insulin Action

Morris F. White

Division of Endocrinology, Children's Hospital Boston, Harvard Medical School, Boston, MA, USA

Key points

- The insulin receptor is a transmembrane protein. The α subunits of the insulin receptor are entirely extracellular and create the ligand binding sites. The β subunits contain a transmembrane-spanning segment that separates the extracellular regions from the intracellular tyrosine kinase.
- Insulin and insulin-like growth factor (IGF) signalling integrates the storage and release of nutrients with animal growth during development and tissue maintenance throughout life.
- The human genome encodes a superfamily of structurally related insulin-like peptides including insulin, insulin-like growth factor-I (IGF-I), and insulin-like growth factor-II (IGF-II), which activate five receptor tyrosine kinases assembled from two genes.
- Insulin resistance, the reduced responsiveness of tissues to normal insulin concentrations, is an important risk factor for the metabolic syndrome and its progression to cardiovascular disease, non-alcoholic fatty liver disease, and type 2 diabetes.
- Insulin receptor substrate (IRS) proteins are composed of tandem structurally similar pleckstrin homology and phosphotyrosine binding domains followed by a long, unstructured tail of tyrosine and serine phosphorylation sites that coordinate insulin and IGF signalling. These domains are strongly conserved in IRS from *Drosophila* (Chico), zebra fish, mouse, chimpanzee, and human.
- During insulin and IGF-I stimulation, some tyrosine residues in the IRS tail are phosphorylated and bind to the Src homology 2 (SH2) domains of various signalling proteins, including the 85 kDa regulatory subunit (p85) of the PI3K and the RAS GTP exchange factor Grb2-Sos.
- IRS1 expression can be regulated by transcriptional repressors, including transcription factor AP-2-beta (AP2 β) or the p160 family of nuclear receptor coactivators p/CIP (p300/CBP/cointegrator-associated protein) and SRC1 (steroid receptor coactivator-1).
- IRS2 transcription is regulated by multiple factors, including cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) and its coactivator CREB-regulated transcription coactivator 2 (CRTC2), FOXO1/3, nuclear factor of activated T cells (NFAT), transcription factor E3 (TFE3), hypoxia-inducible factor-2 α encoded by Epas1 (HIF2 α), and sterol regulatory element binding protein 1 (SREBP1).
- IRS1 and IRS2 can be polyubiquitylated during chronic inflammatory states, nutrient excess, and hyperinsulinaemia through various tissue-specific mechanisms.
- Several pathways are known to promote degradation of IRS1 or IRS2:
 - (i) proinflammatory cytokine-mediated upregulation of SOCS1/3 (suppressors of cytokine signalling); (ii) the cullin-RING E3 ubiquitin ligase 7 (CRL7); (iii) Cbl proto-oncogene B (CBLB), a RING-type E3 ubiquitin ligase; and (iv) mitsugumin 53 (MG53), a tripartite motif-containing (TRIM) family E3 ubiquitin ligase.
- IRS1 and IRS2 can be regulated through a complex mechanism involving phosphorylation of more than 50 serine/threonine residues located in the long-tail regions.
- Pancreatic β cells have a special place in nutrient homeostasis as the unique source of insulin secretion, and like other cells they also require insulin and IGF signalling for growth, function, and survival. Since β cells are always exposed to insulin and IGF, the signalling appears to be regulated through multifactor transcriptional control.

Insulin and insulin-like growth factor (IGF) signalling integrates metabolism, growth, reproduction, and lifespan with environmental signals [1]. Lower animals express many insulin-like peptides – 38 in *Caenorhabditis elegans* and 7 in fruit flies – that bind to a single insulin-like receptor tyrosine kinase [2], whereas the human genome encodes a smaller family of structurally related insulin-like peptides, including insulin itself, IGF-I, and IGF-II. Diabetes is a common metabolic disease of persistent hyperglycaemia owing to various mechanisms that cause deficiency of insulin and/or insulin action, including impaired glucose sensing or insulin secretion by pancreatic β cells (maturity-onset diabetes of youth, MODY); autoimmune-mediated β -cell destruction (type 1 diabetes); or

insufficient β -cell insulin secretory capacity to compensate for peripheral insulin resistance (type 2 diabetes) [3]. MODY is caused by mutations in at least 14 genes associated with β -cell function, notably hepatocyte nuclear factor-4 α (*HNF4 α* , *MODY1*), glucokinase (*GCK*, *MODY2*), and hepatocyte nuclear factor-1 α (*HNF1 α* , *MODY3*) [4].

During the past 50 years, advances in all areas of biomedical science led to a multidisciplinary understanding of insulin receptor signalling. Cloning of the insulin receptor cDNA and its gene revealed novel mechanisms of signal transduction. Dysregulated insulin signalling causes insulin resistance, which includes any state of diminished cellular or systemic insulin action [5]. Mutations in

the insulin receptor were thought to be plausible genetic candidates for insulin resistance [6]; however, after considerable investigation insulin receptor mutations were only identified in very rare cases of severe insulin resistance, but not associated with type 2 diabetes [7]. Physiological, immunological, and metabolic stresses are common causes of chronic insulin resistance, which can lead to type 2 diabetes when pancreatic β cells fail to secrete sufficient insulin to promote an adequate insulin response [8]. Variations in over 100 genetic loci, including variations in MODY genes, are associated with some of the heritability of type 2 diabetes (Chapter 12) [9, 10]. Regardless, which genetic variations might reveal a short list of new drugable targets to prevent type 2 diabetes continues to be a challenging clinical and scientific problem [11, 12].

Insulin

Insulin is synthesized in pancreatic β cells as a single polypeptide called proinsulin that is processed by prohormone convertase-1/3 (PCSK1) to excise the C-peptide and generate the bioactive disulfide linked A-chain and B-chain. Insulin is composed of three α -helices – one in the B-chain and two in the A-chain [1]. Insulin dimerizes through a β -sheet between the C-terminus of the B-chains, including residues Phe^{B24}, Phe^{B25}, Tyr^{B26}, Thr^{B27}, Pro^{B28}, Lys^{B29}, Thr^{B30}, Phe^{B24}, Phe^{B25}, and Tyr^{B26} [13]. Three insulin dimers form a hexamer in the presence of zinc [14]. Biochemical and genetic analysis reveals two asymmetrical receptor binding surfaces called the primary or classical site (S1) and the second or novel site (S2) (Figure 9.1) [15]. Natural mutations, alanine scanning mutagenesis, and structural refinements show that S1 includes residues from the A- and B-chains of insulin, including Val^{B12}, Tyr^{B16}, Gly^{B23}, Phe^{B24}, Phe^{B25}, Tyr^{B26}, Gly^{A1}, Gln^{A5}, Tyr^{A19}, and Asn^{A21} (Figure 9.1a) [16, 17]. The Phe^{B24}–Phe^{B25}–Tyr^{B26} motif at the end of the B-chain undergoes a conformational change to expose the S1 for high-affinity binding ($K_d \sim 0.25$ nmol/l) (Figure 9.1b) [1, 13, 18]. At high concentra-

tions, a second or novel site was discovered on the opposite side of insulin that is composed of different A- and B-chain residues, including His^{B10}, Glu^{B13}, Leu^{B17}, Ser^{A12}, Leu^{A13}, and Glu^{A17} (Figure 9.1a) [14, 15, 19]. The second site binds with lower affinity to a different location on the insulin receptor [13].

Insulin receptor

Extracellular domain of the insulin receptor

The insulin receptor proreceptor is a 150 kb gene comprising 22 exons on human chromosome 19p13.3–p13.2 that encodes the extracellular and intracellular domains (Figure 9.2a). During synthesis, the proreceptor enters the endoplasmic reticulum where it is glycosylated and stabilized by disulfide bonds. Next it migrates into the Golgi, where furin cleaves at the Arg-Lys-Arg-Arg motif to generate the $\alpha\beta\beta$ -dimer (Figure 9.2a) [14, 20]. The extracellular domain comprises the α -subunit and an NH₂-terminal portion of the β -subunit. The α -subunit begins with two NH₂-terminal leucine-rich repeats (L1, aa1–155; and L2, aa315–470) flanking a cysteine-rich (CR, aa195–310) region containing eight modular cysteine-linked repeats (Figure 9.2a). These modules are followed by three fibronectin-III motifs, including Fn_{iii}1 (aa473–591) and Fn_{iii}3 (aa808–904) flanking Fn_{iii}2 (aa597–717), which are interrupted by a 120 amino acid insert domain containing the furin cleavage site (IDA, aa636–690) (Figure 9.2a).

The disulfide-linked α -subunits and extracellular portion of the β -subunits fold into an inverted V configuration with the apex formed by L2 and Fn_{iii}1 domains (Figure 9.2b) [13]. Natural and site-directed mutagenesis, photo-affinity labelling, and structural refinements predicted the location of two insulin binding sites in the α -subunit. The high-affinity S1 is composed of the L1 domain from one α -subunit and CT α' (aa 693–710) from the other (Figure 9.2c) [13, 19, 21]. When the insulin receptor is saturated by high insulin concentrations, cryo-EM reveals the location of a distinct low-affinity S2 near the Fn_{iii}1 \rightarrow Fn_{iii}2a

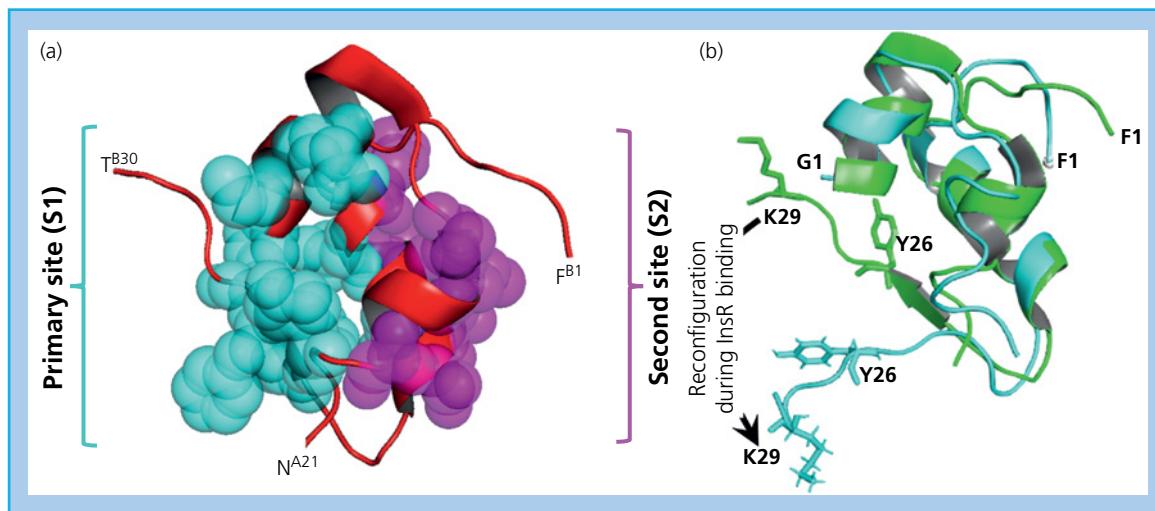

Figure 9.1 (a) Pig insulin structure (pdb id: 4ins) showing the position of some critical amino acids that compose the two binding surfaces (S1 and S2) that interact with the L1•CR•CT and Fn_{iii}1•Fn_{iii}2 domains of the insulin receptor, respectively. The primary receptor bind site (S1) is shown in cyan, and the secondary site (S2) is shown in violet as space-filling residues. The amino terminal residue of the B-chain and the carboxy terminal residue of the A- and B-chains are labelled. (b) Structural alignment of free insulin (green) and insulin (pdb id: 6s0f) bound to the high-affinity site on the insulin receptor (cyan). Cartoons are created in PyMOL Molecular Graphics System, Version 2.0, Schrödinger, LLC.

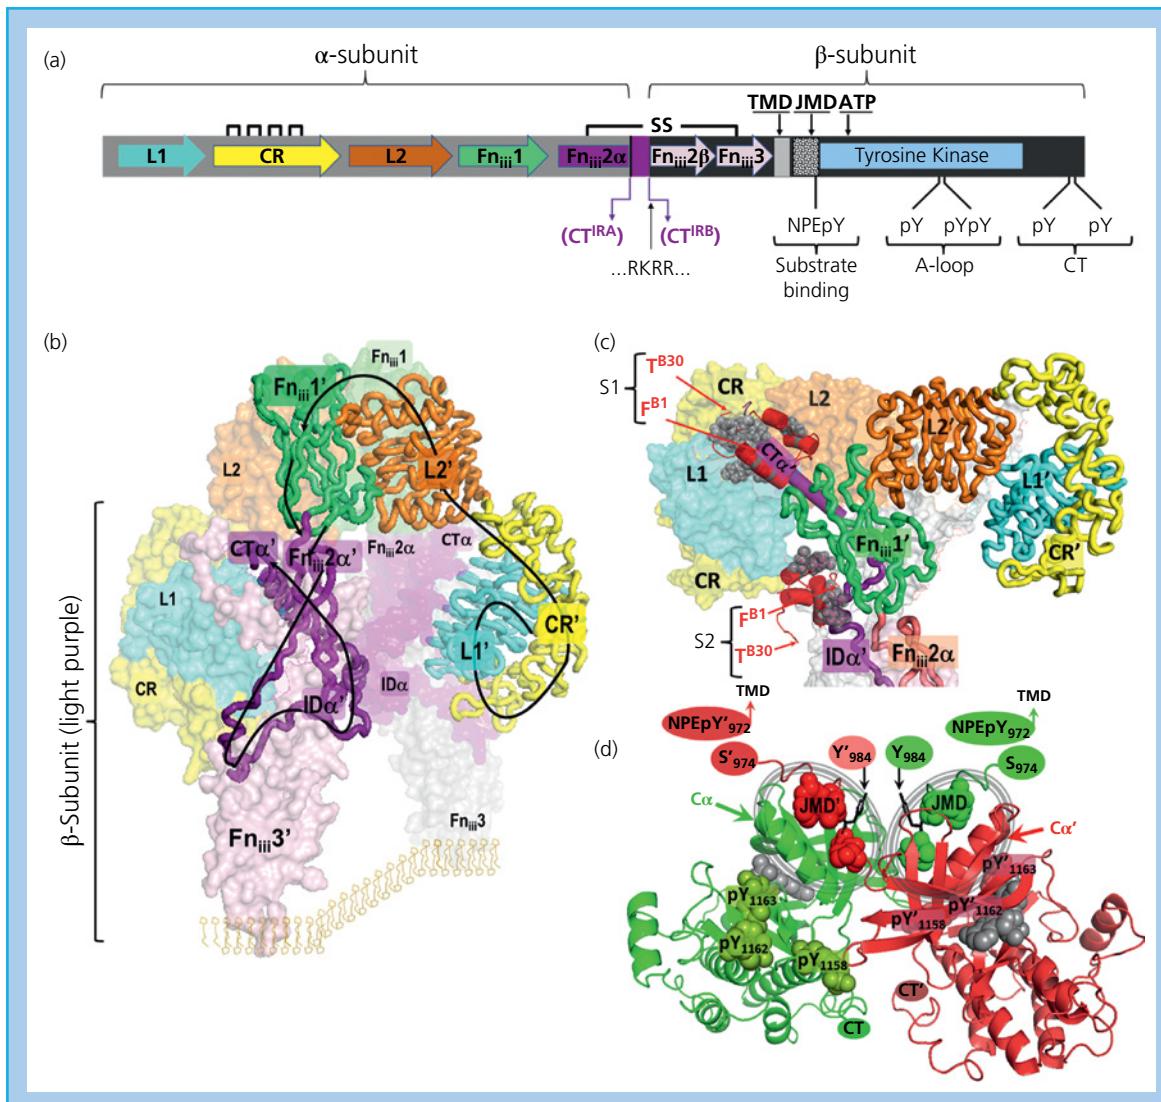

Figure 9.2 (a) Diagram of the insulin receptor precursor showing the position of important domains, including two leucine-rich regions (L1 and L2) flanking a cysteine-rich region (CR); fibronectin iii domains ($\text{Fn}_{\text{iii}}1$, $\text{Fn}_{\text{iii}}2\alpha$, $\text{Fn}_{\text{iii}}2\beta$, $\text{Fn}_{\text{iii}}3$); the insert domains ID α and ID β flanking the Arg-Lys-Arg-Arg furin cleavage site; the alternative IRA/IRB splice site that generates the short CT^{IRA} or long CT^{IRB}; a transmembrane domain (TMD); the IRS binding motif (NPEpY); the A-loop (activation loop) autophosphorylation sites; and carboxyl terminal tyrosine phosphorylation sites (CT). (b) Cartoon of the inactive conformation of the ectodomain of the insulin receptor (pdb id: 6pxv). The insulin receptor subunit is shown as a ribbon diagram with the labelled structural domains, L1', CR', L2', $\text{Fn}_{\text{iii}}1'$, $\text{Fn}_{\text{iii}}2\alpha$, and CT α' traced with a black line; $\text{Fn}_{\text{iii}}2\beta$ ' and $\text{Fn}_{\text{iii}}3'$ are shown in light pink. (c) The structure of the ectodomain of the insulin receptor in the T conformation with insulin bound at S1 and S2. Note the different orientation of each insulin molecule revealed by the position of the B-chain residues F^{B1} and T^{B30}. (d) The dimeric structure of the juxtamembrane domain (JMD) of the insulin receptor shown in green (IRK) and red (IRK'). The grey oval highlights the dimerization region between the juxtamembrane domain and the Ca/b-sheet. Phosphorylated residues of the A'-loop are shown in red (insulin) and green (insulin receptor).

interface (Figure 9.2c) [22–25]. Insulin binding to S1 crosslinks the α -subunits to stabilize the extracellular domain in a T conformation, which might cause the $\text{Fn}_{\text{iii}}3 \rightarrow$ transmembrane domain (TMD) to converge and facilitate transphosphorylation of the intracellular receptor tyrosine kinase (Figure 9.2d) [13, 26, 27].

Exon-11 of the insulin receptor gene is alternatively spliced depending on the tissue and developmental stage to produce two insulin receptor isoforms, including IRA that omits exon-11 and IRB that includes exon-11 to add 12 amino acids at the C-terminus of the α -subunit (CT α) [15]. Insulin binds with high affinity to the homodimeric IRB ($\alpha\beta^{\text{IR}} \bullet \alpha\beta^{\text{IR}}$), which predominates in adult liver,

light purple and grey space-filling structures, respectively. The other insulin receptor subunit is shown as a space-filling structure in the background: L1 (cyan), CR (yellow), L2 (orange), $\text{Fn}_{\text{iii}}1$ (green), $\text{Fn}_{\text{iii}}2\alpha$ (purple), and CT α (purple). $\text{Fn}_{\text{iii}}2\beta$ ' and $\text{Fn}_{\text{iii}}3'$ are shown in light pink. (c) The structure of the ectodomain of the insulin receptor in the T conformation with insulin bound at S1 and S2. Note the different orientation of each insulin molecule revealed by the position of the B-chain residues F^{B1} and T^{B30}. (d) The dimeric structure of the juxtamembrane domain (JMD) of the insulin receptor shown in green (IRK) and red (IRK'). The grey oval highlights the dimerization region between the juxtamembrane domain and the Ca/b-sheet. Phosphorylated residues of the A'-loop are shown in red (insulin) and green (insulin receptor).

muscle, and adipose tissues. IRA binds insulin with slightly lower affinity, but unlike IRB also binds IGF-I and IGF-II in the physiological range [28, 29].

Receptor tyrosine kinase

Most receptor tyrosine kinases reside in the plasma membrane as monomers that form homo- or heterodimers on ligand binding to promote transphosphorylation and signal transduction. Since the insulin receptor is a covalent dimer, a different mechanism inhibits transphosphorylation of the cytoplasmic receptor tyrosine kinase until insulin binds. The intracellular portion of the insulin receptor

β -subunit begins with a 30-residue juxtamembrane domain between the TMD and the receptor tyrosine kinase that terminates with the 70-residue carboxy-terminus (Figure 9.2a) [26]. Each intracellular region contains tyrosyl phosphorylation sites (numbered as in IRB): Y₉₆₅ and Y₉₇₂ in the juxtamembrane domain; Y₁₁₅₈, Y₁₁₆₂, and Y₁₁₆₃ in the activation loop (A-loop) of the kinase domain; and Y₁₃₂₈ and Y₁₃₃₄ in the carboxy-terminus [30–32]. Recent analysis using liquid chromatography–tandem mass spectrometry revealed several serine phosphorylation sites, including S₉₆₈, S₉₆₉, S₉₇₄, and S₉₇₆ in the juxtamembrane domain; and S₁₂₇₈, S₁₃₂₀, S₁₃₂₁, and T₁₃₄₈ in the carboxy-terminus [32].

Before insulin binds, the catalytic activity of the insulin receptor is inhibited by interactions between Tyr₉₈₄ in the juxtamembrane domain with a hydrophobic pocket created from an α -helix (α C) and a five-stranded β -sheet in the N-terminal lobe of the receptor tyrosine kinase. This interaction inhibits transphosphorylation of the adjacent receptor tyrosine kinases by preventing the α -helix from assuming its catalytically active position [26, 33, 34]. Both receptor tyrosine kinase domains are inhibited until the ectodomains converge during insulin binding, which is thought to facilitate transphosphorylation in the A-loop (Figure 9.2c) [35]. Multisite transphosphorylation in the A-loop releases several inhibitory mechanisms [30]:

- The unphosphorylated Tyr₁₁₆₂, the second of the three A-loop tyrosine residues, blocks access of peptide substrates to the active site.
- Asp₁₁₆₁ preceding Tyr₁₁₆₂ stabilizes the closed A-loop to inhibit unstimulated transphosphorylation [36].
- The NH₂-terminal end of the A-loop (D₁₁₅₀FG-motif) competes to elevate the K_m for adenosine triphosphate (ATP) [37].

Intramolecular transphosphorylation begins at Tyr₁₁₅₈ and progresses to Tyr₁₁₆₂ and slowly to Tyr₁₁₆₃ until tris-phosphorylation stabilizes the open A-loop to fully activate the kinase [38, 39]. This model is confirmed by an Asp₁₁₆₁ → Ala substitution that shifts the A-loop towards the open configuration, increasing basal activity [36]. Substitution of Tyr₁₁₆₂ with phenylalanine also increases basal transphosphorylation consistent with its role to stabilize the closed conformation or block ATP and protein substrate entry into the active site [40, 41]. Transphosphorylation appears to destabilize the cis-interaction between Tyr₉₈₄ and α C-helix [26], creating a new trans-interaction between Tyr₉₈₄ and α C' or Tyr_{984'} and the α -helix of adjacent receptor tyrosine kinases (Figure 9.2d). Thus, kinase activation involves both activation-loop phosphorylation and conformation rearrangements that stabilize the receptor tyrosine kinase dimer, so that the catalytic sites are exposed on opposite sides of the insulin receptor kinase to phosphorylate IRS-proteins or SHC recruited by the NPEpY-motif (Figure 9.2d).

Insulin signalling cascade

Following discovery of the insulin receptor tyrosine kinase, many groups searched for cellular proteins that might mediate downstream signals [42, 43]. The first evidence for a substrate of any receptor tyrosine kinase came from anti-phosphotyrosine antibody immunoprecipitates that revealed a 185-kDa phosphoprotein (pp185) in insulin-stimulated hepatoma cells [44]. Purification and molecular cloning of pp185 revealed the first member of a family of signalling scaffolds engaged by receptor tyrosine kinases and the first insulin receptor substrate called IRS1 [45]. Three homologous

IRS-protein genes are expressed in human tissues, including IRS1, IRS2, and IRS4; rodents also express IRS3 in adipose tissue [46]. IRS1 and IRS2 are broadly expressed in mammalian tissues, whereas IRS4 is mainly restricted to the hypothalamus and some cancer tissues [47–52] (Figure 9.3). Work with transgenic mice reveals that systemic insulin signalling is largely mediated through IRS1, IRS2, or both.

IRS proteins couple the insulin receptor to the downstream signalling cascade

IRS proteins are composed of tandem structurally similar pleckstrin homology (PH) and phosphotyrosine binding domains followed by an unstructured tail of tyrosine phosphorylation sites that coordinate downstream signals (Figure 9.4). IRS proteins also contain serine/threonine phosphorylation sites, which modulate insulin signalling through feedback or heterologous mechanisms. IRS proteins are strongly conserved from *Drosophila* (Chico) to humans. On insulin stimulation, the IRS proteins are recruited to the juxtamembrane domain of the activated insulin receptor kinase, where several tyrosine residues in the unstructured tail are phosphorylated. These phosphorylated residues bind to the Src homology 2 (SH2) domains in various signalling proteins, especially the 85 kDa regulatory subunits (p85) of the phosphatidylinositol 3-kinase (PI3K) (Figure 9.4). The binding between phosphorylated YMPM-motifs in IRS1 and both SH2 domains in PI3K was the first insulin signalling cascade to be reconstituted *in vivo* and *in vitro* (Figure 9.4) [53]. Tyrosine phosphorylation of other sites in IRS1 or SHC adaptor protein 1 (SHC) can recruit Grb2•SOS, which activates the mitogen-activated protein kinase (MAPK) cascade composed of RAS → MEK → ERK (Figure 9.4).

Tyrosine phosphorylation of specific residues in IRS is accomplished through at least two mechanisms:

- Specific recruitment of the phosphotyrosine binding domain of IRS or SHC to the phosphorylated NPEpY motif in the juxtamembrane domain of the insulin receptor.
- Recognition of specific phosphorylation motifs in the tail by the activated insulin receptor catalytic domain.

The NPEpY₉₇₂ motif in the juxtamembrane domain fills an L-shaped cleft on the phosphotyrosine binding domain [54, 55]; however, the NPEpY₉₇₂ motif has low affinity for the phosphotyrosine binding domain of IRS1 (K_d ~87 mM), owing to a destabilizing effect of E₉₇₁ that is essential for autoprophosphorylation of Y₉₇₂ [37, 56]. By comparison, the phosphotyrosine binding domain of SHC binds to NPEpY₉₇₂ with a much higher affinity (K_d ~4 mM) (Figure 9.4). Regardless, the structurally similar but functionally distinct PH domain immediately upstream of the phosphotyrosine binding domain helps recruit IRS to the insulin receptor (Figure 9.4) [57–59]. This interaction appears to be specific, as heterologous PH domains borrowed from other proteins reduce insulin receptor signalling [58, 60]. The PH domains of some proteins bind inositol phospholipids to mediate membrane localization and signalling; however, the large majority of PH domains do not bind strongly to phosphoinositides and presumably mediate other functions [61]. The PH domain in the IRS proteins can bind acidic peptide motifs [60]. Whether the PH domain interacts with pSer residues in the juxtamembrane domain or C-terminal of the insulin receptor has not been tested, and whether the PH domain binds pSer residues in IRS itself is worth investigating [32].

IRS2 utilizes an additional mechanism, the kinase regulatory-loop binding (KRLB) domain, to interact with the insulin receptor (Figure 9.3) [62, 63]. Structure analysis reveals that Tyr₆₂₁ of

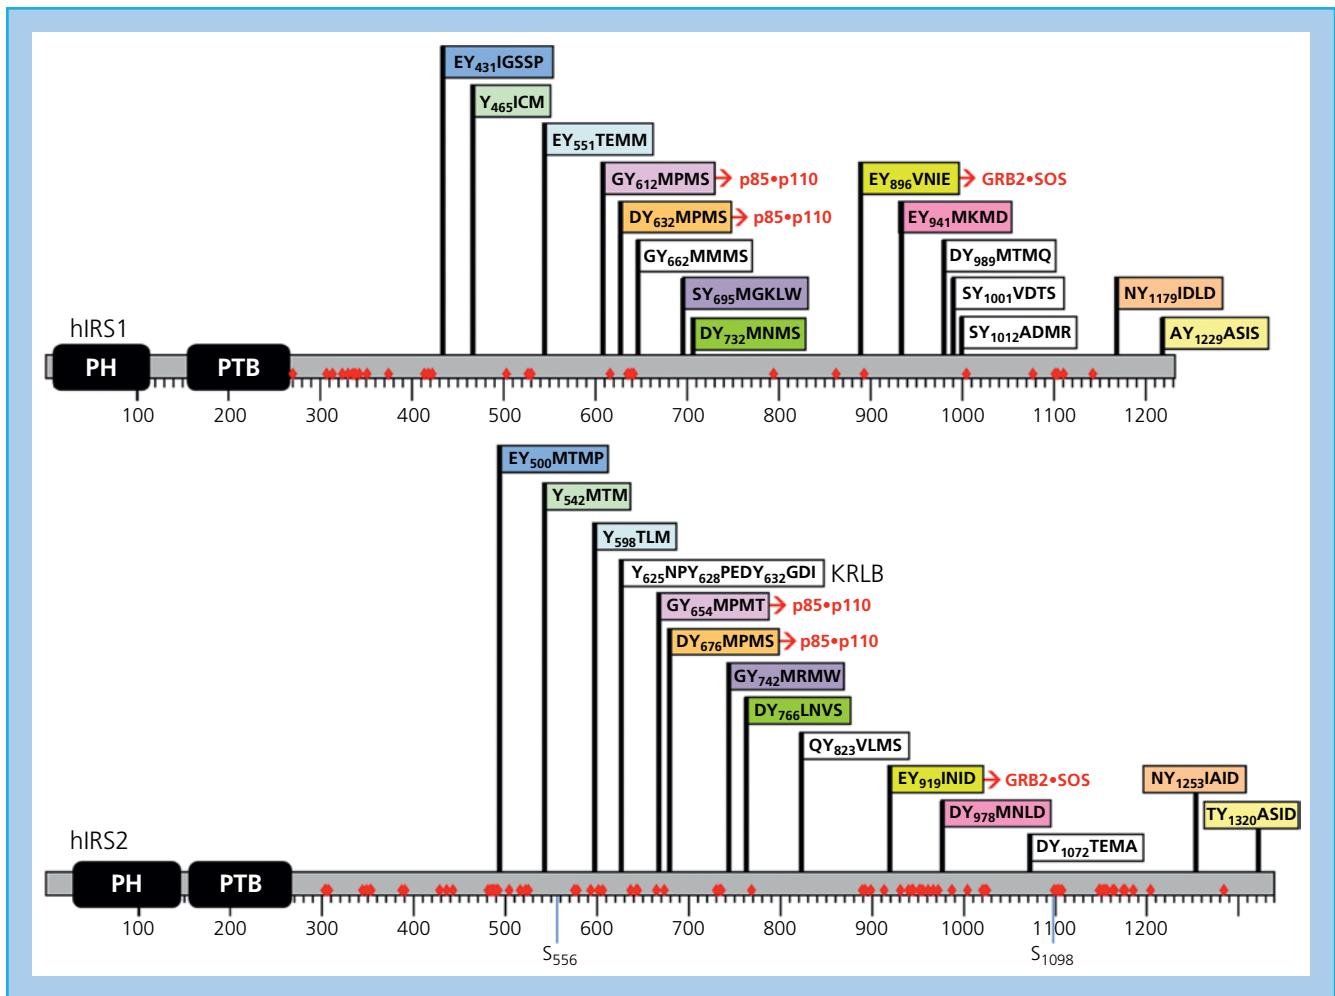

Figure 9.3 Alignment of IRS1 and IRS2 tyrosine phosphorylation sites relative to the amino-terminal pleckstrin homology (PH) and phosphotyrosine binding domains. Conserved tyrosine phosphorylation motifs including their number in the human protein and the surrounding amino acid sequences are colour coded to highlight alignments; white boxes indicate unique sites in IRS1 or IRS2. The relative positions of Ser/Thr-phosphorylation sites in IRS1 or IRS2 revealed by tandem mass spectrometry are indicated with red diamonds (◆). The unique kinase regulatory loop binding (KRLB) domain is indicated in IRS2 but not conserved in IRS1.

IRS2 inserts into the receptor ATP binding pocket, while Tyr₆₂₈ aligns for transphosphorylation [64]. This interaction might promote IR → IRS2 signalling, since the KRLB interaction is apparently absent in the type 1 IGF receptor [64].

Phosphatidylinositol 3-kinase → AKT cascade

Phosphatidylinositol 3-kinase

The PI3K → AKT cascade begins when insulin stimulates tyrosyl phosphorylation of YMPM motifs in IRS proteins, which directly bind and activate the class 1A phosphatidylinositide 3-kinase (PI3K) (Figure 9.4) [65]. PI3K comprises a catalytic and a regulatory subunit. The catalytic subunit, including the widely expressed p110 α (PIK3CA) and p110 β (PIK3CB), and the leucocyte-restricted p110 δ (PIK3CD) and p110 γ (PIK3CG), is inhibited and stabilized on association with an 85 kDa regulatory subunit. Several regulatory subunits exist, including p85 α (PIK3R1) and p85 β (PIK3R2), alternative splicing of PIK3R1 to produce p55 α or p50 α , and PIK3R3 that encodes p55 γ . The short homologues lack some NH₂-terminal regulatory features of p85 while retaining affinity towards the catalytic subunits [66, 67]. All the regulatory subunits contain

two SH2 domains that bind phosphorylated YXXM motifs, which disinhibit the catalytic domain to produce phosphatidylinositol 3,4,5-trisphosphate (PI(3,4,5)P₃) [68–70]. Deletion of p85 α or p85 β also increases PI3K activity, which promotes insulin sensitivity [71, 72]. By contrast, inhibition of the PI3K catalytic activity by chemical or genetic means blocks almost all metabolic responses stimulated by insulin, including glucose influx, glycogen and lipid synthesis, and adipocyte differentiation, confirming that PI3K is a critical node coordinating insulin action [73]; however, p110 α inactivation might benefit metabolism during ageing owing to less downregulation of IRS protein levels [74].

On binding of p85 to phosphorylated YMPM motifs in IRS, the activated PI3K converts PI(3,4)P₂ into PI(3,4,5)P₃ that binds to the PH domains in specific signalling proteins to recruit and activate them at the plasma membrane, including 3'-phosphoinositide-dependent protein kinase-1 (PDK1), v-akt murine thymoma viral oncogene (AKT), and target of rapamycin complex 2 subunit MAPKAP1 (SIN1). AKT is activated by phosphorylation at Thr₃₀₈ in the A-loop (pT308^{AKT}) by the juxtaposed PDK1 (Figure 9.4). SIN1 is recruited to the plasma membrane by PI(3,4,5)P₃, where it is phosphorylated at Thr₈₆ by pT308^{AKT}. SIN1

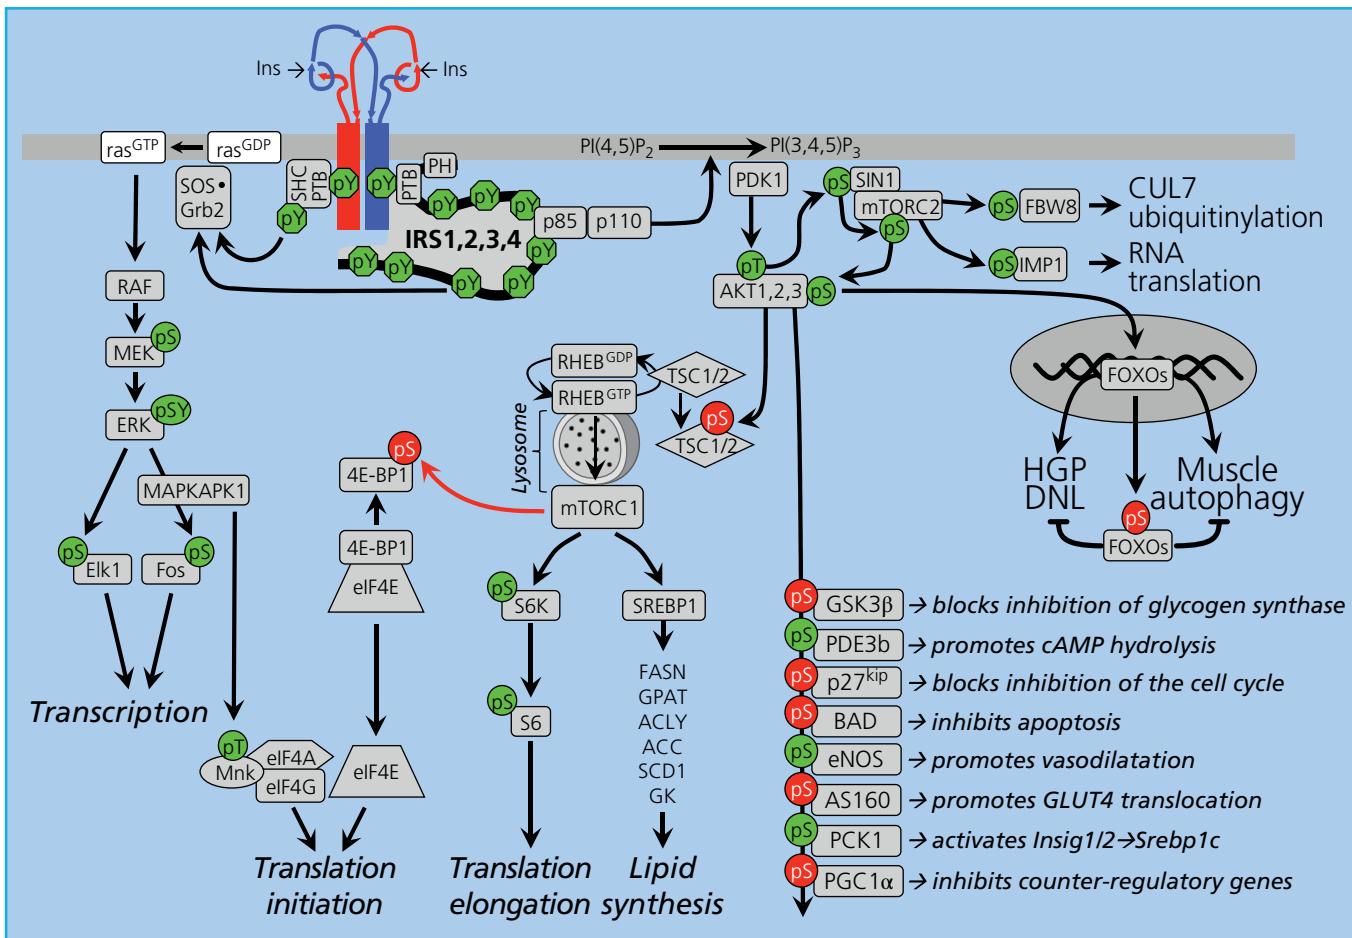

Figure 9.4 A canonical insulin signalling cascade. Two main branches mediate insulin signals initiated by tyrosine phosphorylation of the IRS proteins that bind and activate the phosphatidylinositol 3-kinase (PI3K) (p85•p110) and GRB2•SOS cascades. The Grb2/SOS complex promotes GDP/GTP exchange on p21^{ras}, which activates the ras → raf → MEK → ERK1/2 cascade. Activated ERK stimulates transcriptional activity by direct phosphorylation of ETS domain-containing protein (ELK1) and by indirect phosphorylation of cFOS through MAPK-activated protein kinase-1 (MAPK-APK1). The activation of PI3K by recruitment to IRS produces PI3,4P₂ and PI3,4,5P₃ (antagonized by the action of PTEN or SHIP2), which recruits PDK1 and AKT to the plasma membrane. AKT is activated in two steps. First, AKT is phosphorylated at T308 by PDK1. T308^{AKT} phosphorylates SIN1 to

complexes with mTORC2, which phosphorylates S473^{AKT} [75]. Bis-phosphorylated AKT can phosphorylate a wide array of substrates, including FOXO transcription factors (Figure 9.4). In adipocytes and muscle, SIN1 can recruit atypical protein kinase C (aPKC) to PI(3,4,5)P₃, where it can be activated by PDK1 and promote insulin-stimulated glucose uptake [67,76,77]. Finally, SIN1 can be phosphorylated by ribosomal protein S6 kinase B1 (S6K1), which creates a feedback mechanism to inhibit mTORC2 [75,78,79].

AKT

Mammalian AKT1, -2, and -3 phosphorylate more than 100 substrates that control cell survival, growth, proliferation, angiogenesis, metabolism, and migration (Figure 9.4). Although overlap exists, AKT1 mainly regulates development, growth, and survival, whereas AKT2 regulates metabolism through insulin-stimulated glucose-transporter type 4 (GLUT4) translocation and liver glucose and lipid metabolism [80]. Humans with a rare dominant negative

activate mTORC2, which then phosphorylates S473^{AKT}. mTORC1 is activated by RHEB GTP, which accumulates on inhibition of the GAP activity of the TSC1•TSC2 complex following AKT-mediated phosphorylation of TSC2. mTORC1 mediates phosphorylation of S6K and SREBP1, which promotes protein or lipid synthesis, respectively. AKT phosphorylates many cellular proteins inactivating PGC1α, p21^{kip}, GSK3α, BAD, and AS160, and activating PDE3β, PCK1, and eNOS. AKT-mediated phosphorylation of FOXO1 causes their sequestration and degradation in the cytoplasm, which inhibits their influence on transcriptional activity. Insulin stimulates protein synthesis by altering the intrinsic activity or binding properties of key translation initiation and elongation factors (eIFs and eEFs, respectively) as well as critical ribosomal proteins.

mutation in AKT2 display features of type 2 diabetes [81]. AKT3 promotes neuronal development, and homologous glucocorticoid-regulated kinase 3 (SGK3) synergizes with AKT2 in pancreatic β cells to stimulate proliferation and insulin release [82,83].

mTORC1

mTOR (mechanistic target of rapamycin) is a Ser/Thr kinase that belongs to the PI3K-related kinase family and forms two large functionally distinct protein complexes, mTORC1 and mTORC2, owing to the assembly of common and unique subunits [84]. Both complexes are controlled by insulin and other growth factors through the PI3K → AKT cascade; however, each complex is recruited to different compartments and respond distinctly to nutrients, stress, hypoxia/energy status, and other regulators [84]. mTORC1 is targeted to the lysosome where it is inhibited by the TSC1•TSC2 complex until AKT phosphorylates and inhibits tuberin (TSC2), a GTPase-activating protein (GAP), promoting GTP•RHEB (Ras homolog enriched in brain)

accumulation (Figure 9.4). FK506 binding protein 8 (FKBP38) inhibits mTORC1 until RHEB•GTP promotes its dissociation from mTORC1 [85]. Regulation by TSC1•TSC2 → RHEB is also modulated by AKT-mediated phosphorylation of AKT1S1 (AKT substrate 1, PRAS40), which promotes its dissociation from RAPTOR to activate mTORC1 [82]. RHEB resides on endomembranes including lysosomes where it can interact with mTORC1 only if enough amino acids are available to ensure that the cellular environment is sufficient to support growth (Figure 9.4) [86,87]. Activated mTORC1 promotes many cellular anabolic processes needed for growth and proliferation, including the stimulation of glycolytic flux and mitochondrial function, protein and lipid synthesis, and the inhibition of autophagy and lysosomal biogenesis [79]. mTORC1 promotes the trafficking, processing, and transcription of sterol regulatory element binding proteins (SREBPs), which promotes transcriptional activity that stimulates lipogenesis (Figure 9.4) [88]. Thus, the IRS → PI3K → AKT → mTORC1 cascade controls many key cellular processes that balance cellular integrity, long-term growth, and survival.

mTORC2

In addition to fully activating AKT, mTORC2 plays a role in mRNA processing when it phosphorylates IGF-II mRNA-binding protein 1 (IMP1), which promotes IGF-II-leader 3'-mRNA translational initiation by internal ribosomal entry (Figure 9.4) [89]. Thus, mTORC2 can promote growth by regulating IGF-II production that can activate IRA in the mouse embryo. mTORC2 also regulates protein ubiquitylation by phosphorylating F-box and WD repeat domain containing 8 (FBW8), a Cullin 7 E3 ubiquitin ligase recognition subunit (Figure 9.4). The phosphorylation of FBW8 stabilizes and promotes ubiquitylation of targeted substrates, including IRS1 that contributes to insulin resistance in certain tissues and cells (Figure 9.4) [90]. Thus, mTORC2 signalling can modulate insulin signalling through its direct effect on AKT activity and various feedback regulatory nodes [89].

FOXO

Forkhead box O subfamily (FoxOs) – FOXO1, FOXO3a, FOXO4, and FOXO6 – are integrative transcription factors that control target gene expression to coordinate many biological processes including metabolism, autophagy, apoptosis, ROS detoxification, DNA repair, cell cycle, stem cell maintenance, and longevity [91]. FOXOs contain five highly conserved domains, including the N-terminal region with several AKT phosphorylation sites [92]; a highly conserved forkhead DNA binding domain; a nuclear localization signal located just downstream of the DNA binding domain; a nuclear export sequence; and a C-terminal transactivation domain [93]. Retention of FOXO in the nucleus promotes or suppresses gene expression by binding to TTGTTTAC motifs [94]. FOXO nuclear localization is regulated by various post-translational modifications including acetylation, methylation, glycosylation, ubiquitylation, and phosphorylation [95]. FOXO phosphorylation by AKT or other kinases including IκB kinase (IKK) and SGK promotes nuclear exclusion [92,94]. Deacetylation of FOXOs by Silent mating type information regulation NAD-dependent deacetylase (SirT1) can suppress transcriptional activity directly [96].

FOXOs regulate metabolism by inducing genes that promote hepatic glucose production; insulin secretion in β cells and β-cell growth and differentiation; and fat and muscle mass [97–99]. In mammalian liver, decreased circulating insulin during fasting promotes the nuclear localization of FOXO, where it interacts

with Ppargc1α, peroxisome proliferator-activated receptor gamma coactivator 1α (PGC1α), and cAMP response element-binding protein complexed with CREB regulated transcription coactivator 2 (CREB•CRT2) to increase the expression of glucose-6-phosphatase (G6PC) and phosphoenolpyruvate carboxykinase 1 (PCK1) for hepatic glucose production [100]. FOXO also regulates hundreds of other hepatic genes directly or indirectly to coordinate glucose and lipid homeostasis and systemic insulin sensitivity. During fasting or insulin resistance, nuclear FoxO1 increases follistatin (*Fst*), which provokes white adipose tissue (WAT) insulin resistance and lipolysis to deliver glycerol and non-esterified fatty acids to the liver for hepatic glucose production or re-esterification [101–104]. Severe and persistent starvation can trigger FOXO1-mediated hepatic insulin-like growth factor binding protein 1 (IGFBP-1) expression to reduce circulating IGF-I bioavailability and attenuate somatic growth [105]. In muscle, nuclear FOXO1 promotes autophagy that breaks down muscle protein for use by the liver to make glucose. Thus, reduced insulin signalling in skeletal muscle can underlie the loss of muscle mass and glycaemic levels during chronic insulin resistance [106].

Insulin-regulated glucose transport

Glucose transport is the prototype insulin response that is rate limiting for dietary glucose utilization by muscle and adipose [107,108]. Members of the GLUT (sodium-independent, facilitated-diffusion glucose/hexose transporter) family are distinguished by substrate specificity and affinity, tissue distribution, and mechanism of regulation. GLUT4 is the principal insulin-responsive glucose transporter that is expressed in WAT, brown adipose tissue, skeletal muscle, and heart, where it plays a direct role in insulin-stimulated glucose influx and utilization.

The molecular mechanisms linking the insulin signal to increased glucose influx involves complex multistep coupling between the insulin signalling cascade and vesicle trafficking [107–109]. Under basal conditions, GLUT4 accumulates in a general recycling compartment that on sorting generates GLUT4 storage vesicles that form insulin-responsive vesicles that fuse with the plasma membrane in response to insulin (Figure 9.5) [107,108,110]. In addition to GLUT4, the storage vesicles contain other components, including sortilin that mediates GLUT4 retrieval from trans-Golgi network and sorting endosomes to form the GLUT4 storage vesicles [107].

Insulin acts at several sites to regulate GLUT4 translocation and recycling, including GLUT4 storage vesicle assembly, release from intracellular retention sites, transport and fusion at the plasma membrane, and return (Figure 9.5). AKT substrate of 160 kDa (AS160) and TBC1 domain family member 4 (TBC1D4) are GTPase-activating proteins that maintain their target Ras-associated proteins (RABs), including RAB8A, RAB10, RAB14, and others that regulate intracellular membrane flux, in an inactive GDP bound state under basal conditions [107,108]. AKT phosphorylates and inhibits AS160 in adipose and TBC1Ds in muscle, which promotes RAB•GTP accumulation [111,112]. GTP-loaded RAB8A and RAB14 (muscle) or RAB10 (adipose) facilitate translocation of GLUT4 storage vesicles to the plasma membrane (Figure 9.5) [107,111]. AKT2 also phosphorylates and inactivates RAL•GAP, which leads to the accumulation and activation of RAL•GTP that binds to exocyst components, Sec5 and Exo70, to

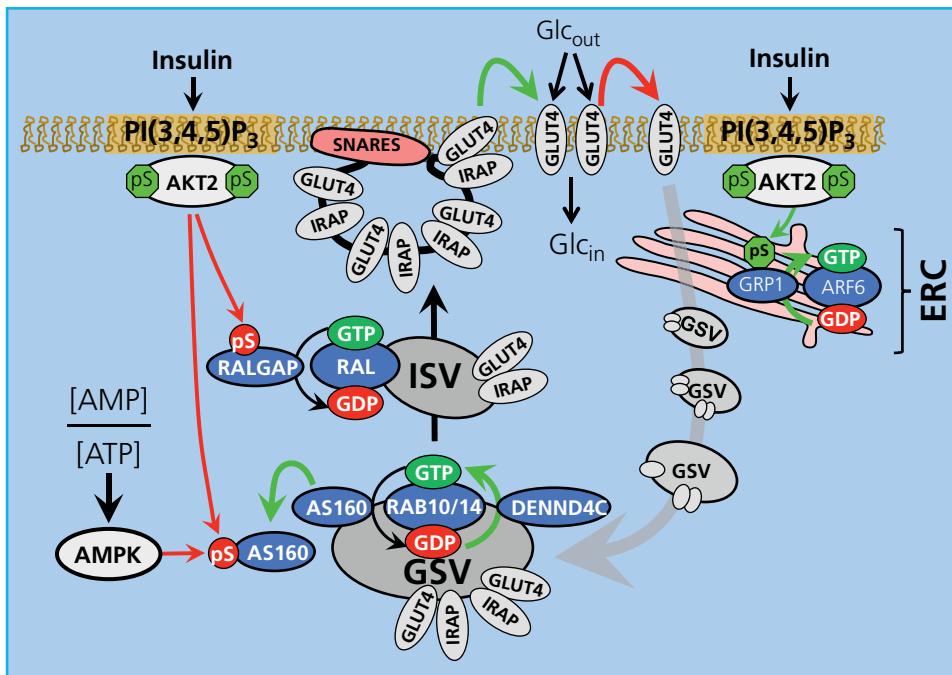

Figure 9.5 A mechanism of insulin-stimulated glucose transport by the PI3-kinase → AKT → AS160/RALGAP/GRP1 branch of the insulin signalling pathway in adipose or muscle. These AKT substrates mediate various steps of the assembly and trafficking of GLUT4 storage vesicles (GSVs). AKT → AS160/RALGAP promotes translocation of the GLUT4 storage vesicles to the plasma membrane. Endocytosis of GLUT4 is stimulated by AKT → GRP1•ARF6 signalling. Insulin-stimulated AKT promotes the accumulation of GLUT4-containing vesicles in the plasma membrane, which increases glucose influx.

tether insulin-responsive vesicles to the plasma membrane (Figure 9.5). Insulin can promote dissociation of a complex of diacylglycerol kinase- γ and phosphatidylinositol 4-phosphate 5-kinase 1 α (DGK γ •PIP5K1 α) from IRS1, which facilitates formation of the IRS1•PI3K complex to activate AKT and Rac family small GTPase 1 (RAC1) [107, 113]. RAC1 might promote AKT membrane compartmentalization or actin remodelling to enhance insulin-stimulated GLUT4 translocation [107, 108]. Thus, insulin-stimulated AKT contributes to translocation, docking, and fusion of GLUT4 vesicles with the plasma membrane [107, 111].

Insulin might regulate GLUT4 recycling back from the plasma membrane into an endocytic recycling compartment [114]. Formation of GLUT4 vesicles from the endocytic recycling compartment relies on a coat complex containing clathrin and ACAP1, an ARF6 GAP, which is recruited to endocytic recycling compartment membranes by GRP1, an ARF6-GEF [115]. Budding of GLUT4 storage vesicles from the endocytic recycling compartment is stimulated through the AKT-mediated phosphorylation of GRP1 [116]. Phospho-mimetic mutations in GRP1 increase plasma membrane GLUT4 localization in 3T3-L1 adipocytes, in large degree bypassing the GLUT4 vesicle retention mechanisms [116].

Heterologous regulation and insulin resistance

Nutrient excess causes insulin resistance, at least in part, because chronic insulin secretion inhibits proximal insulin receptor signals through feedback or heterologous inflammation [117–122]. Although elevated insulin defends against hyperglycaemia, it can increase hepatic lipogenesis, dyslipidaemia, WAT expansion, and hepatic steatosis [8]. Consequently, elevated circulating and hepatic lipids, including non-esterified fatty acids, diacylglycerol, and ceramides, can activate kinases directly or through inflammatory cascades to further inhibit proximal insulin signalling [106, 109, 123–127]. Nutrient excess also stimulates mTORC1-mediated feedback mechanisms that can inhibit insulin receptor → IRS1/IRS2 coupling

and stability [128–130]. Regardless, physiological mechanisms that regulate the concentration and function of proximal insulin signalling components are not understood well enough to guide the development of efficacious and safe treatments.

Transcriptional control of IRS1

Several mechanisms regulate IRS1 transcription, including Wnt/β-catenin signalling [119, 131, 132]. Wnt3A or the constitutively active form of β-catenin increases the IRS1 gene and protein expressions, which decreases during suppression of the Wnt/β-catenin pathway. Moreover, chromatin immunoprecipitation analysis shows that T-cell factor 4 (TCF4), a component of the TCF/LEF lymphoid enhancer factor family, binds to the IRS1 promoter to stabilize Wnt/β-catenin signalling [133]. The TCF/LEF response elements are located between –7000 and –5966 in the mouse IRS1 promoter and transfection by siTCF4 reduces IRS1 mRNA and protein levels in H4IIE cells, suggesting that the β-catenin/TCF4 pathway can regulate IRS1 expression at the transcriptional level [119]. Wnt/β-catenin appears to regulate IRS1 expression in perivenous hepatocytes where lipogenesis predominates [119]. Wnt signalling agonists might modulate glucose homeostasis as a treatment for type 2 diabetes.

IRS1 expression is also regulated by transcriptional repressors, including transcription factor AP2β (AP2β), the p160 family of nuclear receptor coactivators p/CIP (p300/CBP/cointegrator-associated protein), and steroid receptor coactivator-1 (SRC1) [134, 135]. AP2β is expressed in adipose tissue where it promotes adipocyte hypertrophy, inhibits adiponectin expression, and enhances the expression of inflammatory adipokines such as interleukin 6 (IL-6) and C-C motif chemokine ligand 2 (MCP1) [134]. AP2β decreases IRS1 mRNA and protein concentration in adipocyte cell lines. Genome-wide association studies reveal AP2β as a candidate gene for the risk of obesity and type 2 diabetes, which might involve negative regulation of IRS1 expression [136]. By contrast, p/CIP and SRC1 serve as transcriptional coactivators for nuclear hormone receptors and certain other transcription

factors [137]. IRS1 expression increases on inactivation of p/CIP and SRC1 in mice, which increases glucose uptake and enhanced insulin sensitivity in WAT and skeletal muscle. Finally, muscle-specific TAZ (transcriptional coactivator with PDZ-binding motif) knockout mice display decreased IRS1 expression and insulin resistance [138]. Statins can reduce TAZ levels, which might reveal a mechanism of insulin resistance owing to decreased IRS1 expression; however, effects of statins on protein prenylation might also be involved [138].

Transcriptional control of IRS2

Unlike IRS1, IRS2 transcription is regulated by nutrient-sensitive factors – including cAMP response element binding protein (CREB) and its coactivator CREB regulated transcription coactivator 2 (CRTC2); FOXO isoforms; hypoxia-inducible factor-2 α (HIF2 α) encoded by EPAS1; nuclear factor of activated T cells (NFAT); PGC1A; sterol regulatory element binding protein 1 (SREBP1c); signal transducer and activator of transcription 3 (STAT3); and transcription factor E3 (TFE3) [139–142]. Multiple transcriptional mechanisms induce hepatic IRS2 expression during fasting, including nuclear FOXO that creates a direct feedback loop to augment insulin signalling during fasting and suppress it after a meal through AKT → FOXO. Fasting or exercise also induce the CREB•CRTC2 transcriptional complex through glucagon signalling that increases expression of gluconeogenic genes along with IRS2 [140]. Moreover, glucagon acting through PGC1A can increase hepatic IRS2 expression while suppressing IRS1, which can finetune gluconeogenesis and hepatic glucose production during the fasting to feeding transition with a minimal effect on lipogenesis [142]. An E-box overlapping the FOXO site binds basic helix-loop-helix transcription factor E3 (TFE3), which converges with FOXO to promote IRS2 expression [143]; however, these elements also overlap with an SRE that binds sterol regulatory element binding transcription factor 1 (SREBF1), an important transcriptional activator of lipid synthesis [144]. Active hepatic SREBF1 increases during nutrient excess and chronic insulin stimulation, which decreases IRS2 expression to promote insulin resistance while promoting lipogenesis [145, 146]. HIF2 α induces transcription of IRS2 in the hypoxic perivenous zone of the liver to restrain gluconeogenesis compared to other liver zones [119, 147]. Thus, IRS2 expression is highly integrated through multiple metabolic sensors to promote insulin sensitivity and metabolic homeostasis.

miRNA-mediated post-transcriptional regulation

MicroRNAs (miRNAs) are short (~20 nucleotides) non-coding RNA molecules that negatively modulate gene expression through their specific binding within the 3'UTR sequence of messenger RNA (mRNA) to inhibit translation or destabilize the target mRNA. Most of the proximal components of insulin signalling can be regulated in a tissue-specific way by miRNAs [148]. LET7 miRNA interferes with many proximal components, including type 1 IGF receptor, insulin receptor, IRS2, PIK3IP1, AKT2, TSC1, and RICTOR [149]. LET7 interference can be inhibited by the RNA binding proteins Lin28a and Lin28b, which block production of mature LET7 to increase translation of the insulin signalling components. LET7 associates with gigantism, puberty delay, and glucose homeostasis by modulating insulin → PI3K → mTOR signalling and insulin sensitivity [149].

Many other miRNAs display specificity against proximal insulin signalling components during metabolic challenge in various tissues. Hepatic miR-424-5p, miR-15b, miR-195, and miR-

96 increase in mouse liver when fed a high-fat diet, which associates with less insulin receptor expression [150–153]. IRS1 and IRS2 are targeted by miRNAs in multiple peripheral insulin target tissues. miR-222 can suppress IRS1 in liver and adipose during high-fat diet and sucrose feeding [154]. Resistin upregulates miR-145 to inhibit IRS1 levels [155]. miR-29a and miR-29c suppress IRS1 expression in the muscle of individuals with type 2 diabetes or mice fed high-fat diets [156]. IRS1 can be downregulated in mouse endothelial cells by miR-126, which dysregulates angiogenesis [157]. Chronic angiotensin-II-induced hypertension can increase the expression of miR-487b in rat aorta, which suppresses IRS1 expression and promotes hypertension-induced cardiovascular disease and formation of aortic aneurysms owing to the loss of medial smooth muscle [158].

IRS2 expression is also suppressed by various miRNAs. The miR-126 targets IRS2 in pancreatic β cells, which can suppress islet growth [159]. Upregulation of miR-33b reduces hepatic IRS2 → AKT signalling while miR-135a reduces IRS2 → AKT signalling in the muscle of individuals with type 2 diabetes and *db/db* mice [160].

Finally, miR-26b appears to suppress PTEN to promote GLUT4 translocation in adipose and β -cell function during obesity [161]. Other proximal insulin signalling components are also modulated by various miRNAs, including SHIP2 (miR-205-5p), PDK1 (miR-375), AKT (miR-143 → ORP8 [oxysterol binding protein related 8]), PP2A (miR-19b, miR-429, miR-29, and miR-155), and type 1 IGF receptor [148]. Modulating miRNA expression *in vivo* might be a beneficial strategy to restore insulin sensitivity and treat some forms of type 2 diabetes [162].

Regulation of IRS signalling by Ser/Thr phosphorylation

IRS1 and IRS2 can be regulated through a complex mechanism involving phosphorylation of more than 50 potential phosphorylated Ser/Thr residues (pS/Ts) located in the long unstructured tail (Figure 9.6). Understanding how phosphorylated Ser/Thr residues regulate insulin signalling is challenging, because so many sites and mechanisms are involved [167]. Heterologous signalling cascades initiated by proinflammatory cytokines or metabolic excess, including tumour necrosis factor α (TNF- α), endothelin-I, angiotensin II, excess nutrients (free fatty acids, ceramides, amino acids, and glucose), or endoplasmic reticulum stress, are implicated in IRS1 and IRS2 phosphorylated Ser/Thr residues, which associate with less insulin-stimulated tyrosine phosphorylation [167]. Most IRS1/2 phosphorylated Ser/Thr residues are stimulated by the PI3K → Akt → mTOR cascade during insulin stimulation [163, 167]. Thus, IRS1/2 phosphorylated Ser/Thr residues are first and foremost a feedback mechanism that develops during chronic insulin stimulation, which can be co-opted by other agonists during metabolic stress to inhibit insulin signalling and dysregulate metabolic homeostasis (Figure 9.6) [167]. Thus, hyperinsulinaemia might be the important physiological mediator of insulin resistance in animals [5, 121].

Recently, AKT was shown to coordinate negative feedback by phosphorylating IRS1 and IRS2 on several serine residues [168]. AKT-mediated phosphorylation can deplete plasma membrane localized IRS1 and IRS2, which reduces their interaction with the insulin receptor. Reduced membrane-associated IRS protein decreases recruitment and activation of the PI3K, which reduces phosphatidylinositol(3,4,5)-triphosphate (PIP3) synthesis and insulin action. Two AKT-dependent phosphorylation sites in IRS2,

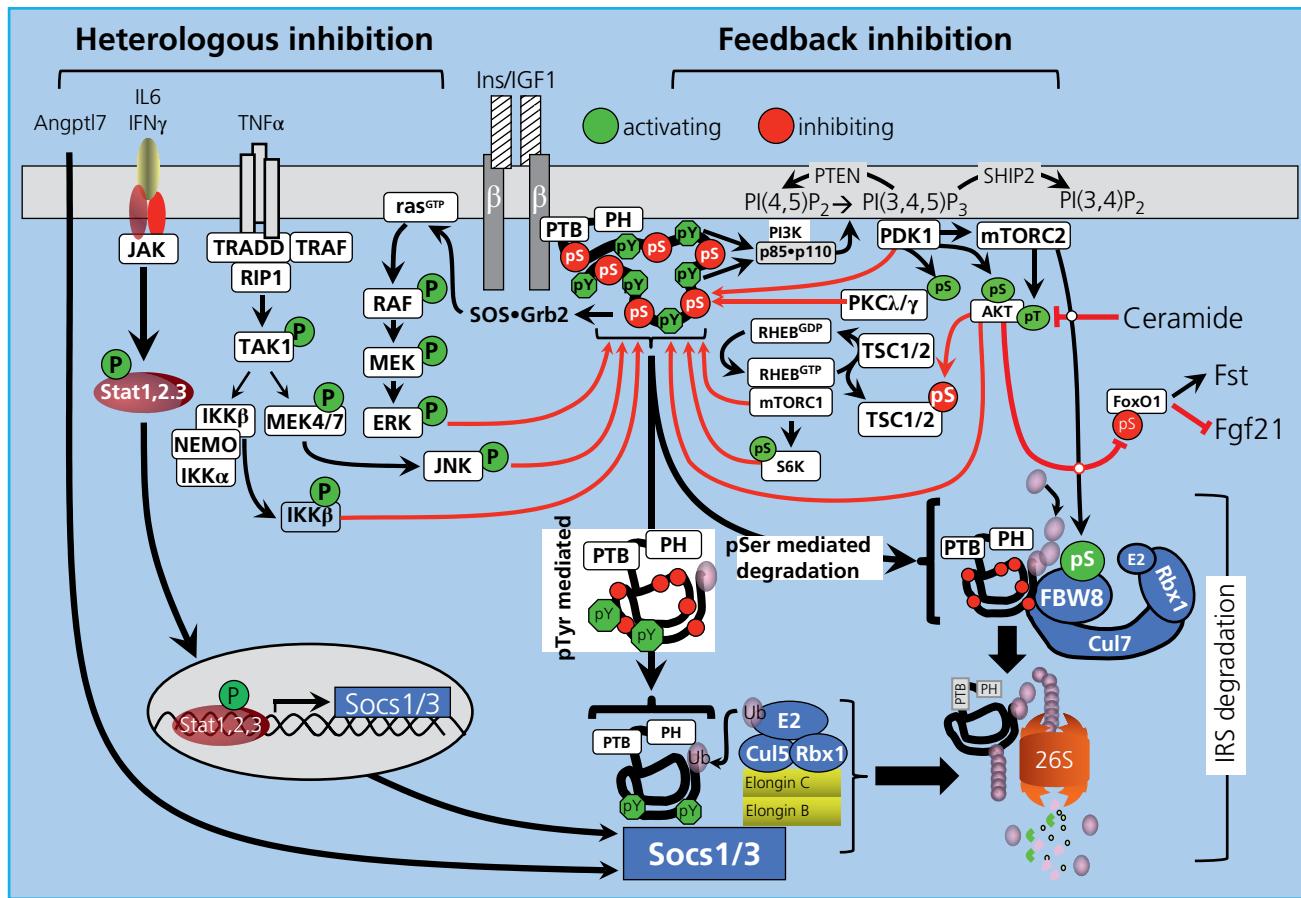

Figure 9.6 Schematic diagram of heterologous and feedback regulation of insulin signalling. Various kinases in the insulin signalling cascade mediate feedback inhibition of IRS, including PKB, mTOR, S6K, ERK, AKT, and atypical PKC isoforms [163]. Other kinases activated by heterologous signals, including lipids such as ceramide, are also involved. Serine phosphorylation of IRS1 can recruit CRL7, which can promote ubiquitylation and degradation of IRS1 through the 26S proteasome. Many proinflammatory cytokines cause insulin resistance through SOCS1 or SOCS3 that targets phosphotyrosine-containing proteins like IRS1 or IRS2 for ubiquitylation by a BC-containing ubiquitin ligase (E3) and degradation [164–166].

mouse S303 and S573 (human S306 and S577), might mediate this negative feedback, but other sites can be involved [163]. These findings establish a novel mechanism by which AKT can feedback to attenuate insulin-stimulated PIP₃ production, providing a mechanism to modulate insulin signalling independent of other signalling pathways.

Mouse S307^{IRS1} (human S312^{IRS1}) is one of the best-studied pS/T in IRS1, which is often used as barometer of insulin resistance [167]. Insulin can promote pS307^{IRS1} phosphorylation through the PI3K → AKT → mTORC1 → S6K1 (Figure 9.6) [163]. In mice, free fatty acids promote pS307^{IRS1}, but insulin resistance and hyperinsulinaemia are not excluded as the cause [167]. c-Jun N-terminal kinase (JNK1) or mTORC1 activated in obese mice promotes pS307^{IRS1} and other sites [169, 170]. Although most if not all cell-based investigations support an inhibitory role for pS307^{IRS1}, mouse-based experiments are less convincing. Genetic knock-in to replace S307^{IRS1} with alanine (A307^{IRS1}) increases fasting insulin and glucose levels while decreasing p110^{PI3K} binding to IRS1 PI3K [171]. During the high-fat diet, A307^{IRS1} mice exhibit more severe glucose intolerance and higher fasting insulin than control S307^{IRS1} mice. In mice, pS307^{IRS1} and other phospho-S/Ts might attenuate the detrimental effects of compensatory hyperinsulinaemia to maintain some relative insulin sensitivity [171]. More work is needed to establish the mechanisms involved.

Regulation of IRS degradation

Proteasome-mediated degradation regulates many biological processes including signal transduction, gene transcription, and cell cycle progression. Proteins targeted for destruction by the 26S proteasome are polyubiquitylated by various complexes comprising a ubiquitin-activating enzyme (E1), ubiquitin-conjugating enzyme (E2), and ubiquitin-protein ligase (E3) [172]. IRS1 and IRS2 can be polyubiquitylated during chronic inflammatory states, nutrient excess, and hyperinsulinaemia through various tissue-specific mechanisms [173]. The first pathway discovered involves suppressor of cytokine signalling 1 and 3 (SOCS1/3), which binds to IRS1 through its SH2 domain and to a ubiquitin E3 ligase through its SOCS box (Figure 9.6) [174, 175]. Mutations in the SOCS box prevent ubiquitylation and degradation of IRS1 or IRS2 [174], and inhibition of SOCS1/3 expression by anti-sense oligonucleotides improves insulin sensitivity in obese and diabetic mice [176]. Cytokines like interferon γ (IFNγ) or IL-6 activate Janus kinases (JAK) promote phosphorylation and dimerization of signal transducer and activator of transcription (STAT) factors, which migrate into the nucleus to induce SOCS1/3 expression (Figure 9.6) [177]. Angiopoietin-like 7 (Angptl7) also increases SOCS3 during obesity [178]. Thus, SOCS-mediated polyubiquitylation of IRS1 or IRS2 can promote insulin resistance and glucose intolerance during infection, inflammation, or metabolic stress.

Other mechanisms of IRS degradation are coordinated by pS/T on IRS1 or IRS2. Cullin-RING E3 ubiquitin ligase 7 (CRL7) mediates IRS1 degradation downstream of pS/T generated by the PI3K → AKT → mTORC1 cascade [179]. CRL7 complex contains cullin 7 (CUL7), a molecular scaffold that assembles F-box/WD repeat-containing protein 8 (FBW8) to recruit phosphorylated substrates, and RING-box protein 1 (Rbx1), associated with an E2 conjugating enzyme (Figure 9.6). FBW8 apparently binds to IRS1 through pS/T residues generated by the mTORC1 → S6K cascade, including human pS307^{IRS1}, pS312^{IRS1}, and pS527^{IRS1}, but possibly others, to mediate polyubiquitylation of IRS1 that progresses to degradation (Figure 9.6) [179, 180]. This regulatory mechanism might be engaged during nutrient excess or hyperinsulinaemia, as it depends on chronically hyperactivated mTORC1 → SK6 [180].

Chronic consumption of high-calorie diets upregulates Cbl proto-oncogene B (CBLB), a RING-type E3 ubiquitin ligase that belongs to the casitas B-lineage lymphoma family of proteins [106]. CBL proteins share a conserved NH₂-terminal region containing a tyrosine kinase binding domain and a RING-finger domain to facilitate E3 ubiquitin ligase activity. Calorie excess induces carbohydrate-responsive element-binding protein (ChREBP) and SREBP1c, which upregulates myostatin in murine muscle to induce CBLB expression that drives insulin resistance through the polyubiquitylation and degradation of IRS1 [181].

Regulation by protein and lipid phosphatases

Phosphatases modulate insulin signalling by dephosphorylating key proteins or lipids in the signalling cascade, including PTP1B (tyrosine-protein phosphatase non-receptor type 1, PTPN1), PTPN2 (tyrosine-protein phosphatase non-receptor type 2, TCPTP), protein phosphatase 2A (PP2A), protein phosphatase 1 (PP1), phosphatase and tensin homolog (pTEN), tensin-like C1 domain-containing phosphatase (C1-TEN), and Src homology 2 domain-containing inositol 5'-phosphatase 2 (SHIP2). PTP1B and PTPN2 are related phosphotyrosine phosphatases that dephosphorylate various receptor tyrosine kinases, including the A-loop of the insulin receptor [182]; however, their biological effects can be distinct owing to different time courses and tissue expression [183]. PTP1B^{-/-} mice display increased insulin sensitivity, lower circulating insulin concentrations, and decreased pancreatic β-cell mass [184]. Physiologically, both PTP1B and PTPN2 can be inactivated by reactive oxygen species generated during insulin stimulation [185, 186]. In pancreatic β cells, PTP1B attenuates the IRS2 → PI3K → AKT cascade that is important for growth, function, and survival of these cells [187]. Thus, inactivation of PTP1B can maintain β-cell mass in mice lacking IRS2, which prevents the early onset of diabetes [187]. Regardless, without IRS2 even the IRS2^{-/-}•PTP1B^{-/-} mice lose β-cell mass between 8 and 9 months of age, as IRS1 signalling fails to compensate. PTP1B also inhibits leptin signalling (LepRb → JAK2) as it dephosphorylates JAK2. PTPN2 dephosphorylates JAK1/3 but not JAK2 [182]. Central nervous system inhibition of PTP1B can protect against obesity, while peripheral inhibition of PTP1B promotes glucose tolerance [188]. Inhibition of PTP1B or TCPTP in the brain, or specific hypothalamic neurons, promotes insulin and leptin signalling and prevents diet-induced obesity, type 2 diabetes, and non-alcoholic fatty liver disease [189]. Regardless, targeting PTP1B and TCPTP for treatment has been problematic due to challenges in targeting the inhibitor to specific tissues; however, intranasal targeting of PTP1B and TCPTP can increase leptin and insulin sensitivity and

promote weight loss by repressing feeding and increasing energy expenditure [190].

pTEN is a potent negative regulator of insulin action and cellular proliferation and is a frequently mutated gene in human cancer [191, 192]. pTEN attenuates insulin signalling by dephosphorylating PI(3,4)P₂ and PI(3,4,5)P₃ at the 3-position, which reduces the recruitment and activation of PDK1, AKT, and others (Figure 9.6) [192]. pTEN heterozygosity can increase peripheral insulin sensitivity in Irs2^{-/-}•Pten^{+/-} mice and normalizes glucose tolerance, as the small islets in these mice produce enough insulin until death between 10 and 12 months age. These experiments highlight the complex relation between nutrient homeostasis, insulin sensitivity and secretion, and cancer that can emerge in rodents and humans without full pTEN activity.

Phosphatidylinositol-3,4,5-trisphosphate 5-phosphatase (SHIP2) encoded by the *INPPL1* gene attenuates insulin signalling by dephosphorylating the 5'-position of PtdIns(3,4,5) (Figure 9.6). Several genetic studies link SHIP2 to metabolic disorders, showing that polymorphisms in *INPPL1* may contribute to the pathogenesis of the metabolic syndrome, hypertension, and type 2 diabetes [193]. Despite this complexity, SHIP2 inhibition might have therapeutic value. Metformin might increase insulin sensitivity by inhibiting SHIP2, which enhances glucose uptake while protecting renal podocytes from apoptosis in diabetic rodent models [194].

Phosphoserine-directed phosphatases, including PP2A and PP1, have complex effects depending on substrate targeting. PP2A is a widely expressed pSer/pThr protein phosphatase that forms a heterotrimeric complex with scaffold and regulatory subunits to target various subcellular locations and substrates [195]. PP2A can be a negative regulator of insulin's metabolic signalling by dephosphorylating and inactivating AKT or dephosphorylating and activating GSK3β [196, 197]. PP2A also targets pS/Ts in IRS1, which stabilizes IRS1 for tyrosine phosphorylation to enhance insulin signalling [198, 199]. PP1 also targets and dephosphorylates IRS1. Phosphoproteomic analysis of L6 skeletal muscle cells reveals the interaction of myosin phosphatase targeting subunit 1 (MYPT1), a targeting subunit of protein phosphatase 1cβ (PP1cβ) with IRS1 [200]. Activation of the MYPT1•PP1 complex by PKA promotes dephosphorylation of serine residues in IRS1 to increase tyrosine phosphorylation and stimulate the PI3K → AKT cascade [201].

Mouse genetics reveal tissue-integrated insulin signalling

During the past 25 years, investigators used genetically manipulated mice to understand the molecular and integrated physiology of insulin action. Proximal insulin signalling steps are similar in all tissues, whereas the downstream effects and heterologous regulation can be tissue specific (Figure 9.7). For example, in liver, post-prandial Pi3k → Akt inhibits FOXO1, which regulates hundreds of genes including increasing genes for *de novo* lipogenesis (\uparrow *Srebf1*, \uparrow *Gck*, \uparrow *Fasn*) and inhibiting genes for hepatic glucose production (\downarrow *Pck1*, \downarrow *G6pc*) [103, 118, 202, 203]. In adipose, Pi3k → Akt activates phosphodiesterase 3β (PDE3β) to reduce cAMP and suppress lipolysis, whereas it inhibits AS160 to stimulate glucose influx (Figure 9.7) [204–206]. In muscle, Pi3k → Akt inhibits protein degradation while stimulating protein and glycogen synthesis and glucose oxidation (Figure 9.7) [207, 208]. The Akt → mTorC1 branch

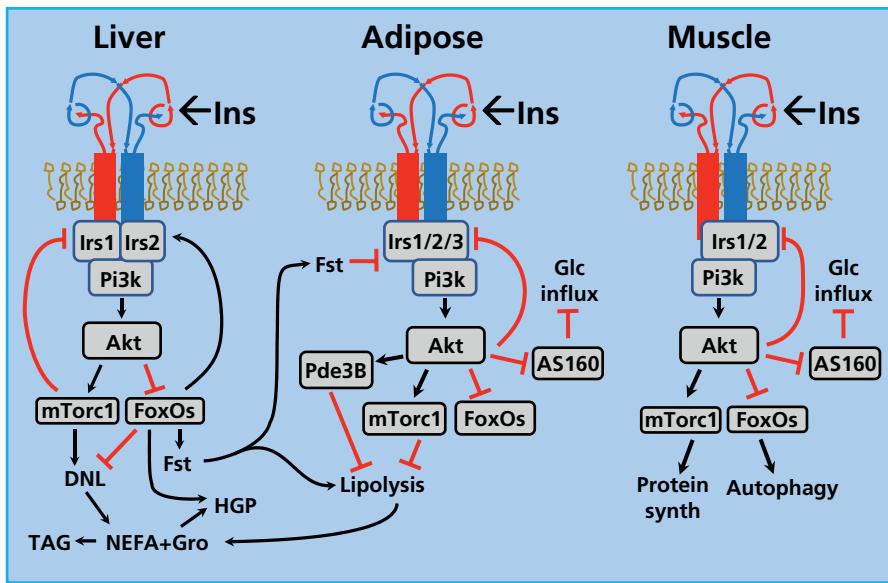

Figure 9.7 Tissue-specific insulin signalling. The insulin receptor is autophosphorylated on multiple tyrosine residues, allowing the docking and activation of multiple signalling molecules, most notably insulin receptor substrates (IRS) proteins. This in turn activates phosphatidylinositol-3-kinase (PI3K) and AKT to mediate the increases in glucose uptake and metabolism as well as changes in protein and lipid metabolism. While the general pathway is similar in all tissues, the final biological effects are specialized to the roles of insulin in liver (inhibits hepatic glucose production and stimulates *de novo* lipogenesis), adipose (inhibits lipolysis and stimulates glucose influx), and muscle (inhibits autophagy and stimulates protein synthesis and glucose influx).

is common to all tissues and stimulates anabolic pathways, including sterol regulatory element-binding factor 1 (Srebp1c)-mediated hepatic *de novo* lipogenesis (Figure 9.7) [209–212]. During fasting or insulin resistance, nuclear FoxO1 induces Follistatin (Fst), which provokes WAT insulin resistance and lipolysis to deliver glycerol and non-esterified fatty acids to the liver for hepatic glucose production or re-esterification (Figure 9.7) [101–104].

Since regulatory tissue cross-talk complicates the analysis of whole-body gene deletion, Cre-loxP technology or specific viral-mediated expression has been used to investigate the role of IR → IRS → AKT → FOXO1 signalling in specific tissues [213, 214]. Even tissue-specific gene deletion has limitations, as insulin signalling is rarely lost completely in common metabolic disease. Moreover, targeted deletions still influence metabolic regulation throughout the organism owing to crosstalk by secreted peptides, metabolites, or neuronal interconnections [103, 215]. Regardless, Cre-loxP technology continues to be valuable to dissect the insulin signalling cascades.

Systemic insulin receptor signalling cascade

Mice lacking the insulin receptor have nearly normal size but less adipose tissue mass at birth, and die a few days after birth with severe hyperglycaemia, pancreatic β-cell failure, and ketoacidosis [216]. Thus, insulin → insulin receptor signalling is essential for postnatal nutrient homeostasis [217]. Insulin receptor-deficient mice can be rescued genetically by transgenic expression of the insulin receptor in the brain, liver, and pancreatic β cells [218]. Unlike mice, humans with rare mutations leading to a lack of functional insulin receptors display intra-uterine growth retardation, failure to thrive, and hypoglycaemia for weeks until hyperglycaemia ensues [217]. This paradox might involve limited availability of gluconeogenic substrates or extreme hyperinsulinaemia that might activate enough IGF-I receptors to generate some insulin-like actions [219].

Systemic IRS1 or IRS2 deletion suggests that each substrate can display unique signalling properties in various tissues. The signalling specificity probably arises from different expression levels, receptor coupling, or feedback regulation [220]. Systemic deletion of IRS1 produces small insulin-resistant mice with nearly normal glucose homeostasis owing to β-cell expansion and life-long compensatory hyperinsulinaemia [221]. These results suggest that

IRS1 is the principal mediator of IGF-I-regulated body growth, but is not essential for β-cell growth. By contrast, mice lacking IRS2 display nearly normal body growth and even gain fat mass; however, male IRS2^{-/-} mice develop life-threatening diabetes after 8 weeks of age owing to the progressive loss of β-cell mass that disrupts compensatory hyperinsulinaemia [222]. Female mice develop diabetes more slowly, and many but not all develop severe hyperglycaemia by 6 months [223]. Thus, other mechanisms might promote β-cell growth and survival in females.

Compound deletion of IRS1 and IRS2 appears to be embryonic lethal; however, littermates retaining one allele of IRS1 (IRS1^{+/-}•IRS2^{-/-}) or one allele of IRS2 (IRS1^{-/-}•IRS2^{+/+}) can be born alive [224]. IRS1^{+/-}•IRS2^{-/-} mice develop severe fasting hyperglycaemia and die by four weeks of age as β-cells fail to grow or survive. By contrast, IRS1^{-/-}•IRS2^{+/+} mice have a very small body but have normal or elevated β-cell mass to secrete enough insulin for glucose tolerance [224]. Thus, IRS1 and IRS2 are essential for development and nutrient homeostasis, and some IRS2 is essential for β-cell growth, function, and survival.

Hepatic insulin receptor → FOXO1 signalling

The liver is an important site of insulin action that plays a role in systemic glucose and lipid homeostasis [213]. LIRKO (IR^{L/L}•Cre^{Alb}; hepatic albumin Cre driver) mice display moderately elevated fasting glucose and severe post-prandial hyperglycaemia and glucose intolerance [225]. LIRKO mice also develop severe hyperinsulinaemia owing to a combination of increased insulin secretion to control hyperglycaemia and reduced hepatic insulin degradation [226]. LIRKO mice display reduced levels of circulating free fatty acids and triglycerides on ordinary chow diets [213, 225]; however, on an atherogenic diet LIRKO mice develop dyslipidaemia that can progress to atherosclerosis [227]. Insulin receptor deletion dysregulates hundreds of hepatic genes, including reduced glucokinase and hexokinase 4 (GCK) and elevated phosphoenolpyruvate carboxykinase 1 (PCK1), glucose-6-phosphatase, catalytic subunit (G6PC), and pyruvate kinase (PK1) [213, 225]. Chronic hyperinsulinaemia in LIRKO mice exacerbates peripheral insulin resistance, while streptozotocin injections to reduce insulin secretion improve peripheral insulin resistance but fail to suppress hepatic glucose

production [228]. Thus, heterologous mechanisms dysregulated by hepatic insulin resistance – including the systemic effects of hyperinsulinaemia – might exacerbate hepatic glucose production through indirect mechanisms that promote adipose insulin resistance and delivery of excess glycerol and non-esterified fatty acids to the liver for hepatic glucose production [103, 229, 230].

For over a decade, we have modelled hepatic insulin resistance by genetic inactivation of hepatic IRS1 and IRS2 in LDKO ($\text{Irs1}^{\text{L/L}} \cdot \text{Irs2}^{\text{L/L}} \cdot \text{Cre}^{\text{Alb}}$) mice [103, 118, 202, 203]. LDKO mice display unsuppressed hepatic glucose production, hyperinsulinaemia, glucose intolerance, and diabetes [103, 118, 202, 203]. At first, these results suggested that hepatic IRS1/2 mediates systemic nutrient homeostasis through hepatic insulin signalling; however, white and brown adipose tissue and skeletal muscle are also insulin resistant in LDKO mice, suggesting that dysregulated hepatic metabolism manifests systemically [103, 231]. Remarkably, metabolic health is restored upon hepatic inactivation of FoxO1 in LTKO (LDKO.FoxO1^{L/L}) mice, even though the liver is mechanistically unresponsive to insulin [103, 118, 202, 203, 231]. These findings are confirmed and extended with compound hepatic-specific LIRKO.FoxO1^{L/L} mice or Akt1^{L/L}.Akt2^{L/L}.FoxO1^{L/L}.Cre^{Alb} mice [80, 232–234].

Genetic disruption of hepatic FOXO1 substantially normalizes the expression of hundreds of dysregulated hepatic genes [80, 202]. Within such mice, FOXO1-dependent gene expression or metabolites generated in hepatocytes and circulating systemically could promote peripheral insulin resistance and the delivery of metabolic intermediates to the liver, including excess glycerol and free fatty acids from adipose tissue [235]. Comprehensive analyses of the LDKO and LTKO mice reveals that *Fst*, best known for its modulation of transforming growth factor (TGF)- β superfamily members Activin and Myostatin [236, 237], is a key FOXO1-dependent hepatokine that promotes WAT lipolysis during hepatic insulin resistance [103]. Thus, while failing to restore hepatic insulin signalling *per se*, disruption of hepatic FOXO1 in LTKO mice and similar models might restore glucose tolerance by normalizing hepatokine secretion [202, 232, 233, 238].

Insulin signalling and glucose homeostasis in skeletal muscle

Skeletal muscle is a major site for utilization and storage of ingested glucose after a meal [8]. Defective insulin signalling at the level of the insulin receptor and IRS1-associated PI3K is associated with reduced insulin-stimulated muscle glucose storage. Regardless, some but not all aspects of metabolic disease emerge on deletion of skeletal muscle insulin receptor in MIRKO ($\text{IR}^{\text{L/L}} \cdot \text{Cre}^{\text{Mck}}$, muscle creatine kinase Cre driver) mice [213, 239]. Unexpectedly, hyperglycaemia and hyperinsulinaemia never develop in MIRKO mice, while they do develop mild obesity with elevated circulating free fatty acids and triglycerides. Moreover, deletion of the insulin receptor and type 1 IGF receptor in MIGIRKO mice ($\text{IR}^{\text{L/L}} \cdot \text{IGFIR}^{\text{L/L}} \cdot \text{Cre}^{\text{ACTA1}}$, human skeletal muscle actin Cre driver) leads to them displaying more than 60% less muscle mass while glucose and insulin tolerance remain normal, owing, at least in part, to increased basal glucose uptake [240]. Consistent with these results, MDKO ($\text{Irs1}^{\text{L/L}} \cdot \text{Irs2}^{\text{L/L}} \cdot \text{Cre}^{\text{Mck}}$) mice also fail to develop hyperglycaemia and glucose intolerance during progressive and fatal skeletal and cardiac muscle autophagy [207]. Akt phosphorylation is completely lost in MDKO mice, suggesting that insulin receptor/type 1 IGF receptor signalling is its major agonist [207]. Isolated

skeletal muscles from MDKO mice show elevated basal but absent insulin-stimulated glucose uptake, while glucose metabolism shifts to lactate production, which elevates the AMP/ATP ratio, activating AMP-activated protein kinase (AMPK). Activated AMPK can promote phosphorylation of AS160/TCB1D4 and TCB1D1 to increase translocation of GLUT4 to the cell surface, which increases glucose uptake during complete insulin resistance [207].

By contrast to the effect of complete muscle insulin resistance, muscle-specific deletion of GLUT4 dysregulates glucose homeostasis and promotes systemic insulin resistance [241]. MG4KO ($\text{Glut4}^{\text{L/L}} \cdot \text{Cre}^{\text{Mck}}$) mice develop hyperglycaemia, glucose intolerance, and insulin resistance by 8 weeks of age [242]. These mice also display dysregulated glucose metabolism in adipose and liver. Hyperglycaemia owing to diminished muscle glucose utilization appears to drive heterologous insulin resistance, because normalization of circulating glucose by kidney excretion can restore insulin action in adipose and liver [241, 243].

Adipose insulin signalling

Insulin signalling promotes adipogenesis, glucose influx, lipid synthesis, and anti-lipolysis in WAT [108, 109]. WAT is important for the storage of post-prandial glucose as triglyceride and the secretion of signalling factors that regulate appetite and energy homeostasis [5, 244]. WAT mainly expresses IRB without a detectable type 1 IGF receptor; however, both receptors play a role in adipogenesis from progenitor cells. Interpretation of the genetic deletion of adipose insulin receptor is complicated by the Cre-drivers used to generate the various experimental mice, including Cre^{aP2} (FIRKO mice; fatty acid binding protein 4 Cre driver) versus $\text{Cre}^{\text{Adipo}}$ (F-IRKO mice; adiponectin Cre driver) [245, 246]. FIRKO mice display variable recombination efficiency in fat depots with some off-target events, whereas F-IRKO mice have more efficient insulin receptor deletion across fat depots with few or no off-target effects [247]. With respect to these caveats, FIRKO mice display beneficial metabolic effects, including systemic insulin sensitivity, normal glucose tolerance, and less fat mass on ordinary chow diets [245]. FIRKO mice also have a longer lifespan, suggesting that leanness and insulin sensitivity are associated with longevity [248]. By contrast, F-IRKO mice display lipodystrophy with hepatomegaly, steatosis, and increased enzymes of *de novo* lipogenesis [246]. F-IRKO mice develop a full spectrum of non-alcoholic fatty liver disease that can progress to non-alcoholic steatohepatitis, fibrosis, and liver dysplasia, which is more in line with the expected effects of adipose insulin resistance [5]. These phenotypes are exacerbated on compound deletion of the insulin receptor and type 1 IGF receptor by $\text{Cre}^{\text{Adipo}}$, which promotes lipodystrophy of white and brown adipose tissue accompanied by diabetes, insulin resistance, increased β -cell mass, and ectopic lipid accumulation [247]. Thus, the insulin receptor appears to be essential for the formation and maintenance of WAT, whereas both insulin receptor and type 1 IGF receptor contribute to brown adipose tissue mass development and thermogenesis.

Insulin-regulated GLUT4-mediated glucose transport is rate limiting for glucose influx into white and brown adipose tissue under normal glucose and insulin concentrations. GLUT4 translocation to the plasma membrane is extremely sensitive to insulin in adipose, as submaximal activation of AKT2 can stimulate glucose transport. Before high-fat diet-induced insulin resistance inhibits AKT phosphorylation, GLUT4 translocation is strongly inhibited, suggesting that decreased glucose utilization might reside

downstream of proximal insulin receptor and AKT activity [5]. Increased adipose GLUT4 expression can rescue systemic insulin resistance of mice fed the high-fat diet [249].

Adipose triacylglycerol storage is regulated by circulating factors with opposing effects on lipolysis – including β -adrenergic receptors (β AR1/2/3) and insulin. Activation of β AR1/2/3 stimulates cAMP production to promote PKA-mediated phosphorylation of perilipin 1 (PLIN1), which releases abhydrolase domain containing 5, lysophosphatidic acid acyltransferase (ABHD5) to fully activate pataatin like phospholipase domain containing 2 (ATGL/PNPLA2), hydrolysing one fatty acid from triacylglycerol [250]. PKA also phosphorylates hormone-sensitive lipase (HLS) to promote its translocation to PLIN1 to hydrolyse fatty acids from diacylglycerol and produce monoacylglycerol [251]. Insulin inhibits lipolysis to promote fatty acid storage as triacylglycerol in adipose lipid droplets [251, 252]; however, the mechanism is only partly understood, as the deletion of AKT2 only partly impairs the ability of insulin to suppress lipolysis [204, 251]. Regulated lipolysis is critical as it controls the delivery of non-esterified fatty acids and glycerol to the liver, which stimulates hepatic glucose production [5, 109]. Insulin inhibits lipolysis by hydrolysing cAMP through an uncertain mechanism. Originally, AKT was thought to activate PDE3B by phosphorylation; however, the direct phosphorylation of PDE3B by AKT might not be required [204]. Instead, AKT phosphorylates α/β hydrolase domain-containing protein 15 (ABHD15), which binds and stabilizes PDE3B for the anti-lipolytic action of insulin [205, 206, 251].

IRS2 as a gateway to β -cell function

The capacity of pancreatic β cells to maintain glucose homeostasis during chronic physiological and immunological stress is important for cellular and metabolic homeostasis [253].

Pancreatic β cells have a special place in nutrient homeostasis as the unique source of insulin that also require insulin signalling for growth, function, and survival (Figure 9.8). Since β cells are always exposed to insulin and IGFs, the proximal signalling cascade appears to be regulated through multifactor transcriptional control of IRS2 – including FOXO1/3, NFAT, and CREB•CRT2 (Figure 9.8) [254]. In β cells, FOXO can account for as much as 80% of IRS2 expression [255]. Since the IRS2 → PI3K → AKT cascade phosphorylates and inhibits FOXO, insulin or IGF-I has inhibitory effects on FOXO-mediated transcription of IRS2. Since β -cell mass and function must be protected or expanded during chronic nutrient excess, other mechanisms, especially glucose-stimulated Ca^{2+} influx and cAMP production, promote IRS2 expression to avoid progressive β -cell failure (Figure 9.8). In addition to its immediate role in insulin secretion, glucose → Ca^{2+} release activates calcineurin, which dephosphorylates NFAT to facilitate its entry into the nucleus, where it induces expression of IRS2 and other genes (Figure 9.8) [256]. Glucose, glucagon-like peptide 1 (GLP-1), and other G-protein-coupled receptor (GPCR) agonists also increase cAMP in β cells, which has many important effects, including the activation of CREB•CRT2 that promotes IRS2 transcription [257, 258]. Through this mechanism, the role of insulin or IGF-I to regulate signalling in β cells is replaced by indirect control through glucose, incretins, or neuronal signals, the physiologically relevant regulators of pancreatic β -cell function (Figure 9.8). IRS2 expression through these mechanisms maintains PDX1 action, which is essential for β -cell growth, function, and survival [259]. Compounds that augment IRS2 expression might provide treatments for β -cell failure during insulin resistance and the progression of type 2 diabetes [253].

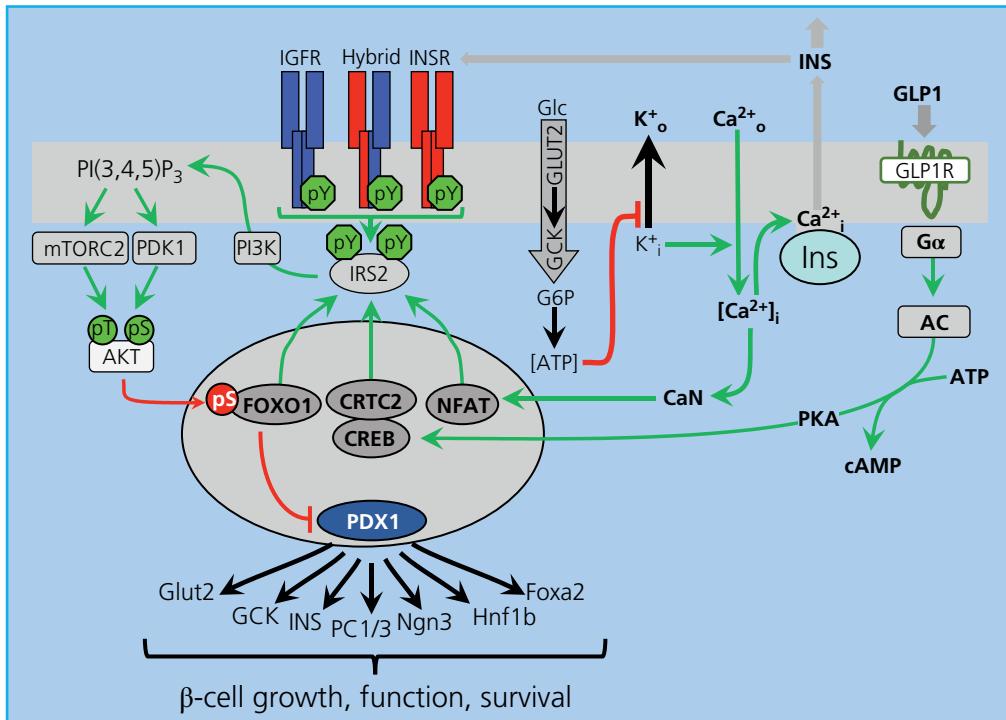

Figure 9.8 The integrative role of IRS2 signalling in pancreatic β -cell function. The diagram shows the relation between the IRS2 branch of the insulin signalling pathway and upstream and downstream mechanisms regulating β -cell growth and function. Since the insulin receptor and type 1 IGF receptor are constitutively active in β cells, activation of GLP1 → cAMP → PKA → CREB, glucose → Ca^{2+} → CRTC2, and calcineurin → NFAT induces IRS2 expression to stimulate the PI3K → AKT cascade, which places β -cell growth, function, and survival under the control of glucose and natural or synthetic incretins.

Central Control of Glucose Homeostasis

Kimberly M. Alonge, Kendra L. Francis, Nicole E. Richardson, and Michael W. Schwartz

UW Medicine Diabetes Institute, Department of Medicine, University of Washington, Seattle, WA, USA

Key points

- Working in cooperation with pancreatic islets, the brain helps to establish the biologically defended level of glycaemia (BDL_G) by influencing both insulin-dependent and -independent glucose disposal.
- Whereas insulin-dependent mechanisms predominate in the post-prandial state, control of the basal glucose level depends largely on insulin-independent glucose disposal. The brain can potently influence both processes.
- Type 2 diabetes pathogenesis involves β -cell dysfunction leading to impaired insulin secretion, in concert with reductions of both insulin sensitivity (usually associated with obesity) and insulin-independent glucose disposal. These defects combine to raise the BDL_G out of the normal range.
- In both humans and animal models, obesity and type 2 diabetes are associated with pathology affecting the mediobasal hypothalamus, a key brain area for glucose homeostasis. One example of this pathology is the activation of mediobasal hypothalamus glial cells, referred to as *reactive gliosis*.
- In pre-clinical diabetes models, therapeutic interventions targeting the hypothalamus are capable of restoring the BDL_G to the normal range.
- Investigation into the therapeutic potential of targeting glucoregulatory neurocircuits to induce sustained diabetes remission in humans is a research priority.

Among many biological variables that are maintained within narrow physiological limits in healthy individuals is the circulating glucose level, and this regulation is achieved through a set of highly coordinated responses that are engaged when the blood glucose level deviates from its biologically defended range. In this chapter we focus on mechanisms underlying the *biologically defended level* of glycaemia (BDL_G), including the roles played by the brain, pancreatic islets, liver, and other tissues, and on how dysfunction of this control system results in type 2 diabetes and related disorders of glucose metabolism. Like other homeostatically defended variables (e.g. body fat mass, blood glucose, body temperature, blood pressure), the BDL_G is established by a highly integrative feedback control system that balances the sum total of all relevant inputs and outputs that influence glucose appearance and removal. Growing evidence places cooperation between brain and pancreatic islets at the centre of this regulatory process, and suggests that dysfunction of either can contribute to the pathogenesis of type 2 diabetes.

other homeostatic control systems, the brain plays a key role in glucose homeostasis. Given the brain's reliance on glucose as its main fuel source, it makes teleological sense for the brain to have evolved mechanisms that ensure a continuous supply of glucose.

Although underappreciated until recently, this view is consistent with evidence that brain control of glucose homeostasis emerged early in the course of evolution. This evidence is based in part on studies in the fruit fly *Drosophila melanogaster* demonstrating that both the systemic glucose level (in haemolymph) and glucose-induced secretion of *Drosophila* insulin-like peptides (DILPs) (the insulin homologue in flies) are governed by a single pair of glucose-sensing neurons (Figure 10.1) [2]. Silencing of these neurons causes insulin secretion to decrease and systemic glucose levels to rise, even though the insulin-secreting cells themselves are not directly impacted [2]. Such findings suggest the following:

- These glucose-sensing neurons are essential for normal glucose homeostasis in flies.
- Glucose sensing developed in neurons before being co-opted by pancreatic β cells in the control of insulin secretion in mammals.
- Glucose homeostasis over the course of evolution originated as a process governed by the brain, with insulin secretion lying downstream of brain glucose sensing.

Although glucose homeostasis in mammalian systems is far more complex, many lines of evidence suggest that elements of the *Drosophila* model have been retained over the course of mammalian evolution (Figure 10.1).

Evolutionary considerations

In 1849, Claude Bernard, a French physiologist and professor of medicine at the Collège de France, introduced the idea of a multiorgan *milieu interne* in the control of complex homeostatic systems [1]. Bernard was also the first to hypothesize that, like most

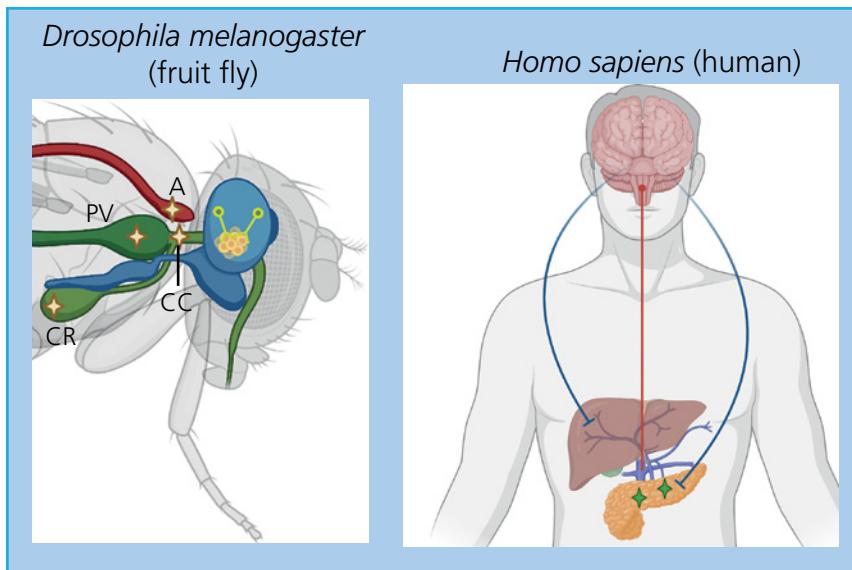

Figure 10.1 Evolution of brain glucose sensing. The brain of the fruit fly *Drosophila melanogaster* contains a pair of glucose-sensing neurons (light green) that, upon stimulation by glucose, promote secretion of insulin-like peptide-2 (DILP-2; yellow star) from insulin-producing cells (IPCs; yellow) into peripheral tissues (corpora cardiaca [CC], aorta [A], PV [proventriculus], and crop [CR]) to promote glucose lowering. Although the system is more complex and less well understood, the human brain is hypothesized to receive afferent information regarding the circulating glucose level via a distributed system that includes neurons

(and perhaps glial cell types) located in circumventricular organs of the brain (such as the hypothalamic median eminence) as well as glucose-sensing neurons supplying peripheral blood vessels (e.g. portal vein, red line). In response to this afferent input, glucoregulatory neurocircuits influence glucose homeostasis via autonomic output (blue lines) to multiple tissues, including liver (to control hepatic glucose production and uptake) and pancreas (to control secretion of insulin and glucagon [green star]). Overview of brain control of glucose homeostasis in normal physiology

Following a meal, ingested glucose and other nutrients enter the circulation from the gastrointestinal tract, eliciting a multitude of responses that both increase glucose disposal and inhibit endogenous glucose production to minimize the resultant blood glucose excursion. Insulin is a key mediator of these responses, promoting glucose disposal into muscle, fat, and other insulin-sensitive tissues, while simultaneously restraining endogenous glucose production by the liver. Meal-induced insulin secretion is stimulated by (i) rising plasma levels of glucose and other nutrients; (ii) release of incretin peptides, such as glucagon-like peptide 1 (GLP-1), from the gastrointestinal tract; and (iii) adjustments of autonomic tone to pancreatic islets. In addition to coordinating the timing and magnitude of the insulin secretory response [3], the brain can also activate insulin-independent mechanisms that lower blood glucose levels, including both suppression of endogenous glucose production and increase in hepatic glucose uptake (Figure 10.2) [4]. These dynamic interactions illustrate how cooperation between brain, pancreas, liver, and other tissues limits plasma glucose excursion in the post-prandial state. Equally important to glucose homeostasis is maintenance of stable glycaemia in the basal state (i.e. in the absence of ingested nutrients). Unlike the response to a meal, however, insulin-independent mechanisms predominate in the control of glucose disposal in the basal state (i.e. in the absence of nutrient entry from the gastrointestinal tract).

Autonomic control of pancreatic islet function

Brain-islet connections involving both the sympathetic nervous system (SNS) and parasympathetic nervous system (PNS)

(Figure 10.2) [5] can rapidly influence both insulin and glucagon secretion in response to changes in the level of circulating nutrients and other stimuli under physiological conditions [6].

Recent 3D imaging of cleared human pancreatic islets shows dense innervation by both SNS and PNS fibres [7] and, whereas insulin secretion during a meal is augmented by an associated increase of PNS outflow [3], glucagon secretion during hypoglycaemia is enhanced by both PNS and SNS outflow to the islet (Figure 10.2) [8]. The liver is also richly supplied with SNS fibres, activation of which stimulates hepatic glucose production, thereby helping to restore normoglycaemia; these fibres are also activated in response to hypoglycaemia [9]. This increased hepatic glucose production is facilitated by increased SNS outflow to pancreatic islets, which potently inhibits insulin secretion in addition to enhancing glucagon release.

The brain also participates in control of islet function under more physiological conditions. For example, the *cephalic phase* of insulin release involves insulin secretion induced by increased PNS outflow to the pancreas that is triggered by feeding cues *before* feeding begins and blood glucose levels begin to rise (Figure 10.2) [10]. This response is mediated primarily by vagal cholinergic signals, is malleable to changing environmental stimuli, and is a large contributor to whole-body glucose tolerance following a meal [11]. Complementing this response is augmented post-prandial insulin secretion resulting from a meal-induced increase of PNS tone.

Autonomic mechanisms also control post-prandial glucagon secretion [12], with local glucagon release in the islet enhancing the responsiveness of insulin-secreting β cells to glucose [13]. These islet responses are likely coordinated by specific glucoregulatory neuronal populations within the hindbrain, midbrain, and hypothalamus that project via multisynaptic relays into the

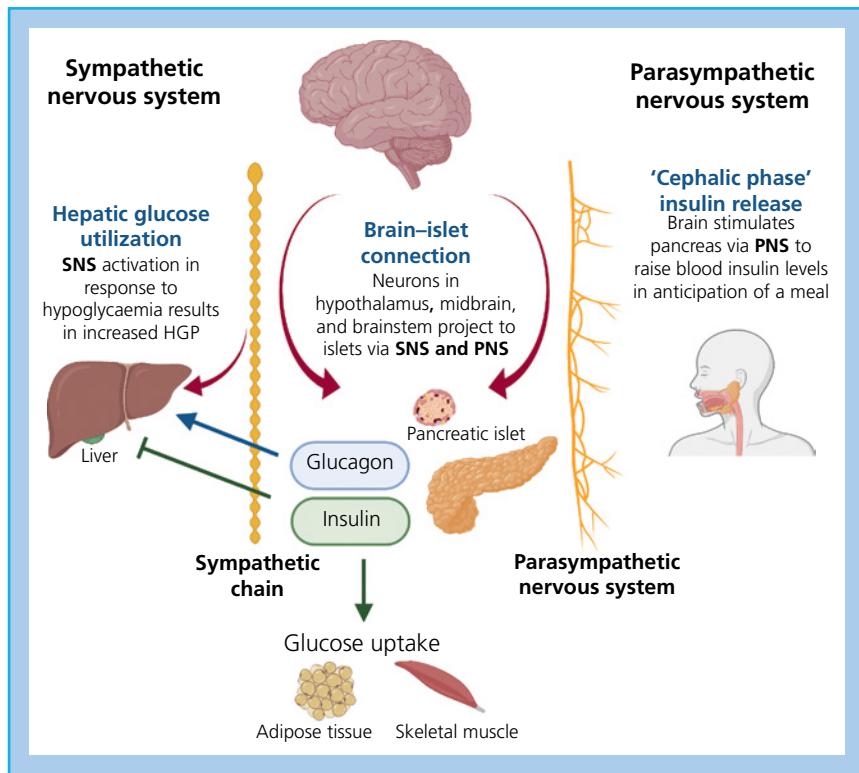

Figure 10.2 Autonomic control of glucose homeostasis. Pancreatic islets receive autonomic input originating with neurons in the hypothalamus, midbrain, and brainstem nuclei that in turn regulate the parasympathetic (PNS) and sympathetic (SNS) nervous system outflow. Glucagon secretion is increased by activation of either PNS or SNS, whereas insulin secretion is stimulated by the former and inhibited by the latter. Sympathetic fibres supplying the liver also affect both hepatic glucose

production (HGP) and uptake. In response to hypoglycaemia, therefore, activation of SNS outflow to the liver and pancreas increases both glucagon secretion and HGP, whereas insulin secretion is inhibited. Conversely, insulin release in response to both food consumption and the mere anticipation of a meal is stimulated by activation of PNS supply to pancreatic islets. Source: Figure generated using <http://Biorender.com>.

pancreas [14–17]. Experimental impairment of neuronal glucose sensing within the mediobasal hypothalamus produces distinct effects on glucose homeostasis through these brain–islet multisynaptic relays [14], which further implicates autonomic input to the islet in its response to both feeding and hypoglycaemia. Although the liver is a major target for the actions of both insulin and glucagon (which suppress and increase hepatic glucose output, respectively), the brain also regulates glucose handling by the liver not only during hypoglycaemia [9], but in response to sustained hyperglycaemia as well. Specifically, both human and rodent studies suggest that intact brain K_{ATP} channel activity is required for the effect of clamped hyperglycaemia to suppress hepatic glucose production [4].

Circadian control of metabolism

The suprachiasmatic nucleus (referred to as the *master circadian pacemaker*) contains neurons whose activity is governed by a system of *clock genes* that is entrained to the light–dark cycle to turn on and off in a circadian manner. This repeating pattern of suprachiasmatic nucleus neuron activation in turn aligns many behaviours and metabolic functions to the circadian clock. For example, hepatic insulin sensitivity (i.e. responsiveness to insulin-mediated suppression of hepatic glucose output) decreases during sleep and increases on waking, in anticipation of the onset of feeding [18, 19], and a specific subset of neurons producing γ-aminobutyric acid (GABA) in the suprachiasmatic nucleus whose rhythmic firing underlies circadian variation in hepatic insulin sensitivity was recently identified [20]. Since normal glucose tolerance depends on proper coupling of

insulin secretion to insulin sensitivity, and since mechanisms underlying this coupling remain to be established, it will be interesting to determine if the brain also governs adaptive β-cell response to daily variation in insulin sensitivity. Such a finding would extend previous work linking the brain to adaptive changes of both insulin secretion and insulin sensitivity during cold exposure (discussed later).

How does the brain sense physiological changes in blood glucose?

Although it makes teleological sense for the brain to sense circulating glucose levels (analogous to the recently discovered *Drosophila* glucose-sensing neuron pair, Figure 10.1), precisely how this process occurs remains uncertain. The balance of available literature points to a distributed network of neurons that convey afferent information to the brain regarding both glucose availability and need. Although this brain glucose sensing process can, in theory, involve *glucose-responsive* neurons (or glia) in brain parenchyma [21–24], many of these neurons are exposed only to glucose levels in brain interstitial fluid and not to levels in the circulation. Reliance on glucose sensing by cells exposed only to brain interstitial fluid is unlikely to explain all the effects observed *in vivo*, given that the glucose level in brain interstitial fluid is much lower than in plasma, and that following a change in the plasma level, changes in brain interstitial fluid occur relatively slowly. For these reasons, information regarding the blood glucose level is likely communicated to the brain via a distributed system of neurons (and perhaps glial cells) that are anatomically well placed to sense the circulating glucose level. These include neurons

located in the vasculature (including the hepatic portal vein, where they are well placed to detect glucose absorbed from the gastrointestinal tract), the gastrointestinal tract itself, and brain areas known as circumventricular organs that are characterized by an incompletely developed blood–brain barrier. Particularly relevant among the latter are the median eminence of the hypothalamus and area postrema of the hindbrain; neurons in these brain areas that are exposed to the circulation may provide the brain with the real-time afferent information needed to mount adaptive responses important for normal glucose homeostasis [25–28].

What, then, might be the primary role in whole-body glucose homeostasis played by cells that sense glucose locally in brain interstitial fluid? While the answer is unknown, many of these parenchymal cells are located within glucoregulatory neurocircuits downstream of peripheral glucose sensors that respond to changes of glycaemia, in addition to detecting changes in brain interstitial fluid glucose levels directly. It is possible, for example, that brain interstitial fluid glucose levels offer a baseline against which afferent information relevant to the circulating level conveyed from peripheral sources can be compared. Additional study is required to clarify the roles of direct and indirect brain glucose-sensing mechanisms in glucose homeostasis; both may in fact contribute, as these possibilities are not mutually exclusive.

Glucose sensing and brain control of energy balance

In addition to multiple hypothalamic nuclei, the bed nucleus of the stria terminalis in the forebrain, and the dorsal vagal complex (comprising the dorsal motor nucleus of the vagus nerve, area postrema, and nucleus of the solitary tract) of the hindbrain are implicated in central regulation of glucose homeostasis [29,30]. Within the hypothalamus, glucose-sensing neurons with intrinsic glucose-responsive characteristics are concentrated in ventromedial, arcuate, and paraventricular nuclei, as well as the lateral hypothalamic area and dorsomedial hypothalamic nucleus (Figure 10.3) [31]. Glucose-responsive neurons can be broadly classified as either glucose excited (analogous to pancreatic

β cells) or glucose inhibited [32], and are capable of responding to changes in glucose concentrations (e.g. 1–5 mmol/l) that associate with daily fluctuations in brain interstitial fluid glucose homeostasis [33]. What is less clear is the extent to which the activity of these neurons is regulated by physiological variation in brain interstitial fluid glucose. An alternative possibility is that these intrinsic glucose-sensing properties serve as a marker of neurons involved in glucoregulatory neurocircuits, in the same way that many hypothalamic neurons involved in thermoregulation are marked by intrinsic thermosensory properties [34], even though they do not participate in temperature sensing under physiological conditions. Additional studies are warranted to sort through these possibilities.

Many defined neuronal subtypes involved in energy and glucose homeostasis have these glucose-sensing properties. The melanocortin system, for example, comprises two arcuate neuronal subsets – proopiomelanocortin (POMC) and agouti-related protein (AGRP) neurons – that mediate opposing effects on downstream neuronal targets that express the melanocortin 4 receptor (MC4R) (Figure 10.3) [35]. Thus, whereas POMC neuron activation induces synaptic release of α -melanocyte-stimulating hormone (α MSH), an MC4R agonist, AGRP is an inverse agonist of MC4R that reduces signalling by this receptor. AGRP neurons also regulate feeding behaviour via release of both neuropeptide Y (NPY) and GABA. AGRP and POMC neurons project to a variety of hypothalamic and extrahypothalamic neurons that express MC4Rs; in the paraventricular nucleus, increased melanocortin signalling reduces food intake while reduced melanocortin signalling (resulting from reduced POMC neuron activity, increased AGRP neuron activity, or both) has the opposite effect [36].

Among many observations that establish the key role played by melanocortin signalling in energy and glucose homeostasis is the phenotype induced by genetically impaired melanocortin signalling. Mutations of MC4R, for example, are among the commonest causes of monogenic obesity in humans [37], and variation at the MC4R gene locus associates with human type 2 diabetes in genome-wide association studies [38]. These phenotypes offer direct evidence of the requirement for intact melanocortin signalling for normal energy and glucose homeostasis.

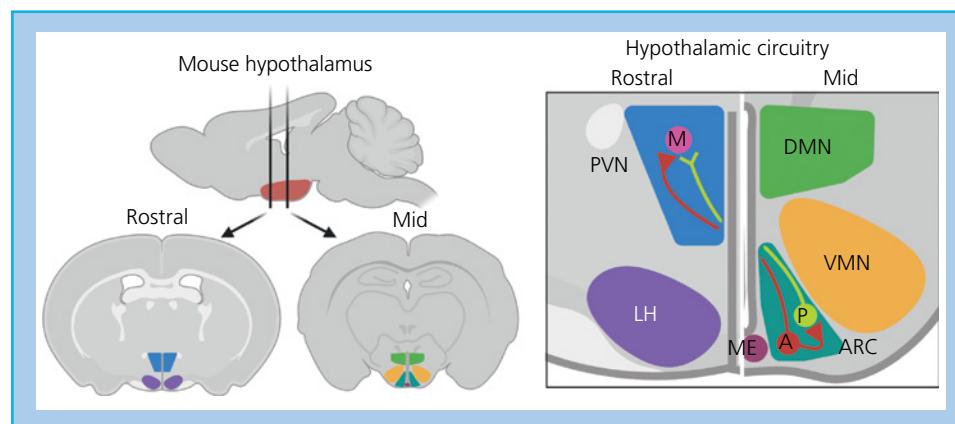

Figure 10.3 Hypothalamic glucoregulatory neurocircuitry implicated in blood glucose control by the brain. Neurons situated in subnuclei spanning the rostral (PVN, paraventricular nucleus; LH, lateral hypothalamic area) and medial (DMN, dorsomedial hypothalamic nucleus; VMN, ventromedial nucleus; ARC, arcuate nucleus; ME, median eminence) hypothalamus are implicated in central control of glucose homeostasis. Melanocortin 4 receptor signalling (M) in neurons in the PVN and elsewhere is stimulated by the agonist α -MSH released by proopiomelanocortin

(P, light green) neurons, and inhibited by the inverse agonist agouti-related peptide (A) released by AGRP neurons (A, red) located in the medial ARC region of the mediobasal hypothalamus. AGRP neurons also synapse onto and inhibit proopiomelanocortin (POMC) neurons, and both POMC and AGRP neurons project into the ME, which lacks a fully formed blood–brain barrier, thus allowing subsets of these neurons to sense the circulating glucose level. Source: Figure generated using <http://Biorender.com>.

Importantly, melanocortin signalling is highly responsive to nutritional state owing to coordinated, reciprocal regulation of AGRP and POMC neuron activity by afferent input from leptin and other relevant humoral signals. In response to fasting or other conditions associated with depletion of body fuel stores, for example, AGRP neurons are activated whereas POMC neurons are inhibited, a combination that potently reduces melanocortin signalling and promotes increased food intake, reduced energy expenditure, and recovery of lost weight [39]. These reciprocal neuronal responses are elicited by the effect of fuel depletion to lower circulating levels of leptin, insulin, and glucose, and to increase secretion of the gastric hormone ghrelin [39]. Although some POMC and AGRP neurons qualify as either glucose excited or inhibited [40], the extent to which these intrinsic glucose-sensing properties drive *in vivo* responses is unclear.

Another hypothalamic area involved in glucose energy homeostasis is the ventromedial nucleus. Subsets of these neurons constitute a key node in the circuit responsible for mounting counter-regulatory responses to hypoglycaemia. Unexpectedly, a specific subset of these neurons is also implicated in the pathogenesis of hyperglycaemia in diabetic mice. Many ventromedial nucleus neurons are also glucose responsive [40], but once again, the extent to which the activity of these neurons is determined by intrinsic glucose sensing *in vivo* (as opposed to afferent input from other neurons in a circuit) awaits further study.

In addition to neurons, many glial cell types are implicated in brain regulation of glucose homeostasis (Figure 10.4). Astrocytes are the commonest glial cell type in the brain, and direct connections (via gap junctions) exist between these cells and both neurons and other glial cells [41]. Interestingly, gap junction subunits (connexins 30 and 43) expressed by hypothalamic astrocytes appear to be critical for brain glucose sensing and control of insulin secretion during a glucose challenge [42]. This may reflect the fact that astrocytes are essential components of the blood–brain barrier, and are implicated in glucose transport into the brain (via glucose transporter 1 (GLUT1) and possibly GLUT2) [43]. Glucose taken up into astrocytes can be metabolized into lactate, which can then be released as a source of fuel for neurons in a process known as the astrocyte–neuron lactate shuttle (Box 10.1) [41,44]. Additionally, astrocytes express insulin receptors, deletion of which reduces the responsiveness of POMC neurons to elevated glucose levels [45].

Tanycytes are another glial cell type implicated in central nervous system (CNS) glucose sensing (Figure 10.4). Tanycyte cell bodies line the surface of the third cerebral ventricle, and from there they extend filamentous processes deep into medial hypothalamic structures including the arcuate, ventromedial, and dorsomedial nuclei and median eminence. One proposed role for these cells is to sense and/or transport glucose from the cerebrospinal fluid to these parenchymal areas [31,46], but the extent to which tanycytes participate in this type of glucose sensing is unclear. One group found that treatment with alloxan to ablate tanycyte glucose sensing strongly interfered with both counter-regulatory responses to hyperglycaemia and responses to hypoglycaemia [47], while another group reported that conditional tanycyte ablation predisposes to obesity and elevated fat mass, but with little effect on glycaemia [48].

Another noteworthy aspect of hypothalamic glial cells in relation to metabolic diseases pertains to their response to consumption of an obesogenic diet [49]. Rodent studies demonstrate that following the switch to a high-fat diet, *reactive gliosis* (characterized by inflammatory activation of both astrocytes and microglia) occurs

Box 10.1 Astrocyte–neuron glucose lactate shuttle hypothesis

Glucose transported across the blood–brain barrier by astrocytes is metabolized into lactate, which in turn is made available to neurons and is hypothesized to serve as both a fuel source for neurons and a mechanism for sensing the peripheral glucose levels [41,44,78]. Evidence in favour of the latter theory is as follows:

- Glucose-excited neurons in the hypothalamus are activated by lactate as well as glucose [79].
- These neurons express monocarboxylate transporters (MCTs), which facilitate lactate transport [80].
- Neuronal lactate sensing is implicated in peripheral lipid metabolism [81] and experimental induction of lactate dehydrogenase (responsible for metabolizing glucose to lactate) in the hypothalamus is sufficient to lower blood glucose in obese rodents [82].

However, the extent to which brain neurons depend on lactate vs. glucose as a fuel is uncertain. Inhibition of glucokinase (a key rate-limiting step for glucose oxidation in these neurons) lowers activity of glucose-excited and increases activity of glucose-inhibited neurons [83,84] implying that they are sensing glucose, rather than lactate. Additional research into the role of astrocyte lactate production in brain glucose sensing is a priority.

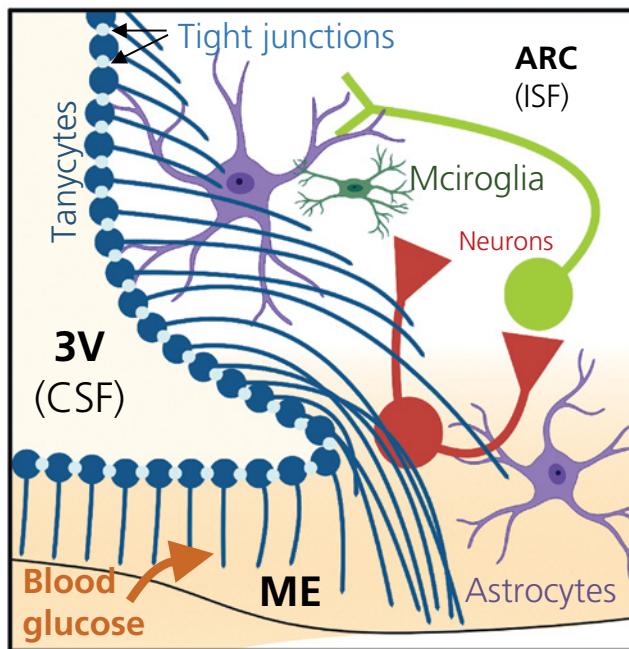

Figure 10.4 Glucose-sensing cells in the mediobasal hypothalamus. The median eminence (ME) is a circumventricular organ situated at the floor of the mediobasal hypothalamus (MBH) that lacks a fully formed blood–brain barrier. Since the ME is bordered dorsally by the third cerebral ventricle (3V), neurons and glial cell types in this brain area and adjacent arcuate nucleus (ARC) have access to glucose in the bloodstream, in cerebrospinal fluid (CSF) and in brain interstitial fluid (ISF). Cell types capable of sensing glucose include neurons (red and green), astrocytes (purple), and tanycytes (blue). Obesity-associated hypothalamic gliosis is characterized by inflammatory activation of astrocytes (purple) and microglia (green) and is hypothesized to impair both energy and glucose homeostasis, potentially by adversely affecting glucose sensing by cells in this brain area. Source: Figure generated using <http://Biorender.com>.

rapidly (within days) in the mediobasal hypothalamus, and that weight gain induced by this diet is limited when this activation response is blocked [50,51]. Thus, reactive gliosis appears to be required for the full expression of diet-induced obesity in mice. This pathological response is also present in humans with obesity and associates with insulin resistance, even after adjustment for differences of body weight [52]. Microglial mitochondrial dynamics are reportedly involved in this gliosis response; in mice with diet-induced obesity [53], abnormal POMC neuron responses to hyperglycaemia depend on these microglial changes. Establishing the contribution made by reactive mediobasal hypothalamus gliosis to the pathogenesis of human obesity and type 2 diabetes is an important scientific priority.

Glucose transporters and brain glucose uptake

Members of the GLUT family vary widely with respect to affinity for glucose, transport capacity, tissue distribution, and physiological function. There are 14 known GLUT family members, with one or more being expressed in almost every cell type to facilitate cellular glucose uptake [54]. Table 10.1 summarizes the characteristics of the different GLUT family members.

GLUT1 is a high-affinity, low-capacity glucose transporter, which means that its glucose transport capacity is saturated at concentrations below those usually maintained in the circulation. Consequently, a rise in the plasma glucose level is not typically associated with a proportionate increase in cellular glucose uptake via this transporter. GLUT1 is widely expressed throughout the body, including by endothelial cells and astrocyte processes that form the blood–brain barrier, and is a major transporter for delivery of glucose into the brain [55]. GLUT1 expression in the blood–brain barrier is upregulated under conditions such as hypoxia and hypoglycaemia where neuronal adenosine triphosphate (ATP) generation is compromised as a means to enhance glucose transfer into the brain [56]. Such findings are consistent with glucose transport across the blood–brain barrier by GLUT1 constituting the rate-limiting step in brain glucose delivery [54]. Interestingly, obesity is associated with reduced blood–brain barrier expression of GLUT1 in mice [70]; the finding that hyperglycaemia is associated with reduced brain glucose uptake in people with type 2 diabetes also suggests that similar changes occur in the blood–brain barrier of humans with metabolic dysfunction.

GLUT2 is expressed uniquely by cell types specialized for cellular glucose sensing, both in the brain (including glucose-responsive neurons, astrocytes, and tanycytes [71–73]) and in the

periphery (pancreatic β cells, intestinal epithelial cells, hepatocytes, and kidney cells) [74]. GLUT2 has a much higher K_m for glucose (17 mM) than other glucose transporters, enabling the rate of cellular glucose transport to vary across the full range of extracellular glucose levels [58]. Consequently, this transporter enables changing circulating glucose levels to elicit a proportionate change in cellular uptake. Most cells that express GLUT2 also express glucokinase, an enzyme that, owing to its similarly high K_m for glucose (compared to other hexokinase isoforms), enables the rate of glucose phosphorylation to vary with the extracellular glucose level in glucose-sensing cells. While GLUT2 levels in the periphery increase during acutely elevated glycaemia, some insulin-resistant conditions are associated with reduced hypothalamic GLUT2 expression [75]. Furthermore, GLUT2 is implicated in the brain's ability to mount counter-regulatory responses to hypoglycaemia [76].

GLUT3 is the predominant GLUT subtype expressed by neurons and is characterized by a lower K_m than other neuronal GLUTs [62], thus enabling efficient neuronal glucose transport from brain interstitial fluid where glucose concentrations are much lower than in the bloodstream [63]. By comparison, GLUT4 is expressed in so-called *insulin-sensitive* tissues (tissues in which insulin binding to its receptor induces glucose uptake, including adipocytes, cardiomyocytes, and skeletal muscle [77]). Translocation of GLUT4 from the cytosol to the plasma membrane in response to insulin is responsible for insulin-stimulated glucose uptake and associated insulin-mediated glucose clearance from the bloodstream. This mechanism plays a key role in promoting glucose disposal following a meal (e.g. when glucose and insulin levels are elevated). In the brain, GLUT4 is expressed in distinct populations, including by forebrain cholinergic neurons that also express GLUT3 [64], but the extent to which this GLUT4 is truly insulin responsive and mediates glucose uptake in these neurons awaits further study.

GLUT8 has a low K_m for glucose, and its role in cellular glucose uptake remains uncertain, since glucose competes with fructose and galactose for transport via this transporter subtype [67]. In the brain, GLUT8 is expressed by neurons of the hypothalamus, cerebellum, brainstem, and hippocampus, where it is located in proximal and distal dendrites [68]. Like GLUT4, this transporter resides primarily in the cytosol and is hypothesized to be translocated to the cell surface in response to stimuli that remain to be identified. The extent to which GLUT8 transports other substrates preferentially over glucose also remains to be determined [69].

Table 10.1 The glucose transporter family.

Glucose transporter	Central cell types	K_m for glucose	Description	References
GLUT1	Endothelial blood–brain barrier, astrocytes	1–2 mM	Implicated as <i>rate limiting</i> for glucose transport across the blood–brain barrier	[55–57]
GLUT2	Glucose-sensing neurons, astrocytes, tanycytes	15–20 mM	High-capacity, low-affinity glucose transporter implicated in cellular glucose sensing	[58–61]
GLUT3	Most neurons	1–2 mM	Lower K_m compared to other GLUTs, implicated as primary neuronal glucose transporter	[59,62,63]
GLUT4	Mostly peripheral, a subset of cholinergic neurons in the forebrain	5 mM	Insulin-responsive glucose transporter implicated in insulin-mediated glucose disposal	[57, 58, 64–66]
GLUT8	Neurons of hypothalamus, cerebellum, brainstem, hippocampus	2 mM	Hypothesized to function similarly to GLUT4 in response to an as yet unidentified signal	[67–69]

Evidence supporting indirect blood glucose sensing by the brain

A defining feature of a homeostatic control system is that it not only accurately interprets the current state of the biological system, but also utilizes past experiences to condition the system to preemptively respond to and effectively counteract anticipated regulatory challenges [85]. Such an arrangement allows for the control system to engage in a corrective response at even the slightest perturbation of homeostasis, prior to a detectable change in the defended biological measure, thus enabling the biological variable to remain within its homeostatic range.

Parallels to brain control of thermoregulation

Brain control of thermoregulation offers a useful paradigm for understanding control of glucose homeostasis by the CNS. To ensure the stability of core body temperature, changes in ambient temperature are continuously relayed from afferent thermosensory fibres supplying the skin. These neurons project to the spinal cord, where they synapse onto ascending sensory neurons that ultimately supply neurons in the hypothalamic preoptic area (Figure 10.5) [86]. Preoptic area neurons in turn transduce this thermosensory input into adaptive responses that govern both heat production and

dissipation (e.g. activation of brown adipose tissue, shivering, cutaneous vasoconstriction) so as to preserve the constancy of the brain's temperature [87].

Homeostasis of body temperature is therefore achieved via a multiorgan process that enables the brain to anticipate the need for adaptive responses before internal body temperature even begins to change. This degree of control would not be possible if the system relied on direct temperature sensing by neurons in the brain (rather than cutaneous sensory innervation), since the brain's temperature would have to change before a homeostatic response would be engaged. Yet many key neurons in the medial preoptic area of the mediobasal hypothalamus that coordinate these responses have intrinsic temperature-sensing properties, analogous to the glucose-sensing properties of neurons involved in brain regulation of glucose homeostasis (Figure 10.5).

Taking this analogy a step further, both 'warm-sensitive' and 'cold-sensitive' neurons have been identified in the hypothalamic preoptic area, just as both 'glucose-excited' and 'glucose-inhibited' neurons populate hypothalamic nuclei involved in glucose homeostasis. Similarly, direct activation of temperature-sensing neurons can powerfully impact thermoregulation, and direct activation of glucose-sensing neurons can powerfully impact glucose homeostasis. Yet under physiological conditions, thermoregulation does not involve changes in brain temperature; instead, this intrinsic

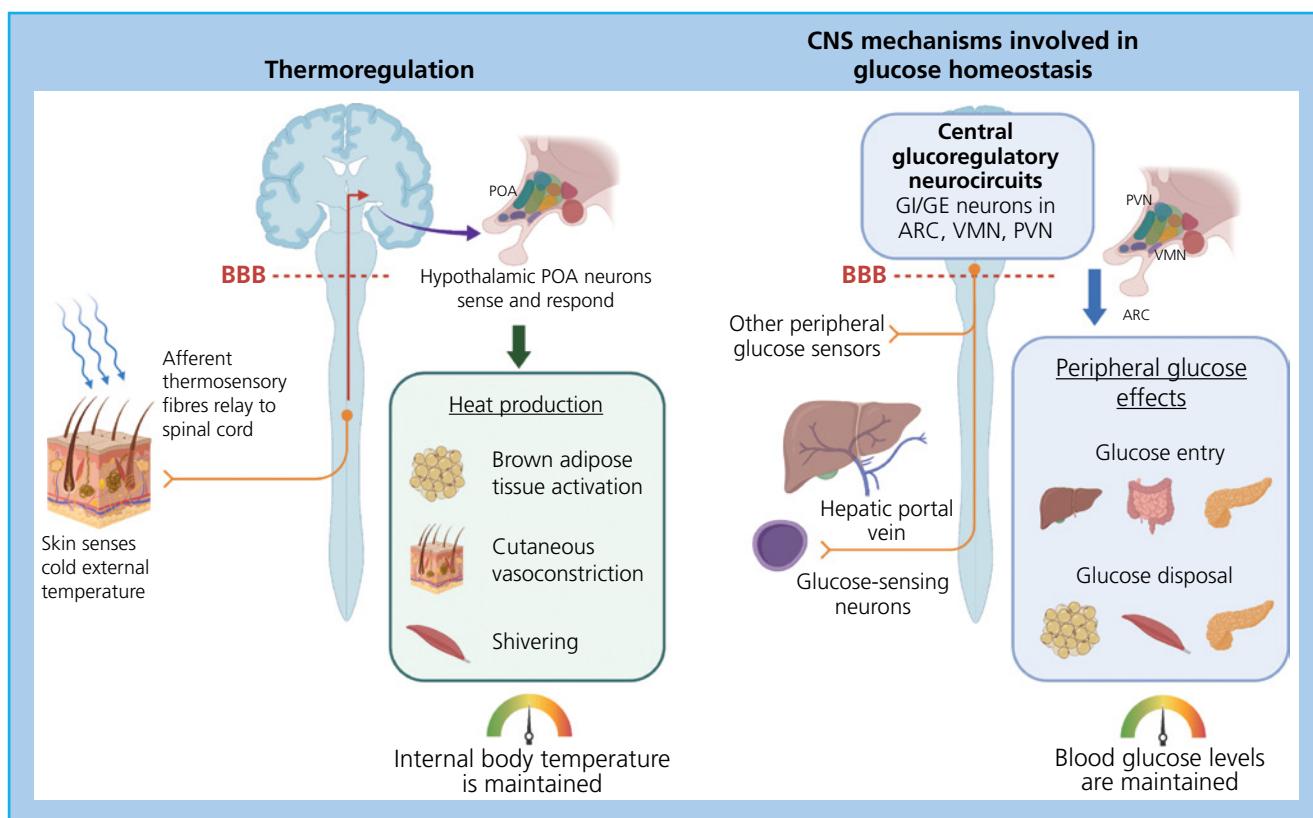

Figure 10.5 Comparison of central thermoregulatory and glucoregulatory systems. The thermoregulatory system senses changes in external temperature via afferent thermosensory fibres supplying the skin, and conveys this information via a multisynaptic pathway to the hypothalamic preoptic area (POA). In this brain area, relevant afferent input is transduced into adaptive changes in heat production and dissipation that effectively maintain internal body temperature within a narrow range. Brain control of whole-body glucose homeostasis is hypothesized to employ an analogous system whereby afferent input regarding the circulating glucose level

is conveyed to glucoregulatory neurocircuits in the hypothalamus and elsewhere by glucose-sensing neurons situated both in circumventricular areas of the brain that lack a fully formed blood-brain barrier and in peripheral vasculature (e.g. hepatic portal vein). In partnership with pancreatic islets, centrally driven changes in peripheral glucose production and utilization promote stability of the circulating glucose level. ARC, arcuate nucleus; BBB, blood-brain barrier; CNS, central nervous system; GE, glucose excited; GI, glucose inhibited; PVN, paraventricular nucleus; VMN, ventromedial nucleus. temperature-sensing capacity may provide a ‘back-up’ or ‘fail-safe’ mechanism that becomes important only when brain temperature deviates from its physiological range (owing to extreme environmental exposure or failure of ‘first-line’ physiological defences). By analogy, direct sensing of glucose by neurons in the brain may be relevant primarily under pathological conditions, with input relevant to physiological control being provided primarily by afferent glucose-sensing neurons innervating the vasculature itself. From this perspective, the capacity to maintain brain glucose levels within a narrow physiological range, even in the face of wildly fluctuating variation in plasma glucose levels [88–90], seems likely to involve afferent input regarding the blood glucose level provided to the brain from the periphery (Figure 10.5).

In support of this type of mechanism, glucose-sensing neurons supply the hepatic portal vein [91] and sense ingested glucose as it enters the circulation from the gastrointestinal tract, prior to entry into systemic circulation. An increase of glucose levels in the hepatic portal vein relative to the systemic circulation constitutes a *portal signal* that is detected by these neurons and implicated as a trigger driving the marked increase of hepatic glucose uptake elicited by a meal. Although the underlying mechanisms have yet to be fully elucidated, this response appears to be mediated via reduced SNS outflow to the liver, which in turn activates liver glucokinase, the rate-limiting enzyme for glucose uptake into hepatocytes [92]. Defects in this response are seen in a canine model of diet-induced obesity [93, 94], and support the hypothesis that reduced hepatic glucose uptake secondary to increased SNS outflow to the liver contributes to glucose intolerance in this setting.

Integration of glucose homeostasis, energy homeostasis, and thermoregulation

In temperate regions, mammals are routinely exposed to ambient temperatures sufficiently low to pose a substantial homeostatic challenge. As the environmental temperature drops, the increase of heat production needed to prevent hypothermia is achieved via increased SNS outflow to thermogenic tissues (primarily skeletal muscle and brown adipose tissue), which generate heat by potently increasing glucose and free fatty acid oxidation [95, 96]. Once in motion, this process creates two additional homeostatic challenges: (i) averting depletion of fuel stores in the face of markedly increased energy expenditure; and (ii) preserving euglycaemia in the face of markedly increased rates of glucose uptake from the circulation.

From this perspective, it seems remarkable that neither body temperature, body fat mass, nor blood glucose levels are detectably altered when mice or rats are moved from a warm to a cool environment, provided they have sufficient access to food. The stability of body temperature is ensured by rapidly increasing heat production in a manner that precisely offsets heat loss, and this effect is associated with (i) an increase of food intake that precisely offsets the increase of energy expenditure; and (ii) an increase of glucose production that precisely offsets the increase of glucose disappearance from plasma. Increased SNS outflow is crucial to these adaptive responses [97], including suppression of glucose-induced insulin secretion, which enables glucose to be mobilized in amounts sufficient to meet the increased demand for tissue glucose utilization. These highly integrated responses highlight how the brain integrates afferent information relevant to a changing external environment with interoceptive signals and humoral cues (e.g. input from leptin and glucose) relevant to changing body fuel requirements, to mount adaptive responses with sufficient precision to protect body temperature while ensuring stability in levels of both stored and circulating fuel (Figure 10.5).

Brain responses to perceived glucose deficiency

The lower boundary of the BDL_G is established primarily by the brain, which mounts counter-regulatory responses that restore low blood glucose levels to their baseline value [98]. The threshold glucose level for activating brain-driven components of the counter-regulatory responses, such as secretion of adrenaline (epinephrine) and activation of SNS outflow to liver and pancreas, serves as a biomarker for what the brain perceives as the lower limit of the physiological range of blood glucose. However, because this lower boundary is seldom crossed in healthy individuals, the brain’s role in the counter-regulatory response is usually viewed as an emergency response to a severe pathological state rather than a fundamental aspect of everyday glycaemic regulation.

The brain’s role in defending the lower boundary of the BDL_G can be investigated using experimental *neuroglycopenia*. This term describes the state induced by reducing glucose availability to the brain through administration of a non-metabolizable glucose analogue (e.g. 2-deoxyglucose [99], which is taken up by cellular glucose transporters and phosphorylated by glucokinase or other hexokinases, but cannot be further metabolized) that impairs neuronal glucose utilization. In response to neuroglycopenia, the brain mounts counter-regulatory responses that mimic those induced by hypoglycaemia. Sympathetic outflow to the pancreas also increases, which inhibits insulin secretion while enhancing glucagon secretion [6, 100]; this glucagon response is impaired by sympathetic denervation of the pancreas [101].

These counter-regulatory responses serve collectively to increase glucose production while decreasing peripheral glucose utilization and, unlike the response to hypoglycaemia, which serves to restore low blood glucose back to normal, the brain response to neuroglycopenia causes blood glucose concentrations to rapidly rise out of the normal range. Intriguingly, so long as the brain perceives an insufficient supply of glucose, it will actively maintain this hyperglycaemic plateau, with blood glucose levels returning to baseline only after the drug effect has worn off [99]. Thus, the brain responds to the perception of reduced glucose availability by inducing and maintaining hyperglycaemia so as to deliver sufficient glucose to the brain to overcome the underlying defect. This hyperglycaemic response can be fully recapitulated in mice by experimental activation of ventromedial nucleus neurons in glucoregulatory neurocircuits responsible for mounting counter-regulatory responses [21, 102, 103].

Hypothesis: reduced brain glucose sensing predisposes to hyperglycaemia in type 2 diabetes

The brain’s ability to raise the defended blood glucose level during neuroglycopenia raises the question of whether a similar mechanism – perception of reduced glucose availability by the brain – might contribute to hyperglycaemia in people with type 2 diabetes. This hypothesis fits with evidence that the defended lower limit of blood glucose is ~40% higher in people with type 2 diabetes than in those without (based on the blood glucose threshold for counter-regulatory response activation) [104, 105]. A similar situation applies to individuals with monogenic diabetes caused by glucokinase mutations [106]. Because glucose sensing is reduced, the

brain can be expected to perceive circulating glucose levels to be lower than they truly are, with the consequence being an increase in the defended blood glucose level, as occurs in response to neuroglycopenia. Consistent with this prediction, these individuals are characterized by generally normal glucose homeostasis, except that (i) the BDL_G is elevated compared to normal individuals [104]; and (ii) the threshold for activating CNS-driven counter-regulatory responses during hypoglycaemia (e.g. epinephrine secretion) is increased, mimicking what is observed in type 2 diabetes [104, 105].

Although glucokinase mutations impair glucose sensing in both pancreatic β cells and neurons, the upward resetting of the glycaemic threshold for epinephrine secretion can only be explained by CNS involvement, since β -cell glucose sensing plays no role in adrenomedullary axis regulation. The elevated glycaemic threshold for epinephrine secretion in individuals with glucokinase mutations therefore offers *prima facie* evidence that impaired neuronal glucose sensing is sufficient to raise the lower boundary of the defended BDL_G in humans, thus raising the possibility of a similar situation in people with type 2 diabetes. Stated differently, these findings suggest that a primary defect in brain glucose sensing and associated elevation of the BDL_G may contribute to the pathogenesis of type 2 diabetes.

Evidence derived from investigation into the role of ventromedial nucleus neurons in glucose homeostasis and diabetes pathogenesis in mouse models strengthens the hypothesis. Specifically, silencing a specific subset of neurons located in the circuit responsible for mounting counter-regulatory responses located in the hypothalamic ventromedial nucleus not only blunts the counter-regulatory response to neuroglycopenia, but also causes a 25% reduction in the circulating glucose level in otherwise normal mice [103]. These neurons, which are marked by expression of the cholecystokinin B (CCKB) receptor subtype, therefore help to establish the BDL_G in mice. More importantly, when mice become diabetic by destruction of pancreatic β cells, silencing of these neurons potently ameliorates hyperglycaemia [103]. Activation of this ventromedial nucleus neuronal subset therefore appears to be required for hyperglycaemia induced by severe insulin deficiency. This in turn raises the possibility that an impaired capacity of the brain to sense blood glucose levels leads to activation of ventromedial nucleus neurons involved in glucose counter-regulation, analogous to the response to neuroglycopenia; in response this perceived glucose deficiency, neurocircuits are activated that raise the BDL_G . This model does not dismiss or exclude key roles for insulin resistance or impaired β -cell function in the pathogenesis of type 2 diabetes; on the contrary, brain responsiveness to rising blood glucose levels may decline in parallel with peripheral metabolic impairments, possibly involving shared underlying mechanisms (e.g. systemic and hypothalamic inflammation).

The transition from obesity to type 2 diabetes

Obesity and type 2 diabetes are closely related metabolic disorders – not only in their tendency to affect the same individuals, but in their underlying pathogenic processes. Analogous to the gradually rising BDL_G characteristic of type 2 diabetes, obesity can be defined as a state in which excessive weight gain and body fat mass remain biologically defended as they increase outside of the normal range [107]. One hypothesis to explain this defended elevation of body fat mass is that the brain becomes *resistant* to input from adiposity-related negative feedback signals (e.g. leptin) that inform the brain regarding the status of body fuel stores [107, 108]. So long as the brain perceives the amount of body fat to be lower than it actually is, it will activate responses that promote a positive energy balance until body fat mass increases sufficiently to overcome the

resistance. The net effect is an increase in the biologically defended level of body fat mass that raises circulating negative feedback signals sufficiently to overcome the brain's resistance to this input. A point to emphasize is that this mechanism is advanced to explain not how weight gain occurs, but rather how body fat stores continue to be defended even as they rise out of the normal range.

The hypothesis that the pathogenesis of type 2 diabetes involves a progressive impairment in the brain's ability to sense glucose availability, thus raising the BDL_G to a level sufficient to overcome the underlying defect, offers a feasible explanation for the transient nature of glucose lowering induced by anti-diabetes drugs currently in use (e.g. metformin, sulfonylureas, or insulin) since, once the drug effect has worn off, the blood glucose level returns to its biologically defended value. From this perspective, the increased BDL_G in type 2 diabetes is hypothesized to result as a compensatory response to an intrinsic impairment in brain sensing of the circulating glucose level (or a defective response to this input) [109]. Indeed, defects in brain glucose responsiveness and transport are both well documented in humans with type 2 diabetes [110–112].

The hypothesis that obesity and type 2 diabetes involve biologically defended elevations of body fat mass and blood glucose level, respectively, and that these responses are mounted by the brain to compensate for impaired sensing of relevant feedback signals, begs the question of whether a shared defect might be at work. While this possibility is speculative at present, the extensive overlap in hypothalamic neurocircuitry involved in the regulation of stored fuel (i.e. body fat mass) and circulating fuel (i.e. glucose) is compatible with this idea. Future research should determine whether the close association between obesity and type 2 diabetes stems in part from a shared defect in sensing of afferent input by brain systems involved in both energy and glucose homeostasis [77, 113].

Roles of insulin-dependent and -independent glucose lowering by the brain

Although glucose lowering in the post-prandial state is mediated predominantly by insulin-dependent mechanisms, glucose disposal in the fasting state is largely insulin independent [114, 115]. It therefore follows that impairment of either mechanism of glucose disposal could contribute to the elevated basal glucose level characteristic of type 2 diabetes.

Glucose effectiveness is a term used to describe the ability of a rise in the plasma glucose level to promote its own disposal independently of insulin, and it provides a useful measure of insulin-independent glucose lowering. Evidence linking reduced glucose effectiveness to the pathogenesis of type 2 diabetes was first provided by Welch et al. [116], who showed that in individuals with type 2 diabetes, not only is insulin sensitivity reduced as expected, but glucose effectiveness is also reduced by ~40%. A follow-up study showed that among 18 lean and obese individuals without diabetes, those with impaired glucose tolerance not only had the expected lowering of insulin-dependent glucose disposal, but also twofold lower glucose effectiveness [117]. Glucose intolerance in individuals without diabetes, therefore, appears to involve impairment of both insulin-dependent and -independent mechanisms.

To investigate the contributions of these impairments to the development of type 2 diabetes, a prospective cohort study was conducted in 181 normoglycemic individuals at high risk of type 2 diabetes (offspring of parents who both had type 2 diabetes) [118]. Over a 20-year follow-up period, 16% of these individuals developed type 2 diabetes, and among these at-risk individuals, reductions of both glucose effectiveness and insulin sensitivity were detectable at

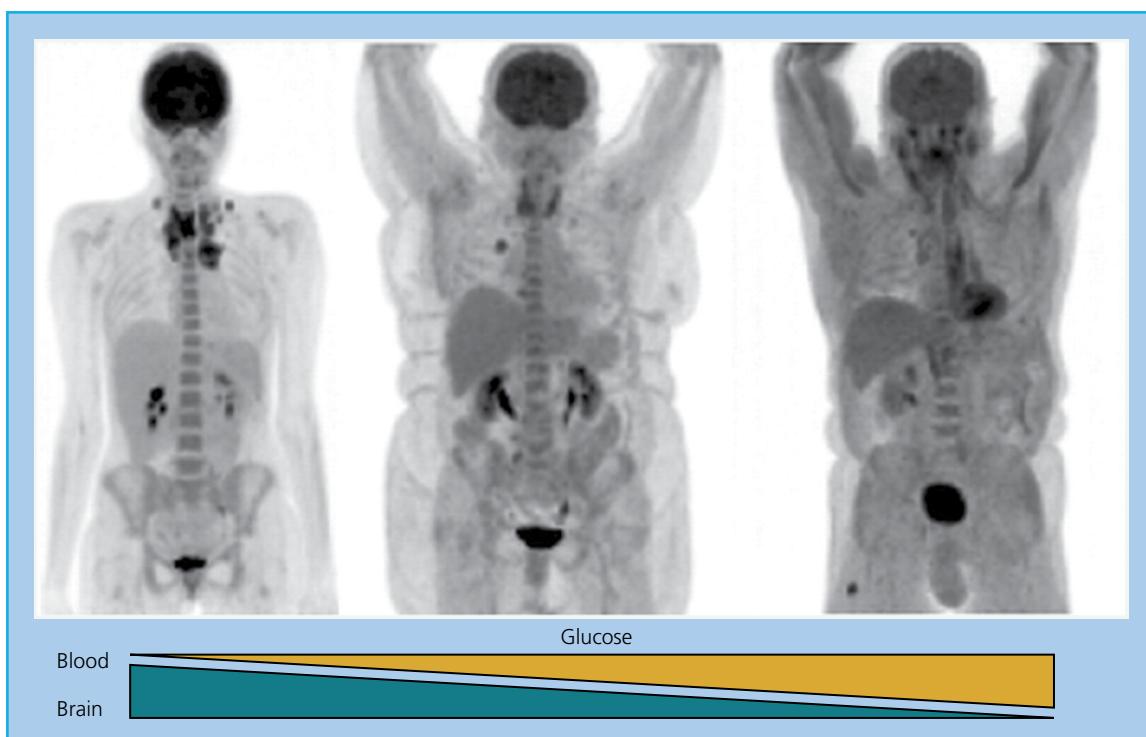

Figure 10.6 Diabetes reduces glucose uptake from blood into brain. 90 individuals were fasted for 6–8 hours before deoxy-2-[¹⁸F]fluoro-D-glucose (¹⁸F-FDG) intravenous administration and positron emission tomography (PET) imaging. The maximum standardized uptake value (SUV_{max}) for cerebral/brain ¹⁸F-FDG uptake was decreased in association with increased serum glucose (BGL): BGL <80 mg/dl, $SUV_{max} 15.9 \pm 5.4$; BGL 80–100 mg/dl, $SUV_{max} 14.5 \pm 3.7$; BGL 100–120 mg/dl, $SUV_{max} 12.5 \pm 3.5$; BGL 120–140 mg/dl, $SUV_{max} 12.3 \pm 3.09$; BGL 140–160 mg/dl,

$SUV_{max} 9.8 \pm 2.6$; BGL 160–180 mg/dl, $SUV_{max} 8.2 \pm 1.9$; BGL >180 mg/dl, $SUV_{max} 8.6 \pm 4.7$. Representative images of ¹⁸F-FDG PET/CT brain glucose uptake in individuals with low (left, BGL 65 mg/dl, no diabetes, no insulin), mid (middle, BGL 155 mg/dl, no diabetes, no insulin), and high (right, BGL 298 mg/dl, no diabetes, after insulin) blood glucose levels. Darker regions represent more sugar utilization and tracer accumulation. Source: From Büsing et al. 2013 [122].

least 10 years prior to diagnosis, with reduced glucose effectiveness conferring the greatest relative risk [118]. These findings clearly implicate impairment of insulin-independent glucose disposal, along with impaired insulin secretion and insulin sensitivity, in the pathogenesis of type 2 diabetes.

Given the large literature implicating β -cell dysfunction in type 2 diabetes, it seems paradoxical that hyperinsulinaemia was recently reported to be predictive of future type 2 diabetes development [119–121]. A key unanswered question is the mechanism underlying this hyperinsulinaemia. Given that this phenotype was reported in individuals with normal glucose tolerance and normal insulin sensitivity [119], and since the combination of hyperinsulinaemia and normal insulin sensitivity should result in improved glucose tolerance unless glucose effectiveness is also reduced, the possibility that hyperinsulinaemia is a biomarker of reduced glucose effectiveness is consistent with evidence linking reduced glucose effectiveness to the future development of type 2 diabetes in humans [118]. Future studies should address two key questions: (i) is hyperinsulinaemia a biomarker of reduced glucose effectiveness in individuals at risk for type 2 diabetes? And (ii) given the brain's ability to regulate glucose effectiveness, does a brain defect contribute to the mechanism underlying reduced glucose effectiveness (and hyperinsulinaemia) in the pathogenesis of type 2 diabetes?

Clinical evidence supporting altered brain blood glucose handling in individuals with diabetes

A clinical study using magnetic resonance spectroscopy (MRS, which can be used to measure relative changes of brain glucose content over

time in humans) reported that compared to healthy individuals, those with obesity have reduced brain glucose uptake during a hyperglycaemic clamp, and that this defect is even more pronounced in individuals with suboptimally managed type 2 diabetes [110]. Similar results have been generated using positron emission tomography (PET) imaging, which can measure glucose uptake into brain or other tissues (using a positron-labelled glucose analogue). One PET imaging study of a large cohort of individuals with or without type 2 diabetes showed that higher blood glucose levels are associated with lower brain glucose uptake (Figure 10.6) [112, 122], and that the brain is the only organ in which glucose uptake was related to glycaemia [112]. Although more work is needed, these brain imaging findings support the hypothesis that the brain's ability to sense and respond to changes in glycaemia is impaired in type 2 diabetes.

Targeting the brain to restore normoglycaemia

Brain-directed treatments have been identified over the past decade that can return elevated plasma glucose levels to the normal range in rodent models of both type 1 diabetes and type 2 diabetes. For the most part, these interventions (i) target the mediobasal hypothalamus; (ii) rely primarily on insulin-independent glucose-lowering mechanisms; and (iii) reset the BDL_G to normal, rather than simply lowering glucose levels in a transient manner.

Several members of the fibroblast growth factor (FGF) family of peptides elicit potent glucose-lowering actions in rat and mouse models of type 2 diabetes following central administration.

Part 2 Normal Physiology

Initially, studies focused on two hormones in this family, FGF-21 and FGF-19, which are secreted primarily from the liver and intestine, respectively [123]. Although each has distinct physiological functions, pharmacological administration of either peptide can normalize blood glucose levels in multiple rodent models of type 2 diabetes [124]. Although these effects were originally proposed to be mediated via peripheral mechanisms, they were subsequently shown to be mediated primarily in the brain [124, 125].

Meanwhile, the growth factor FGF-1 elicits a more durable anti-diabetes action. Like FGF-19 and FGF-21, this effect was first reported following systemic administration [126], but was subsequently found to be highly effective following intracerebroventricular FGF-1 injection at a dose too low to have systemic effects. What

distinguishes FGF-1 from any other pharmaceutical treatments of type 2 diabetes, however, is that a single intracerebroventricular injection can normalize glycaemia for weeks to even months in rodent models of type 2 diabetes, despite having no sustained effect on food intake, body weight, or body adiposity (Figure 10.7) [127]. Cellular mechanisms underlying the hypothalamic response to FGF-1 appear to involve glia–neuron interactions [128] that increase melanocortin signaling and are accompanied by reversal of maladaptive changes in the extracellular matrix [128, 129]. Whether these findings will translate to more effective treatment strategies for human type 2 diabetes awaits additional study. A key final point related to central actions of FGF1 (as well as leptin) in diabetic animals is that beyond simply lowering elevated plasma glucose levels, *these interventions appear to restore the BDL_G to normal*.

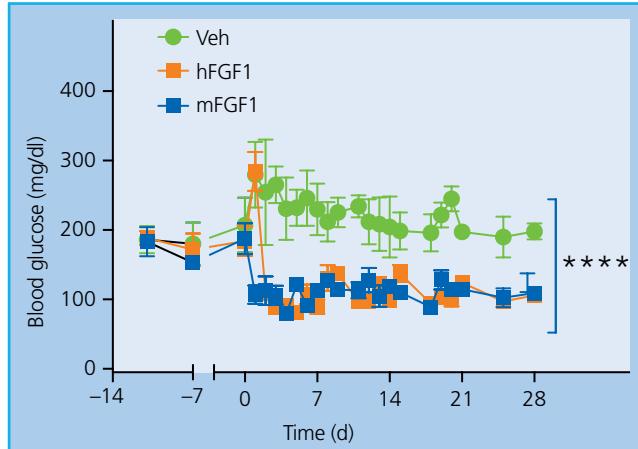

Figure 10.7 Sustained blood glucose lowering by central fibroblast growth factor (FGF)-1 treatment in a mouse model of type 2 diabetes. A single intracerebroventricular injection of human (hFGF1) or mouse (mFGF1) at a dose of 3 µg induces sustained diabetes remission in diabetic Lep^{ob/ob} mice. Current and future anti-diabetes drugs that target central pathways

Anti-diabetes agents in current use can act on tissues ranging from the pancreas to muscle, adipose tissue, liver, kidney, and gut, with some also acting in the brain (Table 10.2). Perhaps the most clear-cut example of the latter is the dopamine agonist bromocriptine, which acts centrally to suppress hepatic glucose production and improve insulin resistance [130, 140]. The amylin analogue pramlintide is another centrally acting anti-diabetes drug that elicits a distinctly different set of effects via its receptor expressed by hindbrain neurons. These include reduced food intake and weight loss, decreased gastric emptying, and inhibition of glucagon secretion [130, 141]. While neither bromocriptine nor pramlintide is particularly effective or is in wide use, both offer proof-of-concept evidence that the brain can be targeted to treat diabetes in humans, although drugs that target both brain and periphery are currently far more efficacious.

Among these are synthetic GLP-1 receptor agonists, which are currently among the most potent anti-diabetes medications. Long-acting GLP-1 receptor agonists can be administered on a weekly basis and are especially effective in lowering HbA_{1c}; unlike insulin,

they do so without weight gain (and often induce weight loss) and with minimal risk of hypoglycaemia [130]. GLP-1 receptors on pancreatic β cells are a key target for these drugs, activation of which augments glucose-induced insulin secretion. In addition, these agents can impact brain function in multiple ways [136]. Activation of GLP-1 receptors on vagal afferent fibres supplying the gastrointestinal tract induces satiety while reducing gastric emptying, and activation of hindbrain GLP-1 receptors can amplify this effect, with the combination leading to significant weight loss. Some POMC neurons also express GLP-1 receptors and increase firing rate, leading to increased melanocortin signalling in response to GLP-1 stimulation [142]. Whether these or other CNS effects promote glucose lowering independently of effects on food intake and weight is presently unknown.

Recent progress in this area includes the development and clinical testing of unimolecular dual- and tri-agonist compounds that combine GLP-1 with glucagon and/or gastric inhibitory peptide (GIP) into a single, long-acting peptide suitable for systemic administration [143]. One of these compounds recently received licensing approval for type 2 diabetes treatment. The dual agonist tirzepatide exerts glucose-lowering and weight loss effects that are more potent than other non-surgical options. Like GLP-1 receptor agonists, these drugs mediate their beneficial effects via actions on both pancreatic β cells and the peripheral and central nervous system.

Another recent development relates to metformin, a first-line drug for type 2 diabetes, with anti-diabetes effects that appear to involve a subset of hindbrain neurons. This inference is based on evidence that metformin induces expression of growth and differentiation factor-15 (GDF-15, also known as MIC-1) [133], a potent endogenous inhibitor of feeding [144, 145] that can be secreted by

several cell types and tissues, typically in response to cellular stress [146–148]. The central effects of GDF-15 are mediated via the binding to its receptor, GFRAL, expressed uniquely by neurons in the area postrema and nucleus of the solitary tract [149–152]. Although the metformin-induced increase of circulating GDF-15 levels is modest (and below that needed to cause pronounced anorexia), the finding that in mice metformin's anti-diabetes effect is abrogated by GFRAL deletion [133] implies a requirement for GDF-15 and its action in the brain. As more is learned about the brain's role in glucose homeostasis and diabetes pathogenesis, successful targeting of the brain to improve diabetes management seems likely.

Conclusion

Growing evidence points to a key role for the brain, working in cooperation with pancreatic islets and other peripheral tissues, in the maintenance of blood glucose homeostasis. The brain's contribution to this process likely hinges on its ability to accurately sense and respond to changes in the circulating glucose level, and although our understanding of how this occurs remains limited, dysfunction of this sensing process may contribute to the progressive rise of the BDL_G during the transition from obesity to type 2 diabetes. Since it is now clear from pre-clinical studies that diabetes remission is achievable via strategies targeting the brain, future research is needed to translate these findings to the clinic. Ongoing drug development efforts that target the brain have the potential not simply to lower blood glucose levels, but to normalize the BDL_G in individuals with type 2 diabetes.

Control of Body Weight: How and Why Do We Gain Weight Easier Than We Lose It?

Janine Makaronidis^{1,2,3} and Rachel L. Batterham^{1,2,3}

³National Institute of Health Research, UCLH Biomedical Research Centre, London, UK

Key points

- Obesity is a chronic, remitting and relapsing disease that can lead to multiple debilitating physical and psychological complications.
- The causes of obesity are complex and multifactorial, including a combination of genetic susceptibility, epigenetic influences, and environmental factors, which all contribute to a biology that favours weight gain.
- Weight loss through energy restriction is followed by powerful physiological adaptations, aiming to defend the higher weight, which drive weight regain.
- Several environmental and physiological factors promote weight gain. Environmental factors, such as food cues and easy access to energy-dense palatable foods, support food choices that are driven by cognitive, social, and emotional factors.
- Exposure to food cues can alter secretion profiles of appetite-regulating hormones and activity in reward areas of the brain, in a manner promoting increased energy intake in an environment of excess energy availability.

Obesity is a chronic multifactorial disease, defined as an excess of adipose tissue, which adversely affects health. The worldwide prevalence of obesity, defined by a body mass index (BMI) of $\geq 30 \text{ kg/m}^2$, has risen by almost 30% in the past 30 years, which equates to over 2 billion people currently living with obesity globally [1]. Obesity-associated comorbidities, including type 2 diabetes, cardiovascular, renal, and liver disease, and certain types of cancer, have a substantial negative impact on quality of life, but also lead to a significantly increased mortality [2]. Consequently, the life expectancy of a person living with severe obesity ($\text{BMI} \geq 40 \text{ kg/m}^2$) is reduced by up to 14 years [3].

Despite the growing disease burden associated with obesity and its complications, public health interventions to date have been largely ineffective at reducing the rapidly growing prevalence of obesity, which on a global level is continuing to rise exponentially [2]. Until recently, treatment strategies have almost exclusively focused on restricting energy intake and increasing physical activity. Although these strategies result in weight reductions in the short term, they are followed by very powerful biological compensatory mechanisms aiming to defend a higher body weight [4]. These physiological mechanisms act beyond voluntary food intake and drive the weight gain that commonly follows weight loss through dietary energy restriction. In order to deliver more effective treatments for people living with obesity, a fundamental understanding of the processes regulating body weight, the genetic variations underlying weight heritability and predisposition to weight gain, as well as the environmental, behavioural, and societal factors that have an impact on weight at a population levels are required. Furthermore, elimination

of the stigma and the societal discrimination against people living with obesity is essential. In this chapter we review the physiological mechanisms regulating weight, as well as the multiple biological, genetic, and environmental factors that affect weight, in order to explain why gaining weight is much easier than losing it.

Body weight regulation

Energy homeostasis: control of appetite and body weight

Appetite and body weight are regulated through an incredibly complex network of interrelated mechanisms, through which signals concerning energy need and availability are collected from peripheral tissues and integrated in the central nervous system (CNS) [5]. The areas of the CNS responsible for body weight control respond to the inputs they receive from the periphery, which include numerous metabolically active neuropeptides influencing appetite and energy storage and expenditure, in order to ensure that available energy meets the body's metabolic requirements [6].

The gastrointestinal (GI) tract and adipose tissue are the body's largest endocrine organs and have a key role in responding to energy needs and availability to regulate body weight and energy balance. Gut-derived signals convey information about the composition and energy content of ingested food to the CNS, whereas adipose tissue conveys signals relating to longer-term energy availability [7]. These signals are conveyed to the hypothalamus, the main CNS centre integrating peripheral homeostatic signals of energy availability into

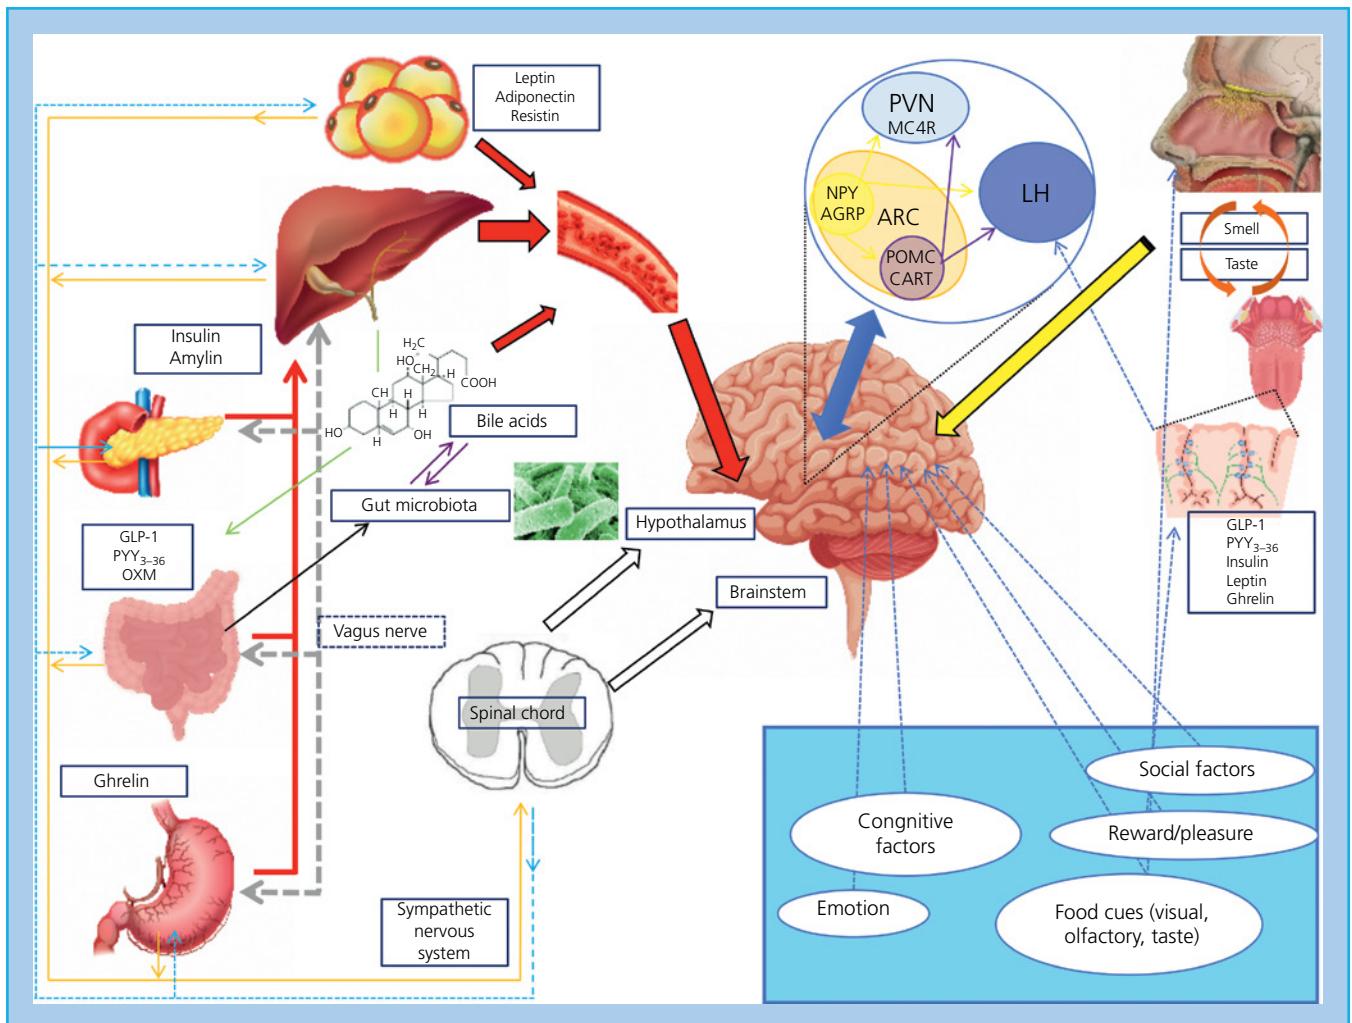

Figure 11.1 The regulation of eating behaviour. Schematic diagram illustrating the major processes involved in regulating eating behaviour. The brainstem and hypothalamus act as the first relay centres for neural and metabolic signals of nutrient availability. The hypothalamus then integrates peripheral signals of energy availability into the central nervous system [5]. In the arcuate nucleus (ARC) of the hypothalamus, neurons expressing neuropeptide Y (NPY) and agouti-related peptide (AgRP) drive orexigenic responses, whereas proopiomelanocortin (POMC) and cocaine- and amphetamine-related transcript (CART) neurons suppress appetite [8].

central networks. This in turn generates feelings of either hunger or satiety, to drive a person's appetite and eating behaviour according to energy needs [5]. The processes involved in the control of eating behaviour are summarized in Figure 11.1.

Physiological regulators of body weight

Gut hormones

Gut hormones are metabolically active polypeptides, which are secreted by enteroendocrine cells along the entire length of the GI tract and have endocrine, autocrine, and paracrine functions [7]. Receptors for gut hormones are located on a multitude of organs and tissues, but most important for appetite regulation are those on the hypothalamus and other CNS regions involved in the control of eating [6]. In conditions of energy depletion, the hormone ghrelin is secreted from P/D1

In the paraventricular nucleus of the hypothalamus (PVN), activation of the melanocortin-4 receptor (MC4R) promotes satiety. The lateral hypothalamus (LH) also receives inputs about the chemosensory properties of food. The appetitive network integrates information from food cues, such as sight, taste, and smell, reward-related information, and social and emotional factors with cognitive processes [5]. GLP-1, glucagon-like peptide-1; PYY, peptide YY3-36; OXM, oxyntomodulin. Source: Reproduced with permission from Pucci and Batterham 2019 [6].

cell populations predominantly in the gastric fundus [9]. Ghrelin is a growth hormone secretagogue and has potent orexigenic effects; when it binds to growth hormone secretagogue receptor type 1a (GHSR1a) in the hypothalamus, it increases appetite and promotes a desire and drive to eat [10]. A multitude of gut hormones are secreted in response to eating, which signal energy availability. Peptide YY 3-36 (PYY), glucagon-like peptide-1 (GLP-1), and oxyntomodulin are secreted from enteroendocrine L cells and have a key role in regulating energy and glucose homeostasis [7,11]. Within the hypothalamus, activation of their respective receptors suppresses appetite and generates a feeling of satiety, in an opposing manner to ghrelin [12].

Table 11.1 summarizes the role of the main hormones secreted along the GI tract in regulating appetite.

It is important to note that gut hormones act synergistically in the control of appetite and body weight. Administration of native peptide infusions of PYY, GLP-1, and oxyntomodulin (OXM) in human studies has shown that their effects on appetite suppression

Table 11.1 Gut hormones and their role in appetite regulation.

Hormone	Secretion from GI tract	Target	Effects on appetite
Ghrelin [9]	P/D1 cells in the gastric fundus, antrum, and duodenum in response to: Fasting Meal patterns Food cues	Following acylation, acyl-ghrelin binds to GHRs1a in the hypothalamus, VTA and other reward areas of the CNS, and the vagus nerve	Increased appetite Hunger Increased gastric emptying Increased reward value of food
PYY [12, 13]	Enteroendocrine L cells, following exposure to nutrients (protein and fatty acids)	Y2 receptors on the vagus nerve and throughout the CNS	Reduced appetite and energy intake Satiety Delayed gastric emptying
GLP-1 [14, 15]	Enteroendocrine L cells, following exposure to nutrients (glucose and fatty acids) and bile acids	GLP-1R are widely distributed on multiple organs and tissues including the hypothalamus, liver, skeletal and cardiac muscle, and vagus nerve	Reduced appetite and energy intake Satiety Delayed gastric emptying
OMX [16]	Enteroendocrine L cells, co-secreted with GLP-1 following nutrient ingestion	GLP-1R and glucagon receptors OMX also directly acts on the hypothalamus (unknown receptor)	Insulin secretion Reduced appetite and energy intake Satiety
CCK [17]	Enteroendocrine I and L cells in response to nutrient intake (lipids and protein)	CCK-1 receptors along the GI tract (stomach, pancreas, gallbladder) and CCK-2 receptors in the CNS	Reduced appetite and energy intake Satiety Delayed gastric emptying Insulin secretion
GIP [18]	Enteroendocrine K cells in response to glucose and lipid ingestion	GIP receptor on pancreatic islet cells, adipose tissue, and the hypothalamus	Reduced appetite and energy intake Insulin secretion
Neurotensin [19]	Enteroendocrine cells in response to nutrient ingestion, mainly lipids	NTR1, NTR2, NTR3 across the CNS, but particularly the hypothalamus and along the GI tract	Suppresses appetite Reduces GI motility Facilitates fat translocation
Uroguanylin [20, 21]	Intestinal epithelial cells in response to nutrient ingestion	GUCY2C receptor on intestinal epithelial cells and the hypothalamus	Suppresses appetite Satiety
Amylin [22]	Pancreatic β cells, co-secreted with insulin, in response to glucose and fatty acid ingestion	Amylin-specific calcitonin on the gastric fundus, throughout the CNS, and on bone	Suppresses appetite Promotes satiety Slows gastric emptying
Gastric leptin [23]	Gastric chief cells and endocrine P cells in response to energy intake, insulin, and CCK secretion	Leptin receptors on vagal afferents	Fasted state: increased appetite and energy intake Fed state: suppressed appetite

CCK, cholecystokinin; CNS, central nervous system; GHRs1a, growth hormone secretagogue receptor type 1a; GI, gastrointestinal; GIP, gastric inhibitory polypeptide; GLP-1, glucagon-like peptide 1; GLP-1R, glucagon-like peptide 1 receptor; GUCY2C, guanylyl cyclase 2C; NTR, neurotensin receptor; OMX, oxyntomodulin; PYY, peptide YY 36; VTA, ventral tegmental area.

are additive, compared to each individual peptide in isolation [19, 24, 25]. In addition, cholecystokinin (CCK) and gastric inhibitory polypeptide (GIP) intensify the anorectic effects on GLP-1 [15, 17, 26].

Gut hormones further control appetite and eating behaviour via their effects on the vagus nerve. Receptors for gut hormones including PYY, GLP-1, CCK, and gastric leptin are located on vagal afferents [23, 27]. It is of note that expression of these receptors is subject to the vagus nerve's innate plasticity and is directly affected by nutritional state [28]. Vagal signals project to the nucleus tractus solitarius (NTS); from there they are conveyed to higher CNS centres.

Hypothalamus and neurotransmitters

The hypothalamus integrates peripheral signals of energy availability into the CNS. Afferent signals from the NTS project to the arcuate nucleus of the hypothalamus [29]. Distinct neuronal populations drive orexigenic and anorectic responses, respectively. Neurons expressing neuropeptide Y (NPY) and agouti-related peptide (AgRP) drive orexigenic responses, whereas proopiomelanocortin (POMC) neurons suppress appetite, in a mutually exclusive manner [30]. POMC neurones also coexpress cocaine- and

amphetamine-related transcript (CART). The melanocortin melanocyte-stimulating hormone (α -MSH) activates the melanocortin-4 receptor (MC4R) in the paraventricular nucleus of the hypothalamus, promoting satiety, improving insulin sensitivity, and increasing energy expenditure [29]. Anorectic gut hormones including PYY, GLP-1, and OXM directly activate α -MSH neurons. In contrast, in conditions of energy deficiency, ghrelin stimulates NPY and AgRP secretion, which in turn inhibit MC4R, generating a feeling of hunger and a drive to eat [8]. Interestingly, MC4Rs have been located on enteroendocrine cells and may act as a further regulator of gut hormone secretion [31]. Furthermore, mutations causing loss of MC4R function result in hyperphagia, accelerated growth, and severe obesity from a young age [32]. Moreover, at the level of the hypothalamus, these signals of short-term energy availability are further integrated with signals of longer-term energy availability, originating from adipose tissue.

Adipose tissue

Adipose tissue is a metabolically active organ that secretes cytokines and adipokines that regulate energy homeostasis. Adipose tissue responds to changes in nutritional status and energy availability

and undergoes remodelling, a dynamic process affecting its metabolic functions. The adipokine leptin is secreted by adipocytes and acts as a signal of long-term energy stored in adipose tissue, and circulating leptin levels correlate with adipose tissue mass [33]. Leptin activates POMC neurons and simultaneously inhibits NPY/AgRP neurons [34]. Consequently, increases in adipose tissue mass will lead to higher circulating leptin levels, which in normal-weight rodents results in an increase in anorectic signals and a reduction in energy intake [35]. In people who are normal weight, increases in leptin following a positive energy balance result in appetite suppression, a reduction in energy intake, and an increase in energy expenditure [36, 37]. In contrast, in conditions of energy deficiency, leptin levels reduce and adipose tissue releases energy for use by other tissues via lipolysis [35]. In addition to leptin's role as a long-term energy availability signal, adipocytes secrete leptin acutely in response to energy intake. Leptin also has a role in modulating reproductive function. Leptin regulates kisspeptin secretion, a neuropeptide that stimulates gonadotropin-releasing hormone-producing neurons, thereby effecting gonadotropin secretion [38]. Furthermore, the leptin receptor is expressed throughout the immune system and leptin acts as a mediator for both innate and adaptive immune responses, triggering secretion of pro-inflammatory immune cytokines [39].

In addition, the adipokines adiponectin and resistin also regulate body weight. Adiponectin has catabolic effects through stimulation of lipid oxidation, has anti-inflammatory effects, and improves insulin sensitivity, reducing body weight [40]. Resistin, in contrast, reduces insulin resistance and promotes weight gain [41]. The exact interaction of adipokines and cytokines secreted by adipose tissue, however, remains incompletely understood.

Furthermore, cytokines have attracted increasing interest in recent years with regard to their role in energy regulation. For instance, growth differentiation factor 15 (GDF15), an inflammation-induced cytokine encoded by the macrophage inhibitory cytokine 1 (*MIC-1*) gene, is expressed in almost all tissues, but high levels have been measured in human studies in the liver, pancreas, adipose tissue, and blood [42]. Interestingly, GDF15 has potent anorectic effects, mediated by downregulating NPY neurons in the hypothalamus and through direct action on the area postrema and the NTS, through pathways independent of MC4R function [43].

Intestinal microbiome

The intestinal microbiome comprises trillions of microbial populations. These microbial populations interact with human intestinal physiology and the host-microbiome interplay in the GI tract thereby has impacts on the physiology that regulates energy homeostasis [44]. Interactions between enteroendocrine cells and certain bacterial populations in the microbiome can directly affect gut hormone secretion, by influencing enteroendocrine cell secretion of PYY and GLP-1 in response to nutrient ingestion [45]. Microbiota also rely on ingested nutrients for their own metabolism and release short-chain fatty acids, a byproduct of microbial metabolism, which stimulates GLP-1 and PYY release [45]. The microbiome also responds to changes in weight, by altering both its composition and metabolic function. However, the degree to which changes in microbial populations *per se* can influence human body weight remains unknown. In summary, the mechanisms by which the microbiome affects human metabolism and weight control are complex and incompletely understood.

Beyond homeostasis: hedonic pathways

Eating constitutes a behaviour and, particularly in an environment where energy availability exceeds energy requirements, food-related decision making is influenced by factors beyond homeostasis and a person's net energy requirement. With the average individual being faced with over 200 food-related decisions per day, food choices are largely driven by cognition, food availability, palatability, and social and emotional factors [5]. The perceived reward of tasting or consuming a certain food can override the satiety signals generated from having met energy requirements. Reward-related responses can override homeostatic signals, leading to an energy intake beyond an individual's net energy requirements [46].

Interestingly, exposure to food cues, such as the sight or smell of food, can generate a metabolic response. Circulating gut hormone levels can directly influence the reward response to food and circulating ghrelin levels rise in anticipation of eating [46]. Neuroimaging studies using functional magnetic resonance imaging (fMRI) have provided insight into the relationship between gut hormone profiles, food cues, and their reward value [6]. Reward centres in the CNS are highly responsive to the effects of gut hormones and exposure to food cues can directly activate these centres in the absence of an energy need [47, 48]. Viewing food images or smelling food can directly stimulate ghrelin secretion and ghrelin levels directly correlate with CNS reward centre activity in fMRI studies [47, 49]. In contrast, PYY and GLP-1 inversely correlate with reward responses to food cues and secretion of these hormones attenuates reward responses [15]. Circulating PYY levels rise following a meal and switch the control of eating behaviour from homeostatic to reward-driven control [13].

Importantly, gut hormones and their cognate receptors are also present in saliva, taste-sensing cells, and the olfactory bulb and likely modulate perceptions of the taste and smell of food, both of which are highly dynamic processes [50, 51]. Ghrelin, for instance, modulates olfactory sensitivity, with circulating levels correlating with CNS olfactory activity [52]. GLP-1, ghrelin, and CCK are all expressed on lingual taste bud cells, suggesting they have a role in modulating taste sensitivity [50, 51]. However, fMRI studies using cognitive tasks also demonstrate that goal-focused behaviour or cognitive processes can reduce food-related reward responses [53, 54].

Metabolic alterations with weight gain

Weight gain occurs when energy intake chronically exceeds energy requirements. Weight gain results in several adaptive changes, including gut hormone secretion profiles, adipocyte function, the intestinal microbiome, as well as gustatory and olfactory functions [55]. It is likely that these changes predispose a person to further weight gain.

Gut hormone secretion profiles are altered with weight gain. Attenuated meal-stimulated secretion of anorectic peptides including PYY and GLP-1 is seen in obesity [12]. Ghrelin secretion profiles also become dysregulated following weight gain. Pre-meal peaks in circulating ghrelin levels are lost in obesity, combined with a reduced suppression of ghrelin secretion following a meal [9, 12]. The cause of the dysregulation of ghrelin secretion and the pathogenesis of obesity remain incompletely understood. An increased number of ghrelin-expressing cells was seen in mice who gained weight after being fed a high-fat diet, compared to normal-weight controls. The number of ghrelin-expressing cells was compared to

genetically obese *ob/ob* mice, who had a lower number of cells compared to both mice fed a high-fat diet and normal-weight mice, suggesting that chronic exposure to a high-fat diet can dysregulate ghrelin physiology [56]. Furthermore, a recent study on stomach samples from people with obesity undergoing sleeve gastrectomy examined ghrelin cells in people with obesity compared to control samples from individuals who are normal weight obtained during gastroscopy [57]. Although the number of gastric ghrelin cells did not differ between the two groups, expression of ghrelin and its activating enzyme ghrelin O-acyl transferase (GOAT) was significantly higher in the samples from people with obesity, suggesting that ghrelin-producing cells are hyperactive in people with obesity. In addition, ghrelin expression positively correlated with glycaemic indices, BMI, and GOAT levels. The literature on whether people with obesity have increased populations of ghrelin-producing cells is inconsistent, with some studies reporting increased numbers of ghrelin-producing cells and other showing no difference in cell density between people with obesity and those of normal weight [58–60]. Taken together, these findings suggest that there may be multiple pathophysiological processes underlying the dysregulated ghrelin physiology in obesity.

Leptin levels initially rise with weight gain, along with adiponectin levels. Following prolonged weight gain, however, leptin signalling becomes impaired, which in turn inhibits further rises in adiponectin [40]. Resistance to the systemic effects of leptin and insulin eventually develops [61]. The elevations in leptin levels that follow weight gain do not result in significant increases in satiety signals or reductions in energy intake, suggesting that in people with obesity, either leptin acts as a signal rather than a regulator of body weight, or its function is overridden [62,63]. Therefore, treatment with leptin supplementation is ineffective at producing significant weight loss in people with obesity [64]. Weight gain leads to increasing oxidative stress within adipocytes, with increased secretion of pro-inflammatory cytokines including tumour necrosis factor (TNF)- α and interleukin-6 [65].

Changes to the intestinal microbiome are also seen following weight gain, with reduced diversity in populations of microbiota in obesity. Furthermore, dysbiotic bacterial populations linked to obesity can increase energy absorption from ingested food [66]. Unfavourable microbial populations contribute to weight gain through farnesoid X receptor (FXR) signalling. Dysregulated secretion of bile acids, which are also FXR ligands, is also seen following weight gain [44]. These changes in the microbiome are likely to have an impact on enteroendocrine cell function; however, it remains unknown whether changes in microbiota have a causative effect or are a mere consequence of weight gain.

Importantly, despite insulin and leptin resistance and the dysregulation in enteroendocrine cell function and gut hormone secretion, sensitivity to the effects of PYY, GLP-1, and OXM from exogenous administration is preserved, which highlights the therapeutic potential of these peptides as treatment modalities for people with obesity [12,25].

Compensatory mechanisms in response to weight loss

Although energy restriction in the short term will result in reductions in body weight, weight loss triggers powerful physiological responses aimed at defending the original higher body weight, which

result in weight regain in the longer term [4]. A landmark study by Sumithran et al. investigated the impact of a 10-week very low-calorie diet (VLCD) on gut hormone secretion profiles [67]. At the end of the 10-week diet, significant reductions in circulating PYY, CCK, insulin, leptin, and amylin levels were seen, combined with increased circulating levels of ghrelin and GIP, which persisted over a 52-week follow-up period. Increased circulating ghrelin levels, coupled with increased appetite levels persisting beyond the original weight loss period, have also been demonstrated in people with obesity who maintained weight loss [68]. Consequently, within the CNS, expression and activity of NPY/AgRP neurons increase, whereas POMC activity decreases, further increasing the motivation to eat [69]. fMRI studies illustrate increased reward responses to food cues following periods of diet-induced weight loss. Recent fMRI study findings also suggest reward region activation could be used to predict longer-term outcomes of weight loss interventions [70,71].

Changes in energy expenditure are also among the compensatory mechanisms that follow weight loss from energy restriction. Energy expenditure decreases through reductions in resting metabolic rate and reductions in thyroid hormone availability and sympathetic tone, which result in an increased ability of peripheral tissues to take up energy, combined with a reduction in energy expenditure [72]. Weight loss also drives metabolic responses within adipocytes themselves. The decline in adipocyte size as a result of weight loss alters their metabolic and inflammatory characteristics, which consequentially favour storage of ingested energy [73]. When adipocytes shrink, the growing extracellular matrix (ECM) causes mechanical stress to build up between adipocytes and the surrounding ECM, triggering inflammation and oxidative stress. In energy-deficit conditions, available energy may not suffice for ECM remodelling around the smaller adipocyte size, inhibiting lipolysis and driving the cell to reaccumulate fat in order to return to its original size [74].

Studies linking metabolic profiles with patterns of weight regain illustrate the association between adaptations to weight loss, weight regain, and the individual variability that exists in the response to energy-deficit diets. Weight loss maintenance following a VLCD has been linked to higher post-prandial PYY and GLP-1 levels [75]. In contrast, weight regain following a total diet replacement diet was associated with lower baseline GLP-1 levels and further reductions in GLP-1 after weight loss [76]. To date, substantial methodological differences still hinder direct comparisons in the outcomes of these studies, but evidence is emerging on how different lifestyle interventions are affecting an individual's physiology. For instance, exercise regimens may counteract some of the ghrelin rises seen following energy restriction and also increase PYY secretion [77,78]. Different approaches to dietary interventions may also have differential impacts on gut hormone profiles. Reductions in ghrelin have been seen with high-protein, low-carbohydrate diets and ketogenic diets, which can also suppress appetite [79,80]. Taken together, these findings suggest that individualizing lifestyle intervention based on a person's gut hormone profile could improve outcomes and weight gain maintenance in the first steps of obesity treatment algorithms.

Weight loss maintenance insights from bariatric surgery

Bariatric surgery, to date, is the most effective treatment for people with severe obesity. The Roux-en-Y gastric bypass and sleeve gastrectomy are the most commonly performed procedures worldwide

and lead to marked and sustained weight loss in the long term, combined with improvement or remission of obesity-related comorbidities such as type 2 diabetes [81]. In contrast to lifestyle interventions, people following bariatric surgery experience a significant change in eating behaviour, characterized by a reduction in hunger, increased satiety, changes in food preference away from energy-dense food, and changes in their senses of smell and taste [82, 83]. These eating behaviour changes lead to a reduction in energy intake, which drives weight loss. In stark contrast to dietary energy restriction, bariatric surgery results in changes in systemic physiology that favour weight loss maintenance. Bariatric surgery therefore offers a unique research opportunity to further our understanding of the physiology of weight loss maintenance in order to develop new and effective management strategies for obesity. Figure 11.2 compares the metabolic effects of energy restriction to bariatric surgery.

Remarkably, bariatric surgery leads to reversal of several pathophysiological aspects of obesity: for instance, meal-stimulated gut hormone profiles change, there are improvements in inflammatory changes, as well as a more favourable intestinal microbial profile [84]. These changes are brought upon through the anatomical changes to the GI tract from the surgical procedure, hence physiological responses also differ between the two procedures. In Roux-en-Y gastric bypass, the stomach is bypassed through creating a small pouch, which is anastomosed with the mid-jejunum [85], allowing ingested nutrients to bypass the stomach, duodenum, and proximal jejunum. Sleeve gastrectomy involves removal of 80–90% of the stomach [86]. Roux-en-Y gastric bypass results in a marked rise in meal-stimulated circulating levels of PYY, GLP-1, and other anorectic peptides; these changes are also seen post-sleeve gastrectomy but to a lesser extent [87]. Sleeve gastrectomy, by means of removing most of the ghrelin-producing cell population, leads to a significant reduction in ghrelin levels. However, responses to bariatric surgery are highly variable and follow a broad normal distribution [88]. Individual variability has also been correlated to meal-stimulated gut hormone profiles, with poor responders having lower levels of meal-stimulated GLP-1 and PYY [88]. Understanding the causality of this variation will provide valuable insights into developing improved and individualized approaches in the treatment of obesity and type 2 diabetes.

Genetic factors

Evolutionary perspectives

Metabolic pathways that control body weight have evolved over thousands of years. Eating is critical to survival and therefore it is hardly surprising that it has evolved to be inherently rewarding [89]. Metabolic and reward-related processes at the level of CNS centres regulating behaviour, including eating behaviour, are subject to evolutionary changes over time. Orientation to locate food, the ability to consume large quantities of food when this was available, as well as the ability to store energy for this to be mobilized when food was unavailable were once critical for survival. Mutations to favour an increased ability to store energy are seen in multiple species. MC4R mutations linked to increasing appetite and resisting starvation have been identified in animals adapting to nutrient-poor environments [89]. The human race, as well as most species, for the majority of its history lived and evolved in conditions of scarce energy availability. Our environment has only

changed to conditions of permanent and surplus energy availability over the past few decades, creating a significant gene–environment mismatch.

Excess adiposity in our current environment where food is permanently available in surplus has been termed ‘a normal response to an abnormal environment’ [90]. However, although susceptibility is largely determined by genetic factors, environmental, epigenetic, social, and cultural factors determine phenotypic expression [91]. The following sections of this chapter review the evidence on genetic predisposition and the multiple additional factors contributing to an individual’s weight and obesity risk, which are summarized in Figure 11.3. Further information about the genetics of obesity is found in Chapter 13.

Monogenic obesity

Monogenic obesity accounts for approximately 7% of cases of severe early-onset obesity [92]. The impact of single-gene loss of function highlights the role of these respective genes and proteins in the regulation of body weight. Understanding the physiological consequences of loss of function has important implications for developing novel management strategies for obesity.

Leptin and leptin receptor mutations

Loss-of-function mutations of the leptin gene, resulting in congenital leptin deficiency, lead to severe obesity from a very young age [93]. Leptin deficiency can be successfully treated with recombinant human leptin, which reverses the associated metabolic abnormalities. Interestingly, a case report of an individual with leptin deficiency receiving supplementation highlights that treatment with leptin resulted in significant rises in meal-stimulated GLP-1, PYY, and insulin levels, as well as reductions in ghrelin levels [94]. This illustrates the regulatory effect of leptin on ghrelin secretion and the interplay between leptin, GLP-1, and PYY. Mutations in the leptin receptor gene account for up to 3% of cases of severe obesity [93].

MC4R melanocortin-signalling pathway mutations

A series of mutations disrupting melanocortin signalling have been identified in humans. MC4R mutations cause 5–6% of cases of early-onset severe obesity [32]. MC4R gene mutations of varying functional significance are present in approximately 1 in 1000 adults in the UK [95]. The degree of receptor dysfunction correlates with the clinical phenotype. Loss-of-function mutations cause early-onset obesity, accelerated growth, and hyperphagia.

POMC null mutations also cause early-onset obesity, hyperphagia, and adrenocorticotrophin (ACTH) deficiency. Heterozygous mutations resulting in loss of function in melanocortins, however, increase the risk of obesity, but do not invariably cause obesity clinically [32]. The prohormone convertase 1 (PCSK1) has a role in converting POMC to ACTH, which is then further converted to α-MSH. PCSK1 mutations lead to severe obesity, hypogonadotropic hypogonadism, post-prandial hyperglycaemia, and, in infants, small intestinal malabsorption, which highlights that melanocortin signalling has a role in enteroendocrine cell function [96, 97].

Other monogenic causes

Further, rarer monogenic causes of obesity involve genes encoding proteins downstream of MC4R, including brain-derived neurotrophic factor (BDNF) and single-minded 1 (SIM1), a transcription factor involved in the development of hypothalamic nuclei [93]. The autosomal recessive Bardet-Biedl syndrome is characterized by

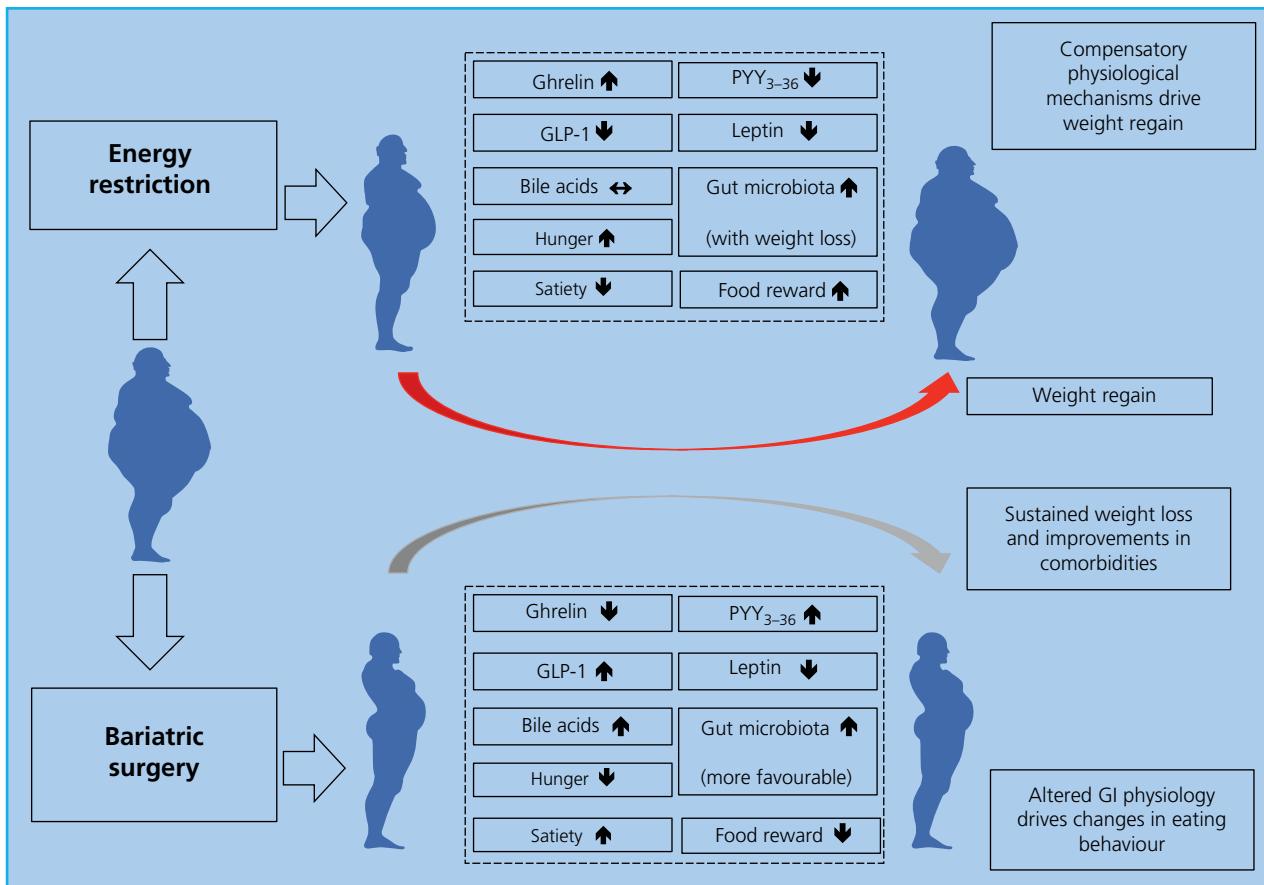

Figure 11.2 Physiological changes following energy-restriction diets compared to bariatric surgery. Weight loss caused by energy-deficit diets is followed by very powerful physiological adaptations that defend the original higher body weight and drive weight regain [4]. Circulating ghrelin levels rise and individuals report increased appetite. Circulating post-prandial levels of glucagon-like peptide-1 (GLP-1) and peptide YY3-36 (PYY) are reduced, leading to reduced perceived satiety. Brain response to food cues, assessed using functional imaging, increases in reward regions. These changes drive the weight regain that commonly follows weight loss

ciliary dysfunction causing obesity, learning difficulties, polydactyly, retinal dystrophy, hypogonadism, and renal disease [98].

Polygenic susceptibility to obesity

The heritability of weight has been well established, from studies on families, twins, and jointly or separately housed siblings, reporting heritability estimates of up to 70% [91]. Genome-wide association studies (GWAS) have identified over 97 BMI-associated genetic loci [99]. The strongest association between these single-nucleotide polymorphisms (SNP) and BMI comes from the obesity-risk variant of rs9939609 of the fat mass- and obesity-associated (*FTO*) gene. The high-risk AA variant is linked to increased appetite levels and preferences for energy-dense foods, and those with the AA variant are on average 3–4 kg heavier than those without the risk allele and have a 1.67-fold increased risk of obesity [100]. Adults of normal weight homozygous for the obesity-risk rs9939609 variant have higher post-prandial circulating ghrelin levels, increased hunger, and altered responses to food cues in CNS reward regions, compared to people with the low-risk variant [101]. While our understanding of these genetic variants remains limited, a recent meta-analysis concluded that GWAS-identified genetic variants

through lifestyle interventions [4]. In contrast, bariatric surgery leads to a multitude of changes in gastrointestinal (GI) physiology, as a result of the altered GI anatomy and/or nutrient transit from the surgical procedures [82]. Post-prandial levels of GLP-1 and PYY are elevated and ghrelin levels are reduced. Favourable changes are seen in the microbiome. Individuals report reduced hunger, increased satiety, a shift in food preference away from energy-dense foods, and the brain's response to food cues is reduced. These changes lead to a change in eating behaviour and a reduced energy intake, which drive weight loss [4].

only explain approximately 6% of population-wide variance in BMI [102]. A novel prediction tool for genetic susceptibility identified a 13 kg gradient in weight and a 25-fold gradient in risk of severe obesity across the polygenic score's deciles [103]. While the degree to which these polymorphisms explain the heritability of BMI remains incompletely understood, it is hypothesized that epigenetic factors may account for at least part of this gap in clarifying BMI heritability [104].

Epigenetic factors

Over recent decades, environment- and lifestyle-driven changes on a background of a strong genetic susceptibility have led to a rising prevalence of obesity [105]. Within population cohorts of people sharing the same environment only a subset develop obesity, and epigenetic studies have offered some insights into understanding weight gain through the interaction of genes and environment. Epigenetic studies have highlighted that, beyond an individual's genome, several factors influencing gene expression have an impact on weight and the risk of developing obesity [106]. The main

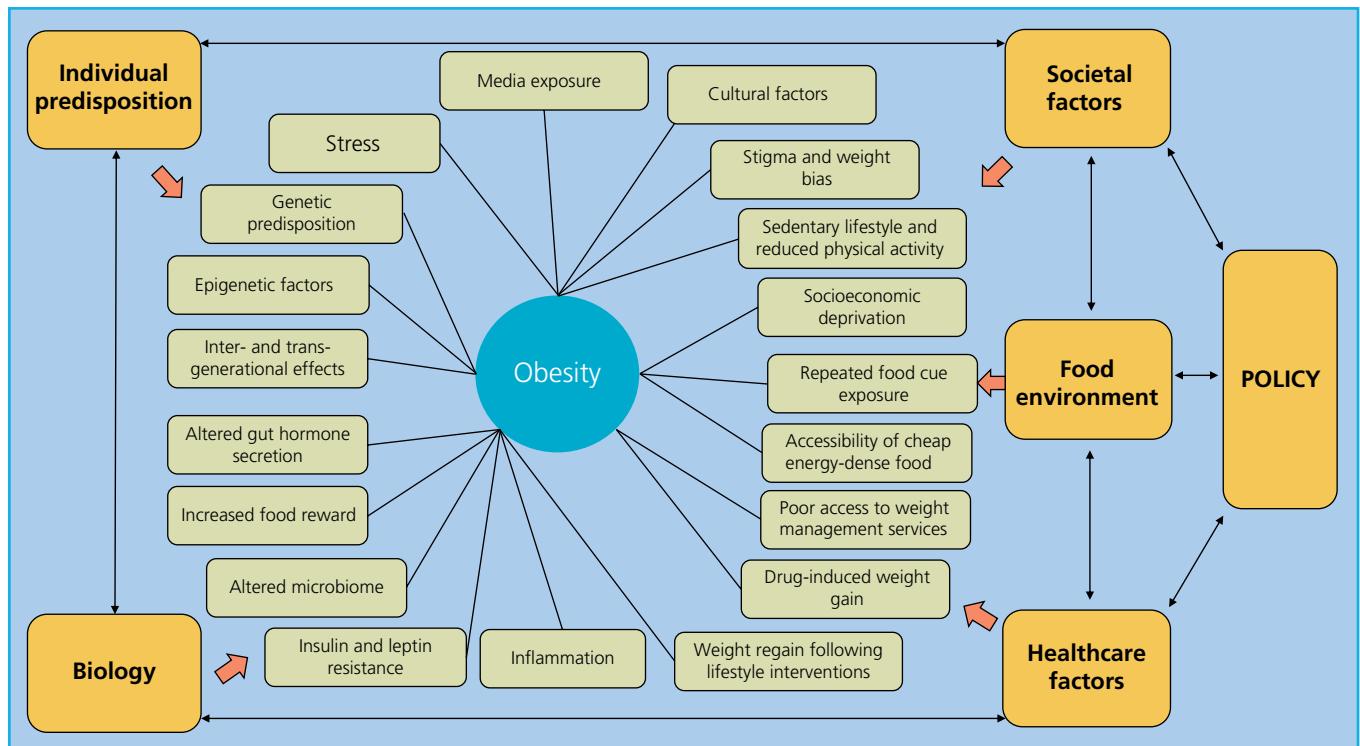

Figure 11.3 Factors contributing to the rising prevalence of obesity. The causes of obesity are numerous and multifactorial. The risk of obesity is an interplay between an individual's genetic predisposition, combined epigenetic factors, environmental exposures, their food environment, as well as social and cultural factors, which determine phenotypic expression [55].

epigenetic mechanisms involve DNA methylation, histone modification, and non-coding RNA, which can be passed on either through cell division (mitotically) or through transgenerational inheritance (meiotically) [107].

Environmental factors drive epigenetic changes in parental reproductive cells, in the intrauterine environment during fetal development, as well as in the perinatal period, which all play a key role in the development of physiological functions within every organ and tissue [107]. Gene expression may further be affected by environmental factors in childhood, up to and throughout adulthood. For instance, leptin gene methylation has been associated with maternal factors, such as maternal pre-conception weight, gestational weight gain, and gestational glycaemia and diabetes, which all contribute to offspring obesity risk [108, 109]. Similar changes in methylation, associated with obesity risk, have been described in the genes encoding adiponectin, POMC, and NPY [62, 110, 111]. Maternal factors during pre-conception and intrauterine development with potential implications for BMI have been associated with methylation changes in genes encoding insulin, immune cells, and growth factors [106]. A growing body of evidence now suggests that maternal nutritional status, stress, and exposure to smoking both in the peri-conception phase, during pregnancy, and during lactation significantly impact offspring obesity risk [112–114].

In addition to maternal factors, recent studies into epigenetic contributors to obesity have also highlighted paternal factors affecting intergenerational obesity risk in their offspring [115]. Increasing evidence suggests that paternal diet and obesity at the time of conception have impacts on the obesity risk of their children [112, 115]. Importantly, new evidence from animal models suggests that short-term changes in pre-conception paternal diet can alter offspring obesity risk [116].

Beyond the direct impact of maternal and paternal nutrition and health on the next generation, transgenerational epigenetic effects further influence obesity risk. An epidemiological study followed up two generations after exposure to intrauterine malnutrition during the Dutch famine of the Second World War. *In utero* famine exposure was associated with increased adiposity and adverse life outcome in the following generation [117]. Both maternal and paternal obesity have also been shown to have transgenerational effects in terms of increasing obesity risk in future generations; however, the link between paternal obesity and future generational obesity risk appears stronger compared to maternal obesity [118, 119].

Studies in weight-disconcordant monozygotic twins highlight the impact of environmental and epigenetic factors on weight and obesity risk [120]. Our epigenome is under constant interaction with the external environment and is continually influenced by environmental exposures. Dietary factors, exposure to toxins, exercise, and stress are among additional lifetime exposures with identified epigenetic consequences for weight and obesity in both childhood and adulthood [106].

Environmental and behavioural factors

Circadian rhythms, sleep patterns, and obesity

Human physiology changes throughout the day and all organs and metabolic processes are subject to diurnal variations and circadian rhythms. This also applies to several metabolic hormones that regulate glucose and energy homeostasis, including ghrelin, leptin, adiponectin, cortisol, and insulin [121–123]. Disruption in the circadian pattern of metabolic hormone secretion has been linked to obesity, and epidemiological data link sleep deprivation and

deranged sleep patterns with an increased risk of weight gain and obesity. Shift workers regularly working overnight, for instance, have an increased risk of developing obesity and night-time eating has been associated with food choices favouring energy-dense foods [10, 124]. Ghrelin secretion is higher in the biological evening compared to the morning, which in healthy adults correlates with hunger [121]. Disrupting this chronicity through a 12-hour behavioural cycle inversion led to higher post-prandial ghrelin levels, combined with increased cravings for energy-dense foods [121]. In a high-fat diet-induced obesity rat model, obesity was associated with altered diurnal rhythms in secretion profiles of GLP-1 and PYY, which occurred prior to loss of glycaemic regulation and persisted even when animals were eating the same amount of calories, suggesting that obesity *per se* can alter the chronobiology of gut hormone secretion profiles [125].

In addition to reversal of sleep patterns, sleep deprivation and fragmentation have both been associated with metabolic hormone dysregulation and weight gain [14]. GLP-1 levels reduce following sleep fragmentation, correlating with lower satiety levels [126]. Sleep deprivation is not only associated with a higher energy intake and reduced insulin sensitivity, but also with a reduction in the amount of weight lost during dietary interventions [127–129]. Sleep duration has been linked to higher weight loss and improved weight loss maintenance in people with obesity undergoing lifestyle interventions [130, 131]. The effect of sleep duration on weight is particularly evident in adolescents, where sleep duration has a strong negative association with BMI, independent of other obesity risk factors [132]. Taken together, these findings suggest that sleep has a role in the preservation of fat-free mass.

The timing of energy intake affects the metabolic control of energy homeostasis. Late eating has been linked to decreased energy expenditure, decreased carbohydrate utilization, and reduced insulin sensitivity [122]. In line with this finding, people who consume the majority of their daily energy intake early in the day have a lower risk of developing overweight or obesity [133]. Maintaining a regular meal pattern throughout the day with the majority of energy intake early in the day, combined with fasting periods overnight, leads to metabolic benefits, including reduced inflammation and a more favourable microbiome profile [134]. Furthermore, a recent systematic review and meta-analysis of intermittent fasting interventions in adults with overweight and obesity demonstrated that intermittent fasting, at least in the short term, had benefits in terms of body weight reductions [135].

The effect of dietary composition

It is without doubt that the increased food availability in the modern environment and the contact exposure to food cues, on the background of genetic predispositions, are major drivers for the increasing prevalence of overweight and obesity. However, in addition to a consistently high energy availability, the type and composition of food also affect weight and risk of developing overweight and obesity. The energy density of available food has been associated with developing overweight and obesity. In particular, consumption of energy-dense nutrient-poor foods in childhood is directly related to weight gain and adult obesity [136, 137]. Furthermore, energy-dense nutrient-poor foods, despite the higher calorie content per gram of food, have been associated with increased post-prandial appetite, food cravings, and lower satiety [138]. Socioeconomic factors are also directly related to energy-dense food consumption during childhood and the risk of obesity in adult life, in parallel with the low cost of energy-dense foods [136, 139].

The impact of food processing has recently been the focus of clinical studies. Hall et al. demonstrated that in healthy adults, a diet comprising ultra-processed food results in weight gain and excess energy intake during *ad libitum* food consumption compared to a diet consisting of unprocessed food [140]. Further findings in this study highlighted that ultra-processed food was consumed faster and that GLP-1 levels were reduced after a two-week period following the diet [140]. Ultra-processed foods commonly have a higher sugar content compared to the sweetness of the taste stimuli they elicit during eating. Integration of sweetness information from taste processing is a strong predictor of the reward value of food [141]. Therefore, one proposed mechanism suggests that in ultra-processed food, a mismatch between sweetness and nutrient contents may disrupt the signalling of its nutritional content from the gut to the CNS and thereby promote excess energy intake [142].

Gene-environment interaction studies have identified consumption of sugar-sweetened beverages and a high intake of fried foods and saturated fatty acids as risk factors for weight gain and obesity in people with an underlying genetic susceptibility [143]. Furthermore, advances in nutrigenetics are beginning to highlight individual genetic variants that may elicit more favourable metabolic responses to diets with different macronutrient compositions [144]. It is evident that there is no universally effective dietary intervention to elicit and maintain weight loss for people living with overweight and obesity. Individualizing interventions based on individual responses remains the most adequate approach for medical nutritional interventions for obesity, until advances in the understanding of gene-environment interactions with respect to nutritional interventions allow further personalization of care [145].

Medications and toxins

With improved treatments for multiple conditions in recent years, a higher percentage of the population now take medical treatments for chronic diseases. Drug-induced weight gain is a common side effect and a considerable contributor to the rising prevalence of obesity. In several areas of medical practice, a growing range of pharmacotherapy options allows the choice of alternatives with a more favourable side-effect profile. Importantly, novel agents with beneficial effects on weight and cardiovascular outcomes for the management of type 2 diabetes now permit a move away from agents causing weight gain in people with type 2 diabetes and overweight or obesity. However, within multiple other areas of clinical practice drug-induced obesity represents a growing challenge, particularly related to the use of antiretrovirals and antipsychotics. These changes in weight have adverse impacts on morbidity and mortality, quality of life, and medication taking. Therefore, understanding the physiological drivers and offering interventions to prevent and/or treat drug-induced weight gain will be crucial both in terms of reducing obesity-related complications but also for outcomes relating to the underlying condition.

Antipsychotics

Antipsychotic-induced weight gain is an important side effect of treatment with first- and second-generation antipsychotic drugs. Importantly, weight gain is common and occurs quickly following initiation of the drug. According to a meta-analysis, the risk of clinically significant weight gain across a range of antipsychotics was estimated at $\geq 7\%$ compared to placebo [146]. Weight gain of variable degrees is associated with almost all antipsychotic agents. Of second-generation antipsychotics, clozapine and olanzapine

carry the highest risk of weight gain, followed by others including aripiprazole, quetiapine, and risperidone [147]. A large trial of antipsychotic drug use showed that 30% of participants taking olanzapine gained 7% or more of their original body weight over an 18-month period [148]. The extent of duration of weight gain also varies between drugs: for instance, weight gain with clozapine has been described to continue for up to 46 months before reaching a plateau.

With regard to understanding the underlying processes driving weight gain, most data stem from olanzapine, as this is one of the most commonly prescribed antipsychotics and causes significant weight gain. Olanzapine directly stimulates appetite and leads to increased energy intake and adiposity [149]. These effects are more pronounced in people with lower baseline BMI and younger age [146]. Both olanzapine's and clozapine's orexigenic effects, although incompletely understood, are thought to be at least partially caused by the drugs' action on hypothalamic appetite-regulating networks. Olanzapine directly stimulates hypothalamic orexigenic neurons, whereas clozapine inhibits CART-expressing anorectic circuits [150]. Both olanzapine and clozapine reduce resting metabolic rate [151,152].

Antiretrovirals

The introduction of antiretroviral therapy has transformed human immunodeficiency virus (HIV) into a chronic disease over the past 30 years. People with HIV on adequate antiretroviral therapy now have a life expectancy comparable to that of the general population. However, antiretroviral therapy is complicated by multiple metabolic side effects, including hyperglycaemia and type 2 diabetes, hyperlipidaemia, weight gain, and obesity. Importantly, whereas weight gain following initiation of antiretroviral therapy in underweight individuals and those within the normal BMI range reduces mortality, overweight and obesity in people with HIV are associated with a greater risk of metabolic complications compared to people without HIV. Most older agents including nucleoside reverse transcriptase inhibitors (NRTIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs) were not directly linked to weight gain. However, the combination with tenofovir alafenamide has been associated with significant increases in weight [153,154]. Protease inhibitors (PIs) have also been associated with weight gain and increases in adiposity compared to NNRTIs [155]. The newer class of integrase strand transfer inhibitors (INSTIs) have become increasingly used in HIV treatment due to improve tolerability and their lack of susceptibility to HIV drug resistance. INSTIs are, however, associated with marked increases in weight from baseline and compared to other antiretrovirals [156]. A pooled analysis of antiretroviral trials with respect to weight gain identified low CD4 cell count, higher viral load, female sex, and black race as risk factors for higher weight gain [156]. The same analysis demonstrated average weight gain of >5% in 37% of trial participants and >10% in 17%.

Although the exact mechanisms through which antiretroviral therapy causes weight gain are unknown, novel research studies are illustrating several pathways, including interactions with adipose tissue, gut hormone secretion, and direct effects on the hypothalamic circuits controlling weight and eating behaviour. HIV itself, as well as antiretroviral therapy, induces direct inflammatory changes within adipose tissue. Viral proteins are commonly deposited within adipose tissue and antiretrovirals directly exert effects on adipose tissue biology, including increased inflammatory markers, lipolysis, and insulin resistance [157].

These processes also result in increased ectopic fat deposition in the liver and pericardium. A mechanistic study into the metabolic effects of antiretroviral therapies in people receiving combinations of NRTIs, NNRTIs, and PIs demonstrated significantly higher levels of ghrelin in people with hypertriglyceridaemia compared to those with normal triglycerides [158]. The higher weight gain associated with INSTIs is suggested to originate due to their direct effect on hypothalamic appetite-regulation circuits. One proposed mechanism is that INSTIs directly inhibit MC4R, thereby directly generating an orexigenic response, as dolutegravir can inhibit α-MSH binding to MC4R [159]. Although these mechanisms are yet not fully elucidated, there is a growing population of people living with HIV and obesity who face a higher risk of metabolic morbidity and mortality.

Antidepressants

Depression is among the most common mental health conditions and often coexists in people living with obesity. Although there is an association between depression and weight gain, certain antidepressant drugs also directly cause weight gain. Mirtazapine, citalopram, fluoxetine, sertraline, and paroxetine are among commonly prescribed antidepressants that have been associated with weight gain [160]. In a 10-year follow-up study, the incidence of >5% weight gain associated with antidepressant use was 11.2 per 100 person-years [161].

Other drugs

Further drugs associated with weight gain include mood stabilizers and anti-epileptic agents such as lithium, valproic acid, gabapentin, and carbamazepine [162].

Weight stigma and adverse impact on biology

People living with obesity frequently experience stigma, weight bias, and discrimination. The impact of stigma and weight bias on people living with obesity themselves, the rising prevalence of obesity, and the efficacy of obesity management strategies have been poorly understood and underestimated. Examples of weight bias include the notions that obesity is a lifestyle choice and that people living with obesity lack self-discipline, and are lazy or unmotivated. Internalized weight bias is highly prevalent even among the general population [163]. Weight stigma and bias have been reported in a multitude of settings including education, healthcare, and employment [164]. Exposure to weight bias and stigma leads to increased energy intake, exercise avoidance, and weight gain [164–167].

Furthermore, weight bias internalization adversely affects both mental and physical health [168]. Physiological mechanisms such as increased stress levels are likely to be driving these adverse effects on health. Exposure to stigmatizing stimuli increases cortisol reactivity in lean and overweight women [169]. Weight stigma was associated with obesity, risk of type 2 diabetes, depression and anxiety, cortisol levels, oxidative stress, and inflammatory markers in recent a meta-analysis [170]. There is now accumulating evidence suggesting that stigma directly contributes to the rising prevalence of overweight and obesity. It is therefore critical, as part of responding to the growing obesity epidemic, to provide fair, effective care for people living with obesity to eliminate weight stigma. A new public narrative challenging existing preconceptions, which is based on scientific knowledge, is necessary [171]. Incorporating strategies to address healthcare-related weight stigma is also required in treatment algorithms and guidelines for healthcare professionals caring for people living with obesity [172].

Effects of societal factors and policy

Factors contributing to the growing prevalence of obesity arise from multiple societal sources. Evidence suggests that regional differences even within the same country can lead to local variations in obesity risk [173]. Suggested factors contributing to obesity risk in children and adolescents include paternal obesity, paternal smoking, low physical activity levels, and media exposure [173]. Moving from a neighbourhood with high levels of poverty to an area of lower poverty reduces the prevalence of severe obesity [174]. A longitudinal UK cohort study identified parental obesity, high television exposure, weight gain in the first year, and short sleep duration as risk factors for childhood obesity [175]. Furthermore, food and beverage marketing increases dietary intake of energy-dense foods and beverages in children [176]. Carriers of the high-risk allele of the *FTO* gene, in particular, are highly susceptible to the effects of food marketing, compared to carriers of the low-risk variant [177]. Further societal factors identified as increasing the risk of weight gain and obesity include the increase of desk- and computer-based work across most occupations, reductions in physical activity, and increased screen time in the entertainment industry [55].

In order to reverse the obesity epidemic, implementation of effective individualized treatment strategies is required for people living with obesity, combined with preventive measures to reduce the rising prevalence of the disease. To be effective, policy changes would require the participation of multiple sectors. The food environment in schools has been highlighted as a potential area for preventive policies to reduce obesity rates among school-aged children. To date, although studies are starting to demonstrate that regulating food standards can lead to significant reductions in energy intake during the school day, the longer-term impacts of such

policies are not yet known [178]. Ensuring that the healthiest food choices for a given individual are also among the most accessible and affordable is among the World Health Organization's recommendations for obesity prevention [2]. Eradicating weight bias and improving knowledge of the science underlying weight gain and obesity among both the public and healthcare professionals are also critical [171]. Finally, available and accessible community and specialist-led obesity services, offering a range of services including nutritional and exercise therapies, psychological interventions, medical and surgical treatments, pre-conception advice and lifestyle modification, and antenatal care, as well as management of obesity-related complications using evidence-based and individualized approaches, will be necessary to improve obesity rates, care, and outcomes [55, 112].

Conclusion

The global prevalence of obesity has tripled since the 1970s and continues to rise exponentially. Obesity is a chronic, remitting and relapsing disease that can lead to multiple debilitating physical and psychological complications. Weight gain and obesity are undoubtedly highly complex and multifactorial. The reasons why we gain weight are multifaceted and involve a combination of genetic susceptibility, epigenetic influences, and environmental factors, which all contribute to a biology that favours weight gain. Due to the complex nature of obesity and the myriad factors affecting predisposition to weight gain and responses to weight loss interventions, individualizing treatment approaches will be essential. An increasing understanding of the complex interrelated mechanisms driving obesity is also necessary to offer effective treatments to people living with obesity, but also to implement successful preventive strategies.

3 Pathogenesis of Diabetes

12 The Genetics of Diabetes

Rashmi B. Prasad^{1,2}

¹Lund University Diabetes Centre, Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, Malmö, Sweden

²Institute for Molecular Medicine Finland (FIMM), Helsinki University, Helsinki, Finland

Key points

- Diabetes can be considered as a spectrum of disorders, with type 1 diabetes and type 2 diabetes as two ends of the spectrum and maturity-onset diabetes of the young (MODY), latent autoimmune diabetes in adults (LADA), and other types being the intermediates.
- Type 2 diabetes is a complex disease characterized by impaired insulin secretion, insulin resistance, or both and is caused by the intricate interplay between genetic, epigenetic, and environmental factors.
- Genetic architecture of a complex phenotype is defined by the number, frequencies, and effect sizes of causal alleles. Current understanding of the genetic architecture of type 2 diabetes points towards a combination of common single-nucleotide polymorphisms (SNPs), protective and rare variants, parent-of-origin effects, structural polymorphisms, and microRNAs, which can further be complicated by gene–gene and gene–environment interactions as well as epigenetics.
- The technical revolution in the field of genetics encompassing genome-wide association studies (GWAS) and next-generation sequencing has allowed identification of >1000 genetic variants in the risk for and protection of type 2 diabetes and many more with diabetes-related traits.
- Reported SNPs significantly associated with type 2 diabetes account for <20% of the heritability of type 2 diabetes. There may be several reasons for these shortcomings: too simple assumptions about the genetic architecture of the disease, ignoring additive and intrauterine effects, and restricting the analysis to only SNPs associated at 5×10^{-8} .
- The CAPN10 gene on chromosome 10 encoding calpain 10 was the first type 2 diabetes susceptibility gene to be identified through linkage studies. The greatest success in linkage studies relates to the

discovery of variants in *TCF7L2* as being associated with type 2 diabetes, but not the cause of linkage.

- The first candidate gene reproducibly associated with type 2 diabetes was *PPARG*, encoding the nuclear receptor PPAR-γ. The PPAR-γ receptor is a molecular target for thiazolidinediones, a class of insulin-sensitizing drugs used to treat type 2 diabetes, making it a compelling candidate gene.
- In 2007 several GWAS on type 2 diabetes were published. Uniquely, for the first time most of them reported associations to the same SNPs and genes: *TCF7L2*, *FTO*, *CDKAL1*, *HHEX*, *SLC30A8*, *IGF2BP2*, and *CDKN2A/2B*. These discoveries were therefore coined by *Science* as the Breakthrough of the Year 2007. Most of these variants have very modest risks. An exception comes from Greenland, where a common variant in the *TCFCB4* gene was strongly (odds ratio [OR] close to 10) associated with glucose tolerance as measured from an oral glucose tolerance test.
- The vast majority of type 2 diabetes-associated risk variants seem to influence β-cell function (e.g. *TCF7L2*, *CDKAL*, *SLC30A8*).
- While monogenic forms of diabetes (MODY) have been successfully ascribed to highly penetrant mutations in more than 10 genes, only a few rare variants have been associated with type 2 diabetes, among them rare variants in the *PAM* and *PDX1* genes.
- Also a few variants protecting from type 2 diabetes have been reported, including variants in the *SLC30A8* and *TCF2* genes. Mimicking how these variants protect from type 2 diabetes represents an ideal scenario for the development of new drugs.
- To describe the full genetic architecture of type 2 diabetes, a systems genetic approach will be needed combining GWAS, DNA methylation and histone modifications, and expression profiling including mRNA, proteins, and metabolites.

Increase in diabetes prevalence

Diabetes refers to a group of metabolic diseases characterized by hyperglycaemia resulting from defects in insulin secretion, insulin action, or both [1]. The chronic hyperglycaemia of diabetes is associated with long-term damage, dysfunction, and failure of different organs, especially the eyes, kidneys, nerves, heart, and blood vessels. Diabetes is currently the fastest growing non-communicable

disease. Worldwide prevalence figures estimate that there were 537 million people with diabetes in 2021, estimated to increase to 783 million in 2045 [2]. India and China have the highest reported prevalence rates of diabetes with 65 and 98 million in 2013, respectively, more than 90% of which is considered to be type 2 diabetes. In Europe, ~8% of the population is affected by diabetes, 90% of which is accounted for by type 2 diabetes, making type 2 diabetes the fastest-increasing disease in Europe and worldwide [3].

The increasing prevalence of type 2 diabetes can largely be ascribed to the worldwide increase in obesity during the last 30 years; for instance, more than 60% of individuals older than 15 years in the UK and USA are overweight [4]. This has been attributed to a collision between genes and the environment. The social determinants of environmental factors tend to vary across populations and have changed rapidly over the last decades. A high energy-consuming lifestyle has been replaced by a Western sedentary one with little or no exercise and the consumption of an energy-dense diet. Meanwhile, genetic factors evolve at a slower rate across generations, and tend to favour the selection of *energy-saving thrifty genotypes*, which might have been beneficial for individuals living in times of unstable food supply by storing energy in times of surplus [5]. While this hypothesis provides an appealing explanation to the increase in obesity and type 2 diabetes, formal proof of it is still lacking.

Diabetes spectrum

Diabetes encompasses a range of heterogeneous metabolic disorders characterized by the inability of the body to assimilate glucose and maintain glucose homeostasis. Diabetes has been traditionally subdivided into type 2 diabetes and type 1 diabetes. However, this is an oversimplification of a rather complex situation. The concept of diabetes has grown over the past decades to the understanding that several different overlapping contributions from genetics and the environment can lead to manifestations of varying forms of disease. Contrary to being dichotomously distinct disorders, type 1 diabetes and type 2 diabetes can be considered rather as the two ends of a diabetes spectrum, with the intermediates comprising maturity-onset diabetes of the young (MODY), latent autoimmune diabetes in adults (LADA), and other subtypes.

Type 1 diabetes, also formerly known as juvenile diabetes or insulin-dependent diabetes, is a chronic condition that is due to autoimmune destruction of pancreatic β cells and is characterized by the (nearly) complete absence of insulin secretion and the presence of autoantibodies including glutamic acid decarboxylase (GAD) antibodies, leading to dependence on insulin injections. It is most often diagnosed in children, adolescents, or young adults under 35 years old. The incidence of type 1 diabetes varies based on geography, age, sex, and family history.

Latent Autoimmune Diabetes in Adults (LADA) is a common subgroup of diabetes accounting for ~7% of all individuals with diabetes in Europe. It is usually defined as GAD antibody-positive diabetes with onset after 35 years of age and no insulin requirement during the first six months after diagnosis [6–8]. LADA with high antibody titres is close to the type 1 diabetes part of the spectrum, whereas LADA with lower antibody titres is close to type 2 diabetes [9]. A family history of any form of diabetes is a strong risk factor for the development of LADA [10].

Maturity-onset diabetes of the young (MODY) refers to monogenic forms of diabetes with well-defined high-penetrance mutations in more than 10 different genes, and this number is still increasing (Chapter 20). The disease is characterized by autosomal dominant transmission of early-onset (<25 years) diabetes and varying degree of β -cell dysfunction [11]. It was long debated whether the MODY genes would harbour common, less-penetrant variants, increasing the risk of type 2 diabetes; now this seems to be the case for most of them, including *HNF1A*, *HNF4A*, *HNF1B*, *GCK*, and *PDX1* [12–14]. MODY shows extreme allelic heterogeneity, meaning that most

MODY mutations are unique; to date, there are >200 mutations described in the *GCK* (MODY2) and *HNF1A* (MODY3) genes [15,16]. The appropriate diagnosis of MODY requires sequencing. With the advent of next-generation sequencing technologies, accurate MODY diagnoses are much more feasible today.

Maternally inherited diabetes and deafness (MIDD) is due to the A3242G mutation in mitochondrial DNA (mtDNA) [15,17]. As mtDNA is only transmitted from the mother, MIDD shows maternal transmission. In addition to hearing loss, many individuals also display neurological problems similar to individuals with the MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke), which is caused by the same mutation in mtDNA.

Neonatal diabetes is defined as diabetes with onset at birth or during the first six months of life and has both transient and permanent forms [15]. Mutations in several genes cause neonatal diabetes (e.g. *KCJN11*, *SUR1*, *GCK*, *INS*), and an appropriate genetic diagnosis is a prerequisite for optimal treatment. Individuals with mutations in the *KCJN11* gene do not only have severe diabetes but also developmental defects (DEND). These conditions are improved after switching from insulin treatment to treatment with large doses of sulfonylureas [18].

Diabetes can also develop secondary to pancreatic disease or other endocrine disorders and is referred to as *secondary diabetes*.

Type 2 diabetes is the most prevalent form, constituting 80–90% of all reported cases. It is the result of a complex interplay between genetic, epigenetic, and environmental factors. Type 2 diabetes develops when pancreatic β cells can no longer produce enough insulin to compensate for the insulin resistance, often imposed by increasing obesity. There is no formal definition of type 2 diabetes; individuals who do not fulfil criteria of type 1 diabetes, LADA, secondary diabetes, or monogenic forms of diabetes are considered to have type 2 diabetes. Type 2 diabetes is more often associated with increased age, wherein age of onset is usually over 35 years [19]. However, it is increasingly reported in adolescents in high-risk countries such as India and China [3]. The heritability of type 2 diabetes is discussed later.

All forms of diabetes represent a range of genetic aetiologies from the monogenic MODY variants to type 2 diabetes, which is a complex heterogeneous polygenic disease with a strong environmental component. The *ANDIS* (*All New Diabetics in Scania*) project in southern Sweden represents a new attempt to reclassify diabetes into subgroups based on genetic markers and biomarkers (Figure 12.1). A similar project has been initiated in Uppsala, Sweden, with the same goal (*ANDIU – All New Diabetics in Uppsala*).

Diabetes heterogeneity

Type 2 diabetes is diagnosed on the basis of one metabolite, glucose, and on the basis of exclusion criteria. If the individual does not have type 1 diabetes or monogenic diabetes, they are classified as having type 2 diabetes. However, this does not consider the underlying pathogenic causes or disease outcomes. Elevated glycaemia can be the consequence of multiple pathogenic processes occurring in myriad combinations, including rising insulin resistance and defective insulin secretion; consequently, type 2 diabetes is a heterogeneous disease [20]. Disease severity, progression, treatment strategies, and response can vary widely between individuals. The *palette model* of type 2 diabetes has been proposed, in which each person's individual risk for dysregulation in one or more component pathways

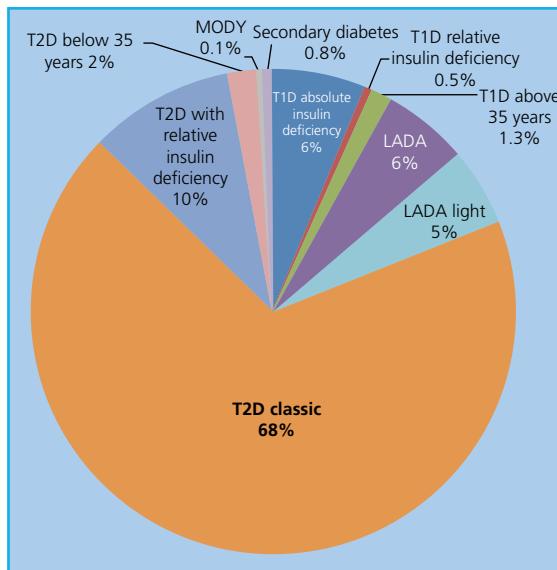

Figure 12.1 The spectrum of diabetes subgroups. The data are from the ANDIS project (All New Diabetics in Scania; <http://andis.ludc.med.lu.se>) in April 2012, which at that time included 5800 individuals with newly diagnosed diabetes aged 0–100 years. The criteria used for diagnosis are as follows: Type 1 diabetes (T1D): age at onset <35 years, C-peptide <0.2 nmol/l, and glutamic acid decarboxylase (GAD) antibodies >20; type 1 diabetes with relative insulin deficiency if C-peptide 0.2–0.6 nmol/l. Type 2 diabetes (T2D): age at onset >35 years, C-peptide >0.6 nmol/l, GAD antibodies <10; type 2 diabetes with relative insulin deficiency C-peptide 0.2–0.6 nmol/l. Latent autoimmune diabetes in adults (LADA): age at onset >35 years, GAD antibodies >20; LADA light if GAD antibodies 10–20. The data clearly illustrate the difficulty in classifying individuals with diabetes at diagnosis, with 19% unclassifiable. MODY, maturity-onset diabetes of the young.

can contribute to the overall development of type 2 diabetes [21]. Three primary approaches have emerged to address this heterogeneity. The first involves utilizing a set of clinical variables to divide individuals into subgroups based on manifestation of disease patterns. To this end, we performed data-driven machine learning on commonly measured clinical variables (age at diagnosis, sex, body mass index, glycated haemoglobin [$\text{HbA}_{1\text{c}}$], and homeostatic model 2 of assessment for insulin secretion [HOMA-B] and resistance [HOMA-IR]) in individuals with newly diagnosed diabetes. Five reproducible clusters were identified: severe autoimmune diabetes (SAID), which included both type 1 diabetes and LADA; severe insulin-deficient diabetes (SIDD); severe insulin-resistant diabetes (SIRD); mild obesity-related diabetes (MOD); and mild age-related diabetes (MARD). Each of these groups differed with respect to characteristics, risk of complications, and progression [22]. These subgroups were replicated in several populations [23, 24] and are partially genetically different [25].

Given that phenotypes may vary across time and with different exposures, a second approach uses genetic information rather than phenotypes to subgroup individuals. This strategy minimizes the contribution of environmental factors and produces subgroups reflecting genetically driven pathways that predispose individuals differentially to type 2 diabetes-related metabolic disease outcomes [26]. A third approach combined both phenotype information including variables derived from oral glucose tolerance tests, magnetic resonance imaging (MRI)-measured body fat distribution, and liver fat content as well as genetic information, and identified six subtypes (implemented in individuals with prediabetes thus far) [27]. The subgrouping also opens up new avenues for research

allowing better definitions of underlying pathogenic defects and refining of stratification. Moreover, more advanced methods using artificial intelligence and detailed phenotypes together with genetic information could allow for better subclassification and identification of individuals at high risk for the disease and development of complications [20, 28, 29]. Genetic studies into these subgroups would further help unravel their underlying pathophysiology.

Heritability of type 1 diabetes and type 2 diabetes

Heritability is a measure of the genetic influence on a particular trait. For type 1 diabetes, the risk in offspring of an affected mother is 2–4%, whereas the risk from an affected father is as high as 5–8% [30, 31]. The sibling relative risk (RR) of type 1 diabetes is estimated at 15 [32–34]. Type 1 diabetes concordance in monozygotic twins is ~40%, but is dependent on age of diagnosis [35]. In twins with type 1 diabetes, the age at diagnosis was strongly correlated in identical pairs ($\text{RR} = 0.94$) compared to non-identical twins ($\text{RR} = 0.59$) [36]. Type 1 diabetes results from the interplay between genetic, epigenetic, and environmental factors. Genetic studies have reported >200 loci associated with type 1 diabetes, which explain ~80% of the heritability [19]. Environmental factors incorporate enterovirus infections, including viruses of the picorna family, as they are seen more often among individuals with newly diagnosed type 1 diabetes than in the general population, and they precede the appearance of autoantibodies, environmental pollutants, gut flora variations, and vitamin D exposure (Chapter 4) [37–39].

Type 2 diabetes clusters in families and the risk of developing type 2 diabetes depend on both genetic and environmental factors. Heritability parameters facilitate understanding of the genetic architecture of complex traits such as type 2 diabetes. However, heritability estimates have varied between 25% and 80% in different studies; the highest estimates are seen in those studies with the longest follow-up periods. The lifetime risk of developing type 2 diabetes is 40% for individuals who have one parent with type 2 diabetes and almost 70% if both parents are affected [40]. The concordance rate of type 2 diabetes in monozygotic twins is ~70%, while the concordance in dizygotic twins is only 20–30%. The proband-wise concordance rates (number of affected twins having a co-twin with diabetes) for monozygotic twins vary between 34% and 100% [41–44]. The relative risk for first-degree relatives – that is, the risk of developing type 2 diabetes if you have an affected parent or sibling compared to the general population – is ~3 and ~6 if both parents are affected [45]. However, these figures vary depending on the cohort and population studied.

The prevalence of type 2 diabetes varies widely among populations, from a few percent among White Europeans to as high as 50% among the Pima in Arizona [46]. While part of the observed ethnic variability could be attributed to environmental and cultural factors, some of the variation seems to depend on genetic differences.

Despite these reservations, there is no doubt the risk of type 2 diabetes is partly determined by genetic factors, many of which have already been identified, and while each identified variant explains only a very small proportion of the risk of type 2 diabetes in humans, overall they have contributed to our understanding of disease pathogenesis. One should also keep in mind that the variance explained by a risk allele in a population is not necessarily an indicator of its

importance in specific individuals, nor is it proportional to the affected pathway's importance or potential as a therapeutic target.

The more than 1000 SNPs identified explain less than 20% of the heritability of type 2 diabetes. There are many possible explanations for the missing heritability, including assumptions made about the genetic architecture of the disease and the definitions of heritability. The estimations of heritability explained assume that only additive effects determine disease risk and that the risk follows the liability threshold model; that is, that the genetic and environmental effects combine to form a normal distribution of liability and that disease arises in individuals surpassing a certain threshold in the distribution [47]. If these assumptions are not true, the estimate of heritability explained will not be correct.

Intrauterine effects can also affect heritability estimates because monozygotic twins are often monochorionic, which results in growth retardation compared to dizygotic twins, and low birth weight is associated with increased risk of type 2 diabetes later in life. Furthermore, there could be other explanations for the missing heritability problem. Heritability can only be estimated from the most recent generations for which information on affected status is available, whereas most of the variants studied thus far are ancestral variants hundreds of generations old. We do not know whether these ancestral variants (which have modest effects and have escaped purifying selection) can really explain the diabetes epidemic we see in the most recent generations or whether this can be ascribed to rare variants with stronger effects.

Moreover, heritability estimates are based on the *top* single-nucleotide polymorphisms (SNPs) from genome-wide association studies (GWAS); novel methods have been proposed that consider (i) a 0–1 scale as opposed to liability; (ii) ascertainment bias; and (iii) quality control of the GWAS SNPs. Estimating the proportion of variance explained by all SNPs in GWAS as opposed to only the most significantly associated SNPs could result in a more detailed estimate of heritability [48]. Applying an approach that considers all SNPs on the chip could in fact explain a much larger proportion of the *narrow-sense* heritability (>50%), supporting the existence of numerous yet unidentified loci with smaller effects [12, 49, 50].

Genetic architecture of type 1 diabetes and type 2 diabetes

The genetic architecture of a complex phenotype is defined by the number, frequencies, and effect sizes of causal alleles. Many hypotheses have been proposed to define the genetic architecture of type 2 diabetes: one hypothesis suggested that the unexplained heritability lies in a large number of common variants with low additive effects and that the disease represents the extremes of a normal distribution [51]. Another proposed that rare alleles might be responsible for effects observed with common variants (synthetic associations) and explain a majority of the heritability [52–54]. One argument against common and more so against rare variants is that they would have been removed from the population by natural selection [46]; however, this is not a valid argument for a disease like type 2 diabetes, where the penetrance of the genetic effect depends strongly on interactions with the environment, especially since this environment has changed in recent years and the genetic risk variants could have been neutral or even beneficial before the introduction of a Westernized lifestyle.

While extreme models are excluded by the present data based on epidemiological and linkage studies and GWAS, models wherein rare variants explain a little (<25%) or a lot (>80%) of heritability remain consistent [55]. Large next-generation sequencing studies in families will hopefully answer the questions about the role of rare variants in complex diseases. There is already substantial evidence for parent-of-origin effects on type 1 diabetes and type 2 diabetes risk, and studies are ongoing to explore this further. Structural polymorphisms and microRNAs add a further layer of complexity and have not yet been exhaustively studied.

The genetic architecture could also be influenced by gene–gene interactions (epistasis), where rare variants with high penetrance could act jointly with common alleles to increase the risk of disease. The extent of allelic heterogeneity seems to be less pronounced for the common forms of type 1 diabetes and type 2 diabetes than for monogenic forms like MODY. Moreover, there could be differences in the genetic predisposition to both type 1 diabetes and type 2 diabetes due to phenotypic heterogeneity within type 2 diabetes cases. For instance, in type 2 diabetes, lean people with type 2 diabetes are likely to carry a disproportionately high load of type 2 diabetes risk alleles [56].

Genetic loci for type 1 diabetes

GWAS have reported at least 257 variants mapping to 190 genes so far (Table 12.1). The main susceptibility genes currently accepted for type 1 diabetes are the human leucocyte antigen (HLA) class II alleles, and non-HLA loci including the insulin gene, *CTLA4*, *PTPN22*, interleukin 2 receptor α (IL2RA), and others [65]. Genes encoding HLA proteins are located within the major histocompatibility complex (MHC) on chromosome 6. The MHC is divided into class I, comprising HLA-A, -B, and -C; class II, comprising HLA-DR, -DQ, and -DP; and class III, comprising genes for complement components. HLA genes are highly polymorphic and variable between populations. Class II genes, especially DQ genes, are highly important for type 1 diabetes risk. Indeed, *HLA-DQB1* and *HLA-DRB1* on chromosome 6p21.3 account for ~50% of genetic susceptibility [66, 67].

A genetic risk score, which is a cumulative contribution of genetic factors to a particular trait in a specific individual, has been developed in type 1 diabetes comprising between 9 and 67 SNPs and has been a useful tool to discriminate between type 1 diabetes and type 2 diabetes or controls in Europeans. The first 9 SNPs that were used to create these genetic risk scores included SNPs tagging the high-risk HLA DR3-DQ2.5 (DR3)/DR4-DQ8 (DR4) alleles and the highly protective HLA DR15-DQ6.2 (DR15) allele. They had the highest effect size and contributed to a majority of the discriminatory power. These were also applicable to non-European populations, including India [68–70]. In addition, genetic risk scores were developed from loci showing specific associations with individuals with type 1 diabetes of African ancestry, which improved prediction of type 1 diabetes in this population [61].

Linkage studies for type 2 diabetes

The *CAPN10* gene on chromosome 10 encoding calpain 10, a cysteine protease with largely unknown functions in glucose metabolism, was the first type 2 diabetes susceptibility gene to be identified through linkage studies. Unfortunately, this locus has been difficult to replicate

Table 12.1 Type 1 diabetes susceptibility loci from genome-wide association studies [57–64].

in subsequent studies. The greatest success in linkage studies relates to the discovery of variants in *TCF7L2* associated with type 2 diabetes. The DeCode team observed a rather modest linkage at a 10.5 Mb region on chromosome 10q, but decided to pursue and fine map it, thereby identifying the variant that shows the strongest association with type 2 diabetes, an intronic variant (rs7903146) in the *TCF7L2* gene contributing to, but not fully explaining, the original linkage [71–73]. This association has since been confirmed in African, Asian, and European populations, rendering it the most consistently replicated genetic association with type 2 diabetes, conferring a relative risk of ~1.4 [74].

Candidate genes for type 2 diabetes

The first candidate gene reproducibly associated with type 2 diabetes was *PPARG*, encoding the nuclear receptor PPAR- γ [75]. The PPAR- γ receptor is a molecular target for thiazolidinediones, a class of insulin-sensitizing drugs used to treat type 2 diabetes, making it a compelling candidate gene. The transcript expressed in adipose tissue has an extra exon B and a substitution of a proline for alanine at position 12 of this protein, which is seen in ~15% of the European population. This variant is associated with increased transcriptional activity, increased insulin sensitivity, and protection against type 2 diabetes [75].

Type 2 diabetes risk variants in *KCNJ11* were also discovered through candidate association studies [76,77]. *KCNJ11* codes for four subunits of the ATP-sensitive potassium (K-ATP) channel, the other four coded by another gene (*ABCC8*). The E23K polymorphisms in *KCNJ11* and P12A in *PPARG* putatively acted in an additive manner to increase the risk of type 2 diabetes [78]. In pancreatic β cells, ATP-potassium channels are crucial for the regulation of glucose-stimulated insulin secretion and are the target for the sulfonylureas, which are oral hypoglycaemic agents widely used in the treatment of type 2 diabetes, and for diazoxide, a potassium channel opener. Activating mutations in this gene also caused neonatal diabetes. Additionally, loss-of-function mutations in *KCNJ11* and *ABCC8* caused hyperinsulinemia in infancy [79].

Genome-wide association studies identify common variants associated with type 2 diabetes

The development of new genotyping technologies and the realization that we inherit stretches of the genome together as haplotypes facilitated cataloguing of common variants (e.g., HAPMAP, 1000 Genomes, TOPMED) and allowed for new possibilities for applying unbiased global approaches to screen millions of common variants for association with complex diseases. Several GWAS for diabetes were published in 2007, termed Breakthrough of the Year by *Science* magazine. The first was a GWAS on early-onset type 2 diabetes reporting two new diabetes loci, *HHEX* and *SLC30A8* [80]. The ultimate proof of the value of GWAS for type 2 diabetes came from three studies published back to back in *Science* in 2007; for the first time in the genetics of type 2 diabetes, three different studies reported the same top findings [81–83].

The first wave of GWAS was followed by a second wave combining existing or new GWAS into meta-analyses of >50 000 individuals [12]. A prerequisite for this was that many research groups

could work together in consortia like DIAGRAM (DIAbetes Genetics Replication and Meta-analysis Consortium) and MAGIC (Meta-Analyses of Glucose-and Insulin-related traits Consortium). GWAS do not inevitably lead to identification of a gene or genes in a given locus associated with disease. Since the most strongly associated SNPs are often only markers for the functional variant responsible for the observed genetic effect and most associated regions harbour several genes, additional fine mapping of the loci in even larger sample sets is often necessary. To do this cost-efficiently a custom-designed chip, the so-called CardioMetabochip (Illumina, San Diego, CA, USA), has been developed for metabolic and cardiovascular gene mapping. This chip contains ~200 000 polymorphisms selected to cover association signals from a wide range of metabolic disorders (type 2 diabetes, lipid disorders, obesity, and cardiovascular disease) and was designed to perform both deep replication of major disease signals and fine mapping of established loci. Meta-analysis of previous GWAS by the DIAGRAM consortium with an additional 22 669 individuals with type 2 diabetes and 58 119 controls genotyped using the CardioMetabochip has recently added another eight new loci associated with type 2 diabetes in the European population and two novel loci not previously reported in populations of European descent [84].

Recently, GWAS and meta-analysis studies have also been performed in non-European cohorts, adding several new loci to the list of genome-wide significant associations [85–95]. Interestingly, most associations found in one ethnic group also show some evidence of association in populations with other ethnicities. GWAS have now provided ~1102 variants for type 2 diabetes mapping to >660 loci (Table 12.2), as well as numerous loci for glucose- or insulin-related traits (Table 12.3, Figure 12.2), and more are likely to come.

Most studies have been limited to SNPs, leaving structural polymorphisms relatively unexplored. However, since common structural variants are likely to be tagged by surrounding SNPs, they are unlikely to explain a large proportion of missing heritability. A recent study identified a common copy number variation, CNVR5583.1 (*TSPAN8*), as associated with type 2 diabetes [102]. This association could be convincingly replicated by previously typed SNPs that tag the copy number variation [103].

Rare variants with stronger effects are often rare

Rare variants are more recent and therefore more likely to be those that arose recently in an extended pedigree. Of course, natural selection removes the more deleterious variants before they reach a high frequency and so risk alleles for diseases should be enriched at lower frequencies. The idea that there are unique rare variant combinations in families that play a role in disease aetiology is referred to as *clan genetics* [52]. Current data suggest that combined effects of rare and common variants contribute in varying degrees to disease causation, not least linkage, and that rare alleles may, in fact, explain the majority of heritability [104]. Next-generation sequencing provides even denser coverage of genetic variation, rendering detection of causal rare variants more feasible. Whole-genome sequencing of 2630 Icelanders and imputation into 11 114 Icelandic cases and 267 140 controls followed by testing in Danish and Iranian samples revealed variants in *PAM* and *PDX1* in the risk of type 2 diabetes [105] (Table 12.4). Array-based genotyping and exome sequencing on a small founder population

Part 3 Pathogenesis of Diabetes

Table 12.2 Genetic loci associated with risk of type 2 diabetes.

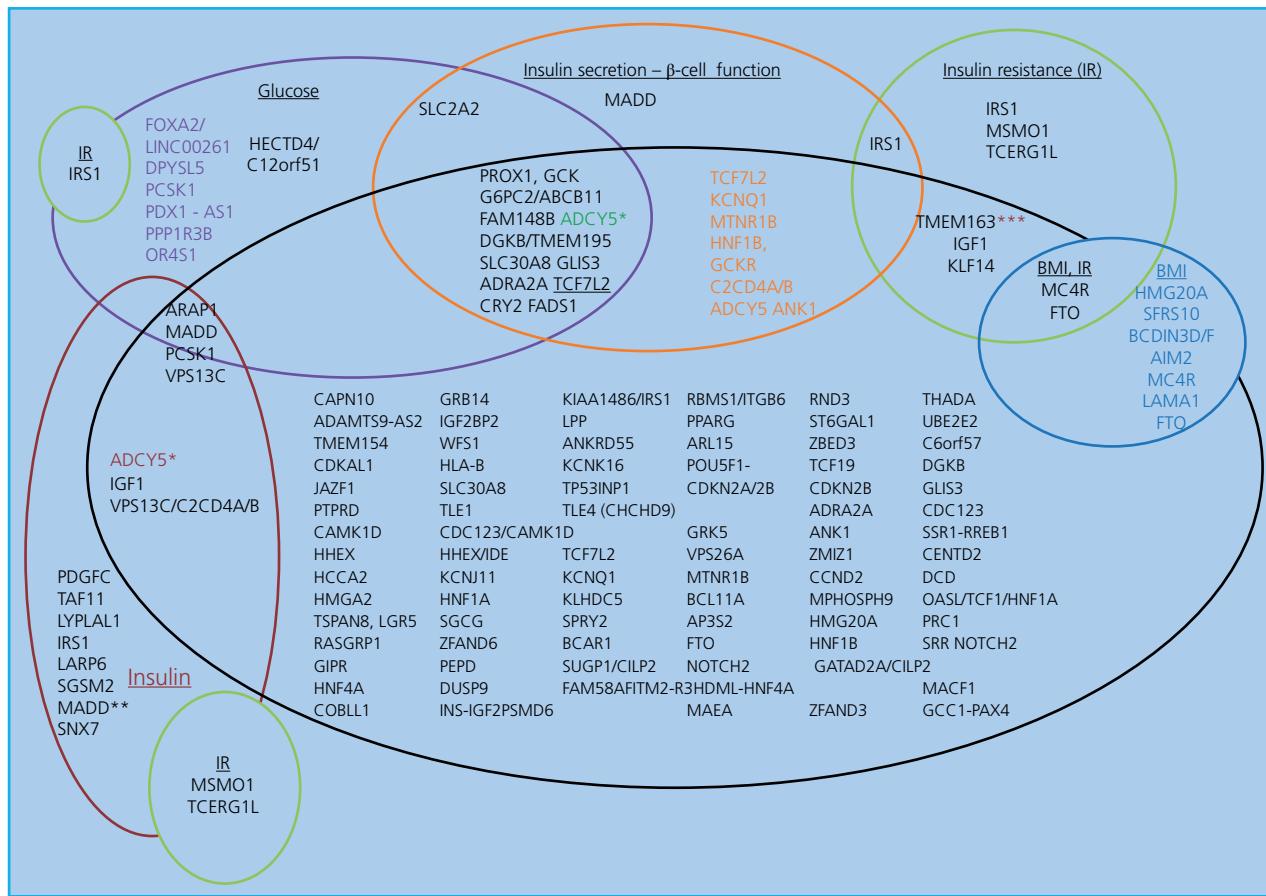

Figure 12.2 Type 2 diabetes- and glycaemic trait-associated variants. The variants are represented by gene names here, which could indicate that the location is present either in the gene or in the vicinity of the gene. The black circle represents type 2 diabetes, and the gene names in black in this represent variants only associated with type 2 diabetes. The overlapping circles indicate additional reporting associations for that variant, e.g. *TCF7L2*, *KCNQ1*, and *MTNR1B* are associated

with type 2 diabetes and also with β -cell dysfunction. *An *ADCY5* variant is associated with two-hour insulin adjusted for two-hour glucose, two-hour glucose/type 2 diabetes (in brown). ***MADD* variants are associated with fasting proinsulin, fasting glucose, and HOMA-B (homeostatic model 2 of assessment for insulin secretion). ***Variants in *TMEM163* are also associated with fasting insulin, and *TCF7L2* associated with fasting and two-hour glucose.

from Greenland revealed a nonsense p.Arg684Ter variant (allele frequency of 17%) in *TBC1D4* associated with higher concentrations of two-hour glucose and serum insulin [109]. Whole-exome sequencing in a Latino population revealed a rare missense variant in *HNF1A* (c.1522G>A [p.E508K]) that was associated with type 2 diabetes prevalence [108]. Additionally, rare variants associated with glycaemic traits were discovered through exome sequencing of 9717 individuals from the METSIM study, Finland [106] (Table 12.4).

Protective variants

The average type 2 diabetes risk variant frequency in the general population is 54%, which raises the question of whether type 2 diabetes is the default condition. If so, then does carrying protective variants makes a difference in disease susceptibility? Studies have been performed to address this question by including controls that, despite having a cluster of risk factors for type 2 diabetes, have escaped the disease. A rare (0.66%) loss-of-function mutation (R138X) was detected in the *SLC30A8* gene in the Botnia region of Finland and was subsequently replicated in a massive effort applying the Exome chip to >150 000 individuals from other European countries. Also, the DeCode group identified another loss-of-function mutation, a

frameshift mutation that also was enriched in Icelandic people without diabetes. The *SLC30A8* gene encodes the islet zinc transporter 8 with a putative effect on insulin secretion. Notably, a common variant in the same gene increases susceptibility to type 2 diabetes, whereas zinc transporter 8 autoantibodies predispose to type 1 diabetes.

Collectively, carriers of these protein-truncating mutations have a 65% lower risk of type 2 diabetes [107]. Other studies based on Icelandic, Danish, and Iranian populations identified a low-frequency variant in *CCND2* that reduced type 2 diabetes risk by half [105]. Moreover, variants in *TCF2* are protective against type 2 diabetes [110]. It is also likely that the more recent such variants that are only a few generations old segregate in families and could be detected through sequencing in families (Table 12.4).

Gene–gene and gene–environment interactions

Gene–gene interactions, or epistasis, have been suggested as a possible explanation for difficulties in replicating genetic associations in complex diseases [111]. The standard statistical methods used in association studies are usually limited to analysis of single marker effects and thereby do not account for interactions between

Chr, chromosome.

markers. Previous attempts to study epistasis in complex diseases have focused on interactions between candidate regions [112, 113]. However, the recent abundance of GWAS has made a comprehensive search across the genome more feasible. Some studies have attempted to account for epistasis in GWAS using a two-step approach in which significant SNPs are tested against each other or against all other SNPs in the study, with variable results [114, 115]. The main problem when studying epistasis is power, since interaction between loci with modest effects is difficult to detect without extremely large sample sizes. However, some studies have pointed at novel tests to increase power [116]. Thorough studies in diabetes addressing epistasis using this approach are missing. A recent paper by Eric Lander et al. provided compelling evidence that gene–gene interaction can also contribute to missing heritability by causing *phantom heritability*, which inflates the estimated narrow sense heritability of the trait [117].

Gene–environment interactions are equally difficult to study, but are likely to play an important role in type 2 diabetes development. The epidemic of type 2 diabetes only dates back 50 years, and it is quite obvious that during this period only the environment, not the genes, has changed. However, our genetic architecture determines our response to the environment. Genetic variants could affect specific metabolic processes to make an individual more susceptible to the harmful effects of a poor diet, but also personality traits that make an individual more or less likely to overconsume and live a sedentary lifestyle. It will, however, be a formidable task to identify the environmental triggers for most of the genetic variants increasing

susceptibility to diabetes, as this will require very large studies with precise information on diet, exercise, energy expenditure, and so on.

Parent-of-origin effects

The risk of type 2 diabetes in offspring is greater if the mother has type 2 diabetes compared to if the father is affected, in contrast to type 1 diabetes, where the risk of type 1 diabetes in offspring is greater if the father is affected [118, 119]. Sex-specific parental effects have been reported for insulin response to an oral glucose load, with male offspring of women with diabetes showing the lowest insulin values, as well as influencing high-density lipoprotein (HDL) concentrations [118]. One potential explanation for this could be preferential parental-specific transmissions of risk alleles to offspring, which is often associated with DNA methylation and imprinting. Epigenetic modifications have the potential to be stable and heritable across cell divisions and manifest as parent-of-origin effects [120, 121]. Insulin was the first gene reported to show parent-of-origin effects. The paternally transmitted class III alleles of the variable-number tandem repeat (VNTR) region upstream of the insulin gene (INS-VNTR) showed an association with type 2 diabetes [122]. Interestingly, class III alleles (one of the two main classes of INS-VNTR allele length, with 141–209 repeats) were also associated with increased length and weight at birth [123] and were protective against type 1 diabetes compared with type I alleles [124]. A large-scale family-based study in

Part 3 Pathogenesis of Diabetes

Iceland determined that variants in *KCNQ1* and *KLF14* show stronger effects on type 2 diabetes when the risk allele is transmitted from the mother than from the father [125, 126] and were replicated in later studies, including our own [127].

The conflict hypothesis suggests that imprinting arose due to a genomic *tug of war* between mothers and fathers over the use of maternal resources in the fetus. The paternal imprinting maximizes the utilization of intrauterine resources by the offspring, which would increase their evolutionary fitness, whereas the maternal imprinting tries to minimize this to conserve it for her future offspring [128]. Conversely, the co-adaptation hypothesis suggests that imprinted genes coevolve to optimize parental care of offspring. While there is insufficient evidence to support either theory, nevertheless the significant role of imprinting in defining paternal and maternal effects has been consistently established [129].

The intrauterine environment plays a significant role in determining fetal programming. Poor maternal nutrition can affect fetal growth and produce permanent changes in glucose–insulin metabolism, and often results in low birth weight [130]. This can induce permanent changes in metabolism and affect chronic disease susceptibility, as proposed by the developmental origins of health and disease hypothesis [131]. If this intrauterine programming results in a reduced β -cell mass, it could predispose to diabetes later in life when the insulin requirements increase as a consequence of obesity, resulting in insulin resistance. *KCNQ1* could represent an example of fetal programming wherein the maternally expressed gene was mono-allelically expressed in fetal tissues and biallelically expressed in adult tissues [132].

Dissection of genetic parent-of-origin effects requires genotype data from families and only heterozygous parents are informative, yielding reduced power for relatively rare variants. However, long-range phasing and imputation methods allow for predicting genotypes with great likelihood, thus making this a valuable method to find *surrogate* parents, even if DNA exists from only a few family members. When the paternal and maternal alleles have effects in opposite directions, for instance a situation where the maternal allele could confer risk while the paternal allele could be protective, such an association would be almost impossible to detect in a traditional case–control GWAS. However, novel parent-of-origin detection methods allow detection of imprinting effects from differences in the phenotypic variance of heterozygotes in very large case–control studies [133]. Parent-of-origin effects could explain a large portion of the missing heritability and must be taken into consideration in investigations of genetic type 2 diabetes susceptibility.

Epigenetics

The environment can also influence the expression of the genome, and ultimately the phenotype, via the epigenome. Even though the DNA sequence is not changed, the phenotype is altered by epigenetic modifications of gene expression by mechanisms including methylation of DNA, post-translational modification of histones, or activation of microRNAs. Changes to the phenotype can be at the level of the cell, tissue, or whole organism.

It is tempting to speculate that environmental factors such as diet and exercise can change the level of DNA methylation and thereby cause changes in gene expression, but evidence that DNA

methylation contributes to the increase in type 2 diabetes is still lacking. Epigenetic mechanisms may, however, play a role in progression of the disease by inducing glucotoxicity in islets and predispose to diabetes-related complications [134]. Elevated glucose is a prerequisite for this condition and cells can memorize changes in glucose concentrations. For example, two large studies, the UK Prospective Diabetes Study (UKPDS) and the Diabetes Control and Complications Trial (DCCT), showed that initial good metabolic management was associated with reduced frequency of diabetes complications decades later. The advanced *metabolic memory* hypothesis suggests that this is because glucose can induce histone modifications in endothelial cells that can be remembered long after (Chapter 42) [135].

Non-coding RNAs – MicroRNAs and LincRNAs

Non-coding RNAs have recently emerged as important regulators of gene expression and function. MicroRNAs (miRNAs) naturally regulate programmes of gene expression. Altered miRNA function contributes to human disease, and manipulation of specific miRNAs is now being explored as a novel therapeutic modality [136]. The efficiency of miRNAs binding to target transcripts depends on both the sequence and the intramolecular structure of the transcript. SNPs can contribute to alterations in the structure of regions flanking them, thereby influencing the accessibility for miRNA binding. Several studies have implicated miRNAs in diabetes and inflammation and common SNPs change the target sequence of miRNAs in several type 2 diabetes susceptibility loci (<http://miracle.igib.res.in/dbSMR>) [137, 138]. Other forms of non-coding RNAs, such as piRNAs (PIWI-interacting RNAs), snoRNAs (small nucleolar RNAs), lincRNAs (long intergenic non-coding RNAs), and lncRNAs (long non-coding RNAs), might also contribute to the development of diabetes. For example, the CDKN2A/B region on chromosome 9 is associated with type 2 diabetes, as well as cardiovascular disease and a number of other disorders. This region harbours a lincRNA, ANRIL (non-protein coding CDKN2B-AS1 CDKN2B antisense RNA 1), which can potentially modify and explain some of these associations [139].

Difficulties in assigning functions to associated genes

Most identified diabetes loci have not been mechanistically tied to the disease. While loci are commonly referred to by the names of genes located close to them, only a few are close to strong biological candidates, such as the melatonin receptor (*MTNR1B*) and the insulin receptor substrate-1 (*IRS1*). For others, like *TCF7L2* and *GIPR*, the evidence is quite strong that an intronic SNP is the causal SNP. Melatonin receptor 1B (*MTNR1B*) has been associated with both fasting glucose and risk of type 2 diabetes [140–142]. Melatonin works as a chronobiotic factor, adjusting the timing of the biological clock. Its receptors are present in the pancreas and melatonin is proposed to contribute to the nocturnal lowering of insulin in humans. The *MTNR1B* risk genotype is associated with impaired early insulin release to both oral and intravenous glucose and insulin secretion deteriorates over time in the risk allele carriers [140]. The proposed

mechanism by which the *MTNR1B* polymorphism could predispose to type 2 diabetes involves altered expression of *MTNR1B* in pancreatic β cells, leading to decreased cyclic adenosine monophosphate/cyclic guanosine monophosphate (cAMP/cGMP) concentrations via G-proteins and, thereby, impaired insulin secretion.

The insulin receptor substrate 1 (*IRS1*) gene encodes a protein that mediates insulin's control of various cellular processes by transmitting signals from the insulin receptor to intracellular signalling pathways. The C allele of rs2943641 is associated with insulin resistance and increased risk of diabetes. The genetic variant causes reduced basal levels of *IRS1* protein and decreased insulin induction of *IRS1*-associated phosphatidylinositol-3-hydroxykinase activity in human skeletal muscle biopsies [143].

TCF7L2 is a transcription factor playing an important role in the Wnt signalling pathway. The risk allele is associated with a decreased insulinogenic index and a lower disposition index, suggesting a reduced capacity for insulin secretion in relation to insulin sensitivity. Since it was identified as a diabetes gene, it has been shown to be important for several vital functions in the pancreatic islet, including pancreas development, determination of β -cell mass, maintenance of the secretory function of mature β cells, and regulation of insulin production and processing [144, 145].

The incretin hormone glucose-dependent insulinotropic polypeptide (GIP) promotes pancreatic β -cell function by potentiating insulin secretion and β -cell proliferation. The GIP receptor (*GIPR*) locus showed an association with post-prandial insulin levels in a meta-analysis performed by the MAGIC consortium, but was surprisingly not associated with risk of diabetes in the DIAGRAM+ study [12, 101]. The reason seems to be that the same variant results in a decreased body mass index, which neutralizes the effect of the SNP on risk of type 2 diabetes. GIP influences expression of the inflammatory cytokine OPN in islets, which in turn has protective effects on β -cell proliferation and potentially apoptosis [146].

Many of the other identified loci can be subgrouped based on their association with other phenotypes with a key role in type 2 diabetes aetiology. Exploration of the effects of type 2 diabetes-associated variants on glucose and insulin traits in people without diabetes has shown that most of the known loci act through an effect on insulin secretion rather than insulin resistance (Table 12.2) [12, 147–149].

Fasting glucose-raising alleles of the *MADD*, *GIPR*, *GCK*, *FADS*, *DGKB*, *PROX1*, *TCF7L2*, *SLC30A8*, and *C2CD4B* loci have all been associated with either abnormal insulin processing or secretion, whereas *GCKR* and *IGF1* are associated with oral glucose tolerance test-based disposition indices and β -cell function [148]. The DIAGRAM+ consortium observed that three loci (*TCF7L2*, *ARAP1*, and *CDKAL1*) were associated with reduced fasting insulin, also suggestive of β -cell dysfunction, whereas the type 2 diabetes risk alleles at *PPARG*, *FTO*, *IRS1*, and *KLF14* were associated with higher fasting insulin, indicating a primary effect on insulin action [12].

Genotype-based treatment

The *ADRA2A* (adrenergic receptor $\alpha 2$) locus was recently identified as a type 2 diabetes risk locus after first having been positionally mapped in congenic GK rats, where it was associated with impaired insulin granule docking and reduced β -cell

exocytosis [147]. Human carriers of the *ADRA2A* risk variant (rs553668) have reduced fasting insulin and decreased insulin secretion as a consequence of increased expression of the ADRA2 receptor in pancreatic islets. It is well known that epinephrine excess can suppress insulin secretion and cause diabetes. The α_{2A} -adrenergic receptor (α_{2A} AR) antagonist yohimbine enhances insulin release *in vitro* in islets from organ donors carrying the risk allele to levels similar to those in non-risk carriers. A randomized clinical study was performed blocking α_{2A} AR pharmacologically to increase insulin secretion in individuals with type 2 diabetes and the rs553668 risk allele. Yohimbine administration enhanced 30-minute insulin and corrected the insulin response and disposition index in the risk group, making secretion similar to individuals carrying the low-risk allele. An insulin secretion defect in individuals carrying the *ADRA2A* risk genotype could be corrected by α_{2A} AR antagonism [150]. This demonstrated the potential application of genetic risk variants to guide therapeutic interventions that target the underlying pathophysiology, one step closer to individualized medicine.

Little common genetic basis for type 1 diabetes and type 2 diabetes

Type 1 diabetes and type 2 diabetes can be considered two extremes of the diabetes spectrum and share a few similarities in manifestation of underlying physiology, including hyperglycaemia, insulin deficiency, and development of complications. However, the genetics of type 1 and type 2 diabetes vastly differ, with very few type 2 diabetes susceptibility loci showing an association with type 1 diabetes. Notable exceptions include the *PPARG* Pro12Ala variant, *MTNR1B*, *HNF1A*, *GLIS3*, 6q22.32, and novel loci near the MHC, which harbour the HLA class II genes associated with about half the type 1 diabetes risk [92, 151–153]. Based on these studies, the mechanisms underlying type 1 and type 2 diabetes appear to be intrinsically distinct. The distribution of type 2 diabetes risk SNPs should be more random in individuals with type 1 diabetes; however, this does not seem to be the case. The strongest type 2 diabetes SNP in the *TCF7L2* gene almost seems to protect from type 1 diabetes. Type 1 diabetes risk variants for *BCARI*, *GLIS3*, and *RAD51L1* were protective for type 2 diabetes, whereas for those in *C6orf173*, *COBL*, and *C10orf59* the effects were concordant [84]. Also, it has been reported that *APOC3* haplotypes increase the risk of type 1 diabetes; however, the same variants increase the risk of type 2 diabetes in lean carriers, while having a protective effect in overweight carriers [154]. Common variants in *SLC30A8* are associated with an increased risk of type 2 diabetes, and rare variants with a protective effect [80, 107]. Puzzlingly, *SLC30A8* was also found to be a major autoantigen eliciting 60–80% of autoantibodies in people with new-onset type 1 diabetes [155].

Curiously, gene variants associated with type 1 diabetes underwent recent positive selection and have been increasing in prevalence. There is more selection in alleles increasing, rather than decreasing, susceptibility to type 1 diabetes. This is indicative of an evolutionary benefit, wherein these variants were possibly protective against viruses and bacterial infections. However, no such link has been reported for type 2 diabetes risk variants, as could be expected from the thrifty genotype hypothesis [156]. In terms of genetics, type 2 diabetes seems to have more in common with

that of cancer rather than of type 1 diabetes [157]. There may rather be a specific yin–yang relationship between cancer and type 2 diabetes, with too much cell proliferation resulting in cancer and insufficient proliferation of pancreatic islets resulting in type 2 diabetes [157].

LADA is considered an intermediary form between type 1 diabetes and type 2 diabetes. There is much less information available as to the genetic basis of LADA compared to type 1 diabetes and type 2 diabetes. One way to understand this would be to assess to what extent LADA shares genetic similarities with type 1 diabetes and type 2 diabetes. The HLA locus, conferring 50% of the genetic susceptibility to type 1 diabetes, also shows similar associations with LADA, with a few differences. The type 1 diabetes variant *PTPN22* shows a weak association with LADA. Data on the INS class I VNTRs have been inconclusive and associations have been reported with both type 1 diabetes and type 2 diabetes, wherein the short tandem repeat is associated with type 1 diabetes and the long with type 2 diabetes. While several type 1 diabetes-associated variants could be tested for association with LADA, it was not until the discovery of the common variant in the *TCF7L2* gene being strongly associated with type 2 diabetes that the genetic contribution of type 2 diabetes to LADA really could be tested. This variant is clearly associated with LADA and type 2 diabetes, but not with type 1 diabetes. This indicates that LADA is indeed a genetic admixture of both type 1 diabetes and type 2 diabetes. There are more lessons to be learned from differences between type 1 diabetes and type 2 diabetes rather than similarities. Elucidating the genetic heterogeneity of the spectrum of diabetes disorders will help us in understanding the mechanisms underlying the phenotypic heterogeneity of diabetes and would be a step towards individualized therapy.

A holistic view: systems genetics

A restricted focus on the genome through GWAS provides limited insights into the molecular mechanisms driving disease and is akin to a snapshot of the genetics of the disease. To obtain an understanding of disease pathogenesis, it is important to analyse the data from GWAS in the context of complementary follow-up analyses, including DNA methylation and histone modifications, expression profiling under conditions relevant for the disease, related protein analysis, and analysis of genotype–phenotype associations. Global transcriptome profiling in relevant tissues such as pancreas has facilitated

identification and cataloguing of a wide array of transcription-based events in the pathogenesis of type 2 diabetes [158]. For example, by combining GWAS information with metabolomics, it has been possible to identify strong associations between SNPs and metabolic reactions that otherwise would have been missed [159]. Network- or pathway-based approaches, including enrichment in pre-defined pathways by for example KEGG [160] (<http://www.genome.jp>) and Gene Ontology (GO; <http://www.geneontology.org>), have also been used to identify disease genes for various diseases. Thus, an integrative approach of several data types is likely to discover disease genes that would not be identified using classical GWAS approaches alone. This was also illustrated in a recent studies of human islets identifying novel candidate genes for type 2 diabetes based on expression differences and co-expression with known type 2 diabetes genes as well as protein–protein interaction analyses [161, 162]. Integration of GWAS with such data could thus facilitate a systems-based understanding of the pathogenic mechanisms.

Conclusion

Advances in genomics technology have initiated a myriad of novel genetic discoveries, including many common variants contributing to the risk of complex disease. This has led to a deeper understanding of the underlying biology and pathogenesis of these diseases. The genetic landscape of type 2 diabetes susceptibility is as yet incomplete, so far only explaining a small proportion of the total heritability of diabetes. Many possibilities for dissecting the architecture of type 2 diabetes aetiology have emerged in the form of large-scale genetic studies, meta-analyses, and sequencing in families. It has already greatly contributed to our understanding of disease mechanisms by identifying pathways that could not be linked to diabetes by existing hypothetical models, even though many genetic findings are recent and have yet to make their contribution to our knowledge about diabetes pathogenesis. However, one must bear in mind that diabetes is probably a much more diverse disease than the current subdivision into type 1 diabetes and type 2 diabetes implies, and more precise division into subgroups may both facilitate the investigation of type 2 diabetes genetics and pave the way for more individualized treatment. A holistic systems biology approach will also be required to obtain a complete picture of how genetic variation leads to diabetes. The rapid development of technology during the past years holds promises that this will be possible in the not too distant future.

13 Genetics of Obesity

I. Sadaf Farooqi

Wellcome-MRC Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, UK

Key points

- Although the rise in prevalence of obesity is strongly influenced by environmental and social factors, within a given environment there is considerable variation in body weight.
- Some people appear to be more susceptible to obesity and it is clear that genetic factors play a major role in influencing the variation in body mass index in the population.
- Twin and familial studies have indicated that the heritability of body weight is 40–70%.
- Several intermediate traits are heritable, including energy intake, satiety responsiveness, basal metabolic rate, energy expenditure in response to a fixed amount of exercise, and body fat distribution.
- Up to 20% of children with severe obesity have rare chromosomal abnormalities and/or highly penetrant genetic mutations that drive their obesity.
- There are at least 30 Mendelian disorders characterized by developmental delay, dysmorphic features, and/or organ-specific developmental abnormalities in addition to obesity.
- Body weight is regulated by hypothalamic neurons, which integrate signals from adipose tissue stores and meal-related signals from the gastrointestinal tract. Rare mutations in several of the molecules involved in this signalling pathway cause severe obesity in humans without developmental delay.
- Common variants involving over 150 loci have been associated with body mass index and/or obesity in the population in genome-wide association studies.
- As many common variants lie in non-coding regions, the mechanisms by which they influence body weight have been challenging to dissect.

Obesity is defined as an excess of body fat which adversely affects health, most commonly by causing type 2 diabetes and cardiovascular disease. In addition, obesity is a cause of non-alcoholic fatty liver disease and a major cause of certain cancers [1]. As the direct measurement of adipose tissue mass requires specialist equipment (dual energy X-ray absorptiometry) that is not widely available, body mass index (BMI; weight in kg/height in m²) is commonly used as a surrogate marker of adiposity. Based on World Health Organization criteria, people with a BMI >30 kg/m² are considered to have obesity. There is increasing recognition that the risk of type 2 diabetes is seen at a lower BMI in people of different ethnicities.

The prevalence of obesity has increased substantially in the last 40 years such that at least 20–25% of people in many high-income countries have obesity. There is no doubt that the rise in prevalence is strongly influenced by environmental and social factors, in particular the easy access to palatable, energy-dense, and highly processed food and reduced levels of physical activity during work and leisure time associated with urbanization. Socioeconomic factors play an important role: the prevalence of obesity in children and adults is twice as high in areas of socioeconomic deprivation compared to more affluent areas. However, within a given environment, there is considerable variation in body weight. Some people appear to be more susceptible to obesity, whereas others can remain thin despite the obesogenic environment. It is now clear that genetic factors play a major role in influencing the variation in BMI in the population.

Evidence for the genetic contribution to obesity

Classically the genetic contribution to a trait or disorder is estimated by studying twins to calculate heritability, the proportion of phenotypic variation that can be explained by genetic variation. Studies in monozygotic versus dizygotic twins, in particular in twins who were separated at birth and were then raised separately, have indicated that the heritability of body weight is 40–70% [2–4]. Similar estimates emerged from studies of children in the 1980s, during the obesity epidemic [5]. Additional evidence was provided by longitudinal studies of adopted children who were found to have body weights that are comparable to their biological rather than adoptive parents [6, 7]. Extensive studies in twins and families (e.g. the Quebec family study) have shown that several intermediate traits are heritable, including energy intake, satiety responsiveness (fullness after a fixed meal), basal metabolic rate, energy expenditure in response to a fixed amount of exercise, and body fat distribution [8–10]. Elegant studies by Bouchard et al. showed that genetic factors influence the physiological response to overeating [11]. In a carefully supervised study in which identical twins were provided with excess calories, members of a twin pair gained similar amounts of weight, whereas there was considerable variability in the amount of weight gained by different sets of twins. Similarly, when twins were provided with a diet that led to a

negative energy balance, members of a twin pair lost similar amounts of weight [12].

Finding the genes that regulate body weight

Different approaches have been used to identify the genes that regulate weight. The first, and to date the clearest, evidence supporting the genetic contribution to obesity comes from the study of people with severe obesity that begins in early childhood. Several genetic obesity syndromes display Mendelian inheritance (sometimes with incomplete penetrance). Genetic testing for these conditions is now recommended as part of the clinical assessment of people with severe obesity that begins before the age of 5 years [13]. For clinical purposes, it is useful to categorize the genetic obesity syndromes as those with dysmorphism and/or developmental delay and those without these features.

Obesity with developmental delay

There are at least 30 Mendelian disorders characterized by developmental delay, dysmorphic features, and/or organ-specific developmental abnormalities in addition to obesity (pleiotropic syndromes). There are many more potential disorders where specific chromosomal deletions or duplications have been reported in people with obesity and other features, but where the causative gene has not been established.

Prader-Willi syndrome

Prader-Willi syndrome is an autosomal dominant disorder caused by sporadic or, less commonly, inherited deletions of an imprinted region on the paternal chromosome 15q11–q13 [14]. Classic clinical features include low birth weight (in common with other imprinting syndromes), hypotonia, and poor feeding due to reduced swallowing reflexes, resulting in failure to thrive. Hyperphagia in early childhood results in severe obesity. Other features include impaired learning and development, behavioural abnormalities, and hypogonadotropic hypogonadism. Growth hormone deficiency leads to reduced linear growth and altered body composition, features that are improved by growth hormone treatment, which is often commenced in early childhood [15, 16].

Small deletions of small nucleolar RNAs (HBII-85 snoRNAs) recapitulate the classic features of Prader-Willi syndrome [17, 18], suggesting that these non-coding RNAs play a causal role in the syndrome. Reduced expression of brain-derived neurotrophic factor (BDNF), its receptor TrkB, and oxytocin may play an important role in the neurodevelopmental phenotype seen in individuals with Prader-Willi syndrome [19]. Clinical trials of intranasal oxytocin are being conducted in young children with the syndrome [20].

Albright hereditary osteodystrophy

Albright hereditary osteodystrophy is an autosomal dominant disorder caused by heterozygous loss-of-function mutations in GNAS, the gene encoding G α_s (stimulatory G-protein alpha subunit), which mediates G-protein-coupled receptor (GPCR) signalling [21]. Imprinting at the GNAS locus results in selective silencing of the paternally inherited GNAS allele in some tissues. Mutations on the maternally inherited GNAS allele are usually associated with hyperphagia and childhood-onset obesity, which is sometimes associated with low basal metabolic rate. Other classic features

include low birth weight, developmental delay, brachydactyly, subcutaneous ossifications, short stature (height below the third percentile), and in some cases hormone resistance syndromes. This clinical spectrum is most often seen in individuals with non-sense or frameshift mutations. A more variable clinical phenotype is seen in those with missense mutations [22]. As such, screening for mutations in GNAS should be part of the diagnostic assessment of children with severe obesity [23]. Obesity-associated missense mutations in GNAS impair signalling through the melanocortin 4 receptor (MC4R), findings suggesting that therapies that enhance or bypass melanocortin signalling may be effective in these individuals.

Ciliary disorders

Several disorders affect the function of cilia, causing obesity with renal, retinal, and other organ-specific abnormalities. Bardet-Biedl syndrome is characterized by obesity, developmental delay, syndactyly, brachydactyly, or polydactyly, retinal dystrophy, hypogonadism, and renal abnormalities [24] caused by biallelic mutations in at least 20 genes that affect the function of cilia [25]. There is some evidence that Bardet-Biedl syndrome proteins affect leptin signalling and the MC4R agonist setmelanotide has been trialled in these individuals with some success [26]. Alstrom syndrome is an autosomal recessive condition that affects the centrosome and cilia, resulting in severe visual difficulties from infancy, with photophobia, nystagmus, and loss of central vision due to a rod-cone retinal dystrophy [27]. These individuals can develop a dilated cardiomyopathy in infancy, hepatic and renal dysfunction, hypothyroidism, hypogonadism (males), short stature, and mild to moderate developmental delay. Severe insulin resistance due to impaired adipose tissue expandability [28] results in the early development of type 2 diabetes, for which treatment with glucagon-like peptide-1 (GLP-1) receptor agonists can be effective.

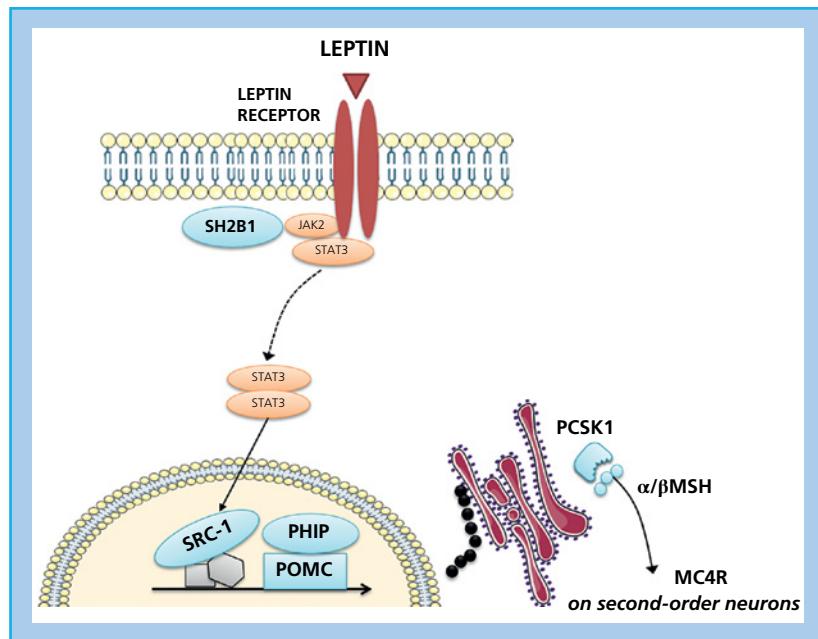

BDNF, TrkB, and SH2B1 deficiency

BDNF signals through tropomyosin-related kinase B (TrkB) to regulate the development, survival, and differentiation of hippocampal and hypothalamic neurons [29]. Heterozygous deletions and missense mutations in BDNF and TrkB (often *de novo*) cause severe hyperphagic obesity, developmental delay, and a spectrum of neurobehavioural abnormalities, which include hyperactivity, stereotyped behaviours, autistic traits, impaired short-term memory, fearlessness, and in some cases aggression [30]. Src-homology-2 (SH2) B-adaptor protein-1 (SH2B1) is an adaptor protein that modulates signalling by receptor tyrosine kinases including TrkB and cytokine receptors including the leptin receptor (LEPR) [31]. Chromosomal deletions on 16p11.2 which include SH2B1 [32] and heterozygous mutations in the gene itself [33] are associated with hyperphagia, dominantly inherited severe early-onset obesity, and disproportionate insulin resistance. Male mutation carriers often have behavioural problems, including social isolation and aggressive behaviour from childhood [33, 34], phenotypes seen in mice with brain-specific deletion of SH2B1 and restored when gene expression is normalized in the brain [35].

Obesity without developmental delay

Experimental studies in rodents first showed that body weight is regulated by hypothalamic neurons that integrate signals from adipose tissue stores, such as leptin with short-term, meal-related signals from the stomach and gastrointestinal tract (PYY, GLP-1,

Figure 13.1 Molecular mechanisms involved in the maintenance of body weight in the hypothalamus. Leptin signalling in proopiomelanocortin (POMC) neurons. Leptin binds its receptor, which is expressed on the surface of the POMC neuron. This interaction leads to the phosphorylation of Janus kinase 2 (JAK2), which is potentiated by Src-homology-2 B-adaptor protein-1 (SH2B1). The next step is the phosphorylation of the transcription factor STAT3, which dimerizes and translocates into the nucleus. Here it interacts with steroid receptor coactivator (SRC)-1 to modulate the transcription of POMC. Pleckstrin homology domain-interacting protein (PHIP) interacts directly with DNA to regulate POMC transcription. POMC is cleaved to yield α - and β -MSH (melanocyte-stimulating hormone), which activate signalling by the melanocortin 4 receptor (MC4R). MC4R is expressed on second-order neurons, which receive projections from POMC neurons and act to decrease food intake. Mutations in these pathways can lead to severe obesity in humans.

CCK, and ghrelin) [36]. In the fed state, leptin stimulates the expression of proopiomelanocortin (POMC), which is cleaved by prohormone convertases to yield the melanocortin peptides, which act to reduce food intake through the MC4R. Mutations in several of these molecules cause severe obesity in humans (Figure 13.1).

Leptin and leptin receptor deficiency

Homozygous and compound heterozygous (different mutations on both alleles) loss-of-function mutations in the genes encoding leptin (*LEP*) and the leptin receptor cause rapid weight gain in infancy, resulting in severe obesity in the first year of life [37,38]. Children have an intense drive to eat (hyperphagia) [39,40]. Resting metabolic rate and total energy expenditure are appropriate for the degree of adiposity; impaired sympathetic nerve function likely contributes to impaired fat oxidation [41,42]. Both conditions are associated with hypothalamic hypothyroidism and delayed puberty due to hypogonadotropic hypogonadism. There is some evidence for delayed but spontaneous onset of menses [43]. Children have impaired T-cell function, consistent with high rates of childhood infection and a high rate of childhood mortality [41,42].

Congenital leptin deficiency can be diagnosed based on undetectable serum leptin concentrations. However, a small number of missense mutations that result in detectable but bioinactive circulating leptin have been reported [44]. While serum leptin levels are appropriate for the degree of obesity in most individuals with leptin receptor deficiency, specific mutations, which result in a truncated extracellular domain that binds leptin, can result in markedly elevated leptin levels [45]. Treatment of congenital leptin deficiency with recombinant leptin results in a dramatic improvement in hyperphagia, weight loss, and correction of thyroid and T-cell dysfunction (Figure 13.2) [39,42]. Leptin treatment permits the progression of appropriately timed pubertal development, suggesting that leptin is a permissive factor for the development of puberty [42]. Until recently, leptin receptor deficiency was not treatable. However, the MC4R agonist setmelanotide reduces hunger and weight loss in clinical trials [46] and is now licensed for the treatment of leptin receptor deficiency in many countries [47].

POMC and PCSK1 deficiency

Leptin stimulates the expression of the POMC precursor peptide, which is post-translationally processed into the melanocortin peptides α - and β -MSH (melanocyte-stimulating hormone). In the pituitary gland, POMC is cleaved to yield adrenocorticotrophin (ACTH), which acts on the melanocortin 2 receptor (MC2R) to regulate the synthesis of cortisol by the adrenal gland. In the skin, POMC-derived melanocortin peptides regulate pigmentation by signalling through the melanocortin 1 receptor (MC1R), and in the brain α - and β -MSH activate signalling via MC4R to reduce food intake [48]. As a result, homozygous or compound heterozygous mutations in POMC lead to hyperphagia and early-onset obesity, isolated ACTH deficiency (often presenting with neonatal hypoglycaemia or cholestatic jaundice), and hypopigmentation resulting in red hair in people of European ancestry [49,50].

Homozygous or compound heterozygous mutations in prohormone convertase 1 (PCSK1), the enzyme that processes POMC and other peptides, lead to hyperphagic severe early-onset obesity and ACTH deficiency as well as hypogonadotropic hypogonadism and postprandial hypoglycaemia due to impaired processing of proinsulin to insulin [51]. Where these assays are available, the finding of high proinsulin levels in the context of a low plasma insulin suggests this diagnosis. Impaired processing of gut-derived peptides in the enteroendocrine cells that express PCSK1 [52] may contribute to neonatal enteropathy; indeed, these individuals may first present to gastroenterologists with these symptoms. A single family with a homozygous mutation in carboxypeptidase E has been reported with overlapping clinical features [53]. Setmelanotide is effective in POMC and PCSK1 deficiency [54] and has been licensed for chronic weight management in these disorders.

MC4R deficiency

Targeted disruption of *Mc4r* in mice leads to increased food intake, weight gain, increased lean mass, and greater linear growth [55]. Heterozygous loss-of-function mutations in MC4R are found in 5–6% of individuals with severe early-onset obesity [56] and at a frequency of approximately 1 in 330 in the general UK population,

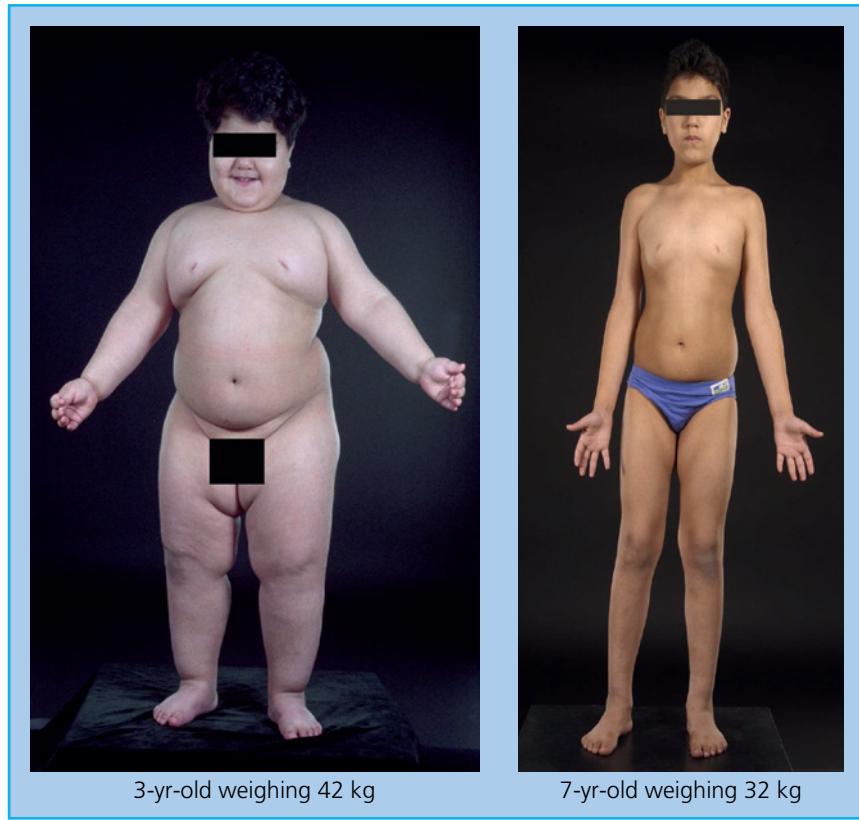

Figure 13.2 Recombinant leptin therapy reduces body weight in a child with congenital leptin deficiency.

making this the commonest gene in which variants contribute to obesity [57]. On average, at the age of 18 years, people who carry a heterozygous loss-of-function mutation in MC4R are ~18 kg heavier [57]. Most disease-causing MC4R mutations disrupt the expression and trafficking of the receptor to the cell surface [58]. Additionally, mutations can affect the production of cyclic adenosine monophosphate (cAMP), the homodimerization of MC4R, its endocytosis, as well as the recruitment of β -arrestins [59]. MC4R mutations are inherited in a co-dominant manner, with variable penetrance and expression in heterozygous carriers [56]; homozygous and compound heterozygous mutations have also been reported in people with severe obesity. The clinical features of MC4R deficiency include hyperphagia, early hyperinsulinaemia, increased lean mass, and increased linear growth [56, 60]. Complete loss-of-function mutations have a larger impact on phenotype than partial loss-of-function mutations [61].

Loss-of-function MC4R mutations in people are associated with a reduced prevalence of hypertension, relatively low systolic blood pressure, lower urinary noradrenaline excretion, and reduced peripheral nerve sympathetic activation compared to similarly obese people without MC4R mutations [62]. Liraglutide, the GLP-1 receptor agonist, is effective in some people with MC4R deficiency [63] and some individuals with heterozygous (but not homozygous) mutations benefit from Roux-en-Y bypass surgery [64].

SIM1 deficiency

SIM1 directs the development and function of the paraventricular nucleus of the hypothalamus where MC4R is highly expressed. Deletions that encompass SIM1 and heterozygous loss of function *SIM1* mutations cause hyperphagia, severe obesity, and increased

linear growth, features that closely overlap with MC4R deficiency [65, 66]. Many *SIM1* mutation carriers have speech and language delay in childhood and exhibit neurobehavioural abnormalities, including autistic-type behaviours. A small number of mutations in *OTP*, another transcription factor involved in paraventricular nucleus development, have been reported in individuals with obesity and autistic behaviours [67].

Rare variants in multiple genes associated with obesity

Alongside genetic disorders that follow a clear Mendelian pattern of inheritance, rare variants in several genes can drive obesity without always being causative in every variant carrier in the family. The characterization of these rare obesity-associated variants presents some challenges, but can be relevant for diagnostic and therapeutic purposes. Heterozygous loss-of-function mutations in *POMC*, which impair the function of α - and β -MSH, significantly increase obesity risk but are not invariably associated with obesity [68, 69]. Similarly, rare variants that impair the function of semaphorin 3 ligands, receptors, and co-receptors, which direct the development of melanocortin circuits, are associated with severe obesity [70]. Rare heterozygous variants that disrupt the function of the transcription factor steroid receptor coactivator (SRC)-1, which interacts with phosphorylated STAT3 to modulate leptin-mediated *POMC* transcription, are also associated with obesity [71]. Heterozygous pleckstrin homology domain-interacting protein (PHIP) deletions and frameshift mutations impair *POMC* transcription [72] and are associated with a variable spectrum of

developmental delay, reduced growth, hyperphagia, obesity, insulin resistance, and early type 2 diabetes. Informed by these mechanistic studies, clinical trials are ongoing to investigate whether setmelanotide may be effective in individuals with rare disorders affecting the melanocortin pathway.

Heterozygous mutations in the kinase domain of kinase suppressor of Ras2 (KSR2) are associated with reduced basal metabolic rate as well as hyperphagia in childhood [73]. Some KSR2 mutation carriers experience marked weight loss in childhood when prescribed the anti-diabetes drug metformin (for severe insulin resistance).

Conclusion

Cumulatively, up to 20% of children with severe obesity have rare chromosomal abnormalities and/or highly penetrant genetic mutations that drive their obesity [72]. This figure is likely to increase with greater detection driven by wider access to comparative genomic hybridization and whole-exome/genome sequencing. A genetic diagnosis can inform clinical management, as these individuals are relatively refractory to weight loss through changes in diet and exercise and several therapies now exist. A genetic diagnosis can inform decision making around bariatric surgery, which is

feasible in some disorders (heterozygous MC4R deficiency), but high risk in others (homozygous leptin receptor deficiency and Prader-Willi syndrome) where the procedure does not address the underlying cause of the obesity.

Genetic studies continue to play a powerful role in shaping our understanding of the pathways regulating weight and their disruption in obesity and can inform strategies to target these pathways for the development of new weight loss strategies. Common variants involving over 150 loci have been associated with BMI and/or obesity in the population in genome-wide association studies (GWAS) [74]. Generally, each common variant has a very small effect size. For example, homozygous carriers of a common variant at the *FTO* locus, which has the greatest effect size seen in GWAS, are 2–3 kg heavier than non-carriers [75]. As many common variants lie in non-coding regions, the mechanisms by which they influence body weight have been challenging to dissect, but progress is being made [74]. There is increasing interest in the understanding of whether polygenic risk scores, which capture the cumulative effects of millions of common and rare variants combined and may predict the development of obesity [76], will be useful in clinical practice.

14 Autoimmune Type 1 Diabetes

Omar Akel and Åke Lernmark

Department of Clinical Sciences, Lund University CRC, Skåne University Hospital, Malmö, Sweden

Key points

- The prevalence and incidence of autoimmune type 1 diabetes continue to increase worldwide.
- The clinical onset peaks in childhood, but may occur across the age span.
- Autoimmune type 1 diabetes aetiology is marked by the appearance of a first β -cell autoantibody against either insulin or glutamic acid decarboxylase 65 (GAD65). Some children may present with both autoantibodies.
- The natural history of type 1 diabetes may be divided into three distinct stages:
 - The development of multiple β -cell autoimmunity: Stage 1.
 - Asymptomatic loss of β -cell secretory capacity: Stage 2.
 - Loss of β -cell function along with diabetes symptoms: Stage 3.
- Autoimmune type 1 diabetes results from a loss of immunological tolerance to certain β -cell autoantigens.
- Human leucocyte antigen (HLA) genes represent the strongest genetic determinants for the risk of β -cell autoimmunity, but may not contribute to the progression to type 1 diabetes.
- Environmental factors may trigger β -cell autoimmunity, accelerate the pathogenic process, or both.
- β -cell destruction occurs during the pathogenesis of β -cell autoimmunity and is likely to be mediated by cytotoxic CD8+ T cells.
- β -cell destruction may occur prior to β -cell autoimmunity, but the precise mechanism remains unclear.
- Multiple β -cell autoantibodies (≥ 2) usually appear within 6–12 months following the appearance of the first autoantibody and markedly increase the risk for progression to type 1 diabetes.
- The appearance of either autoantibodies against islet antigen-2 (IA-2) or zinc transporter 8 (ZnT8) in children with insulin or GAD autoantibodies is a strong marker of accelerated progression to the clinical onset of type 1 diabetes.
- The progressive destruction of β cells is likely to vary in intensity and duration, affecting the time between the first appearance of the autoantibody biomarker and the clinical diagnosis.

The differentiation between type 1 diabetes (previously known as insulin-dependent diabetes or juvenile-onset diabetes) and type 2 diabetes (non-insulin-dependent or adult-onset diabetes), the two main forms of diabetes, has been deliberated for almost 60 years. Insulitis was rediscovered in 1965, supporting the view that islet mononuclear cell infiltration was associated with the development of type 1 diabetes [1]. The evidence for islet autoimmunity was further supported by the identification of mononuclear cell reactivity with islet extracts [2] and the association between type 1 diabetes and other organ-specific autoimmune disorders [3]. More importantly, long sought-after autoantibodies against islet cells (ICAs) were reported using indirect immunofluorescence on pancreas frozen sections and sera of people with concomitant type 1 diabetes and autoimmune polyendocrine syndrome [4,5]. At the same time, type 1 diabetes was found to be strongly associated with human leucocyte antigen (HLA) [6,7]. It was also noted, however, that ~10% of adults diagnosed with type 2 diabetes whose sulfonylurea treatment had failed (so-called *secondary failures*) [8] were positive for ICAs, a group of people now commonly known as having latent autoimmune diabetes of adults [9–11]. There are several genetic and autoimmune similarities between childhood and adolescent type 1 diabetes and latent autoimmune diabetes of adults, but the two entities differ in genetic and autoimmune processes as well as

the clinical features [11,12]. Several years of research, initiated by studying children from birth followed by genetic studies [13–18], have resulted in a paradigm shift of the understanding of the aetiology and pathogenesis of type 1 diabetes. In this chapter, we summarize the current knowledge of possible trigger(s) of β -cell autoimmunity (aetiology) and factors affecting the progression to the clinical onset in individuals who have developed one or more β -cell autoantibodies (pathogenesis).

ICAs were described in 1974 [4,5], islet surface antibodies (ICSA) in 1978 [19], and complement-dependent antibody-mediated islet cell cytotoxicity in 1980 [20]. The first autoantigen recognized by islet antibodies, an islet protein of 64 000 relative molecular mass (64 K), was described in 1982 [21]. The 64 K protein had glutamic acid decarboxylase (GAD) activity [22], but molecular cloning showed that the human islet GAD was a novel isoform, GAD65 [23]. Autoantibodies to insulin were demonstrated in 1983 [24]; to islet antigen-2 (IA-2), a tyrosine phosphatase-like protein, in 1994 [25]; and to the zinc transporter 8 (ZnT8) in 2007 [26]. In contrast to T-cell analyses, GAD65, IA-2, and ZnT8 autoantibodies may be determined in standardized assays [27].

Autoimmune type 1 diabetes is recognized by the appearance of a first β -cell autoantibody against either insulin (IAA) or GAD65 (GADA), or both, in early childhood [28–30]. Rarely, the first islet

Table 14.1 Biomarkers of islet autoimmunity predict clinical onset of type 1 diabetes.

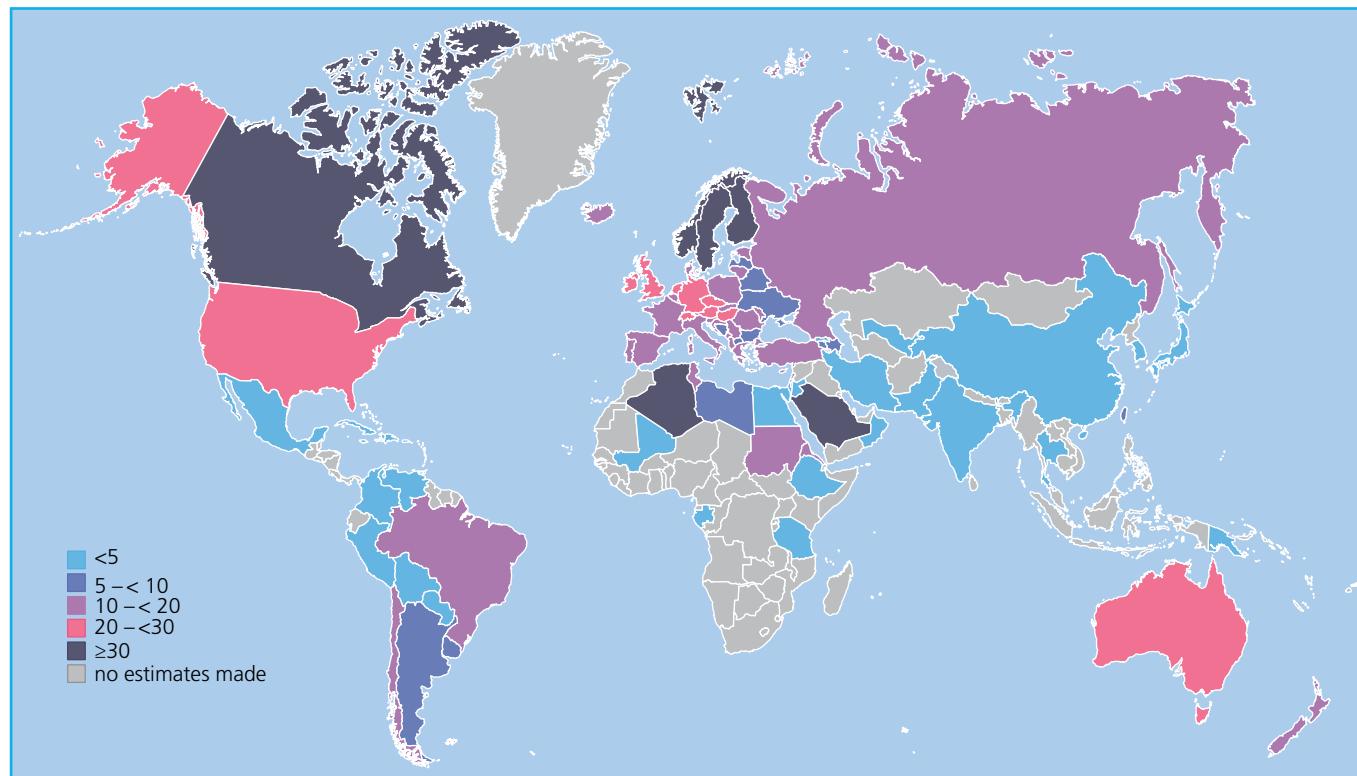

Autoantibody abbreviation	Protein autoantigen	Protein abbreviation	Gene and location	References
IAA	(Pro)insulin	Insulin	INS 11p15.5	[24, 33]
GADA	Glutamic acid decarboxylase	GAD65	GAD2 10p12.1	[21–23, 34]
IA-2A	Islet antigen-2	IA-2	PTPRN 2q35	[25, 35, 36]
ZnT8A	Zinc transporter 8	ZnT8	SLC30A8 8q24.11	[26, 37, 38]

autoantibody is directed against IA-2 (IA-2A) or ZnT8 (ZnT8A) [28, 30–32]. These four autoantibodies (Table 14.1) are strong biomarkers, since the development of a first autoantibody (IAA or GADA) and the appearance of a second, a third, and often a fourth autoantibody will result in type 1 diabetes in 100% of individuals when followed for 10–20 years [18, 32, 39]. The epidemiology of β-cell autoantibodies in children or adults in different countries is currently unknown, as population screening for IAA, GADA, IA-2A, and ZnT8A is yet to be implemented. It remains to be determined in multiple populations whether the incidence of β-cell autoantibodies eventually equals that of type 1 diabetes.

Epidemiology

The incidence of type 1 diabetes varies 50–100-fold worldwide, with the highest rates occurring in individuals of northern European descent (Figure 14.1). In most countries, the lifetime risk of type 1 diabetes is less than 1%. Both sexes are equally affected in childhood, but men are affected more commonly in early adult

life [41, 42]. An incidence rate of 20 per 100 000 individuals per year corresponds approximately to a cumulative incidence of 0.3% at age 15 years, or 1 in 330, and a prevalence in age group 0–15 years of ~0.15%. The incidence of childhood type 1 diabetes is rising rapidly in all populations, especially in children younger than 5 years, where the incidence in Europe has doubled during the last 20 years [42]. The 2–4% increase per year would correspond to doubling times of 35–18 years. Because of the wide differences in absolute incidence rates across countries (Figure 14.1), the magnitude of change over time appears somewhat suppressed in the low-incidence regions such as Japan. There is a tendency that low-incidence countries have experienced a larger relative increase than high-incidence countries. The increasing incidence of type 1 diabetes suggests a major environmental contribution. However, given the significant decrease in incidence rate among children reported in Australia [43] and Finland [44], the role of specific pathogenic factors remains largely unsettled; nevertheless, recent longitudinal observational clinical studies of children at increased genetic risk for type 1 diabetes are providing novel insights into possible mechanisms of virus infections [45, 46].

**Figure 14.1** Age–sex standardized incidence rates (per 1 000 000 population per year) of type 1 diabetes in those 0–14 years of age. Source: Adapted from Sun H et al. 2022 [40].

The incidence rates of type 1 diabetes are from the time of clinical onset, but the incidence rate of islet autoimmunity is largely unknown and islet autoimmunity may have been present for several years. The clinical onset represents the end-point of a progressive, silent pathogenesis. The rate of loss of pancreatic β cells is difficult to estimate and may be affected by environmental factors. For example, enterovirus infection in children who are positive for two or more islet autoantibodies may accelerate the pathogenesis and result in an earlier age at onset [47].

The epidemiology of type 1 diabetes represents two stages. The first stage reflects the aetiology, the actual trigger of the disease that includes the genetic and environmental aetiology. Currently, the genetic aetiology indicates that the HLA haplotypes DR4-DQ8, DR3-DQ2, or both (the genotype is DR3-DQ2/DR4-DQ8) are necessary but not sufficient for the disease [48]. The environmental aetiology may represent enterovirus infection and prolonged viral shedding and possibly other factors (genetic as well as environmental) [45, 46, 49, 50] in combination that trigger islet autoimmunity reflected by the appearance of a first islet autoantibody. Dependent on the HLA type and other genetic factors of the child, the first appearing autoantibody may be either IAA or GADA [28, 30, 51–53]. Future studies of the epidemiology of autoimmune type 1 diabetes should therefore take into account not only the clinical onset of the disease, referred to as *type 1 diabetes* or *autoimmune diabetes*, but also the epidemiology of *islet autoimmunity* or *autoimmune islet disease* [54]. At present, autoimmune islet disease is defined by the presence of persistent islet autoantibodies, IAA, GADA, IA-2A, and ZnT8A, in various combinations.

The epidemiology of autoimmune islet disease would be important to better understand the relationship to infections, but also genetic propensity and contributions by other environmental factors. A program of primary care-based screening showed an islet

autoantibody prevalence of 0.31% among children aged 2–5 years in Bavaria, Germany [55]. Testing islet autoantibodies at random or in select populations such as schoolchildren should inform about the epidemiology of autoimmune islet disease and what to expect in the years to come about the epidemiology of autoimmune type 1 diabetes.

Natural history and staging type 1 diabetes

The description of the natural history of autoimmune type 1 diabetes has changed in a major way during recent years. The aetiology and pathogenesis are better understood, especially as the aetiology can be better defined in terms of genetic and environmental aetiology and that the cause and origin of autoimmune type 1 diabetes are beginning to be understood. First, HLA genetic risk for type 1 diabetes allowed screening to identify neonates at increased genetic risk [15, 56]. Second, islet autoantibodies detected in standard radiobinding assays were validated and found to be reliable biomarker end-points of islet autoimmunity [57–60]. The four commonly used islet autoantibody markers (Table 14.1) are detectable not only in radiobinding assays but also in double-sided enzyme-linked immunosorbent assay (ELISA) [61], chemiluminescence [62, 63], and autoantibody detection by agglutination polymerase chain reaction (ADAP) [64]. Third, general population screening at birth has been proven to be both feasible and well tolerated by parents and children [65–68].

Follow-up studies from birth in more than 26 000 individuals in nine different studies have made it possible to stage the pathogenesis of type 1 diabetes (Figure 14.2). The Environmental Determinants of Diabetes in the Young (TEDDY) study is by far the largest and represents a major effort by the National Institutes of Health (NIH) that brought DIPP, DAISY, DiPiS, BABYDIAB, PANDA, and DEW-IT (Table 14.2) together to increase the power of the

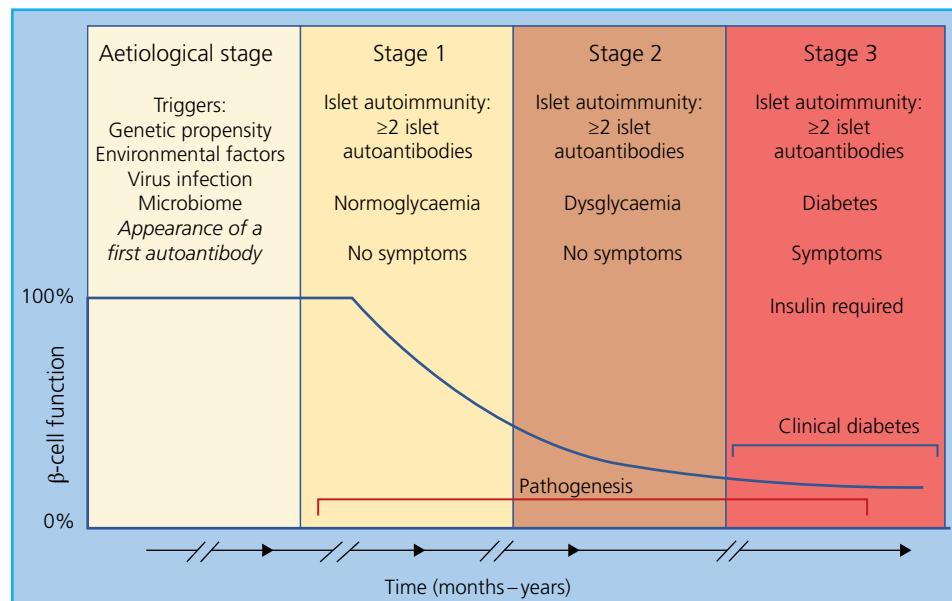

Figure 14.2 Staging of the natural history of autoimmune type 1 diabetes. The aetiological stage is thought to be associated with enterovirus infection in people at increased genetic risk for type 1 diabetes. A series of unknown events, such as prolonged shedding of virus, may trigger islet autoimmunity by yet unknown mechanisms. A first islet autoantibody against islet antigen or glutamic acid decarboxylase, dependent on genetic risk, appears and represents the biomarker for islet autoimmunity. Following the appearance of a second autoantibody, the person is classified in stage 1, which is

defined by the presence of two or more islet autoantibodies, normoglycaemia, and no symptoms. In stage 2 the person has multiple autoantibodies and has developed dysglycaemia or impaired glucose tolerance without symptoms. Stage 3 is also characterized by multiple autoantibodies. Individuals may lose autoantibodies prior to stage 3. Diabetes is diagnosed according to the American Diabetes Association and World Health Organization criteria and the person may have symptoms and will also require insulin. Sources: Adapted from Insel et al. 2015 [82] and Lloyd et al. 2022 [116].

Table 14.2 Observational birth cohorts in autoimmune type 1 diabetes.

Year start	End	Acronym	Name	Newborns followed	Inclusion	Reference

FDR, first-degree relative; HLA, human leucocyte antigen.

investigation. Because type 1 diabetes is detected in most individuals with type 1 diabetes after a relatively short period of symptoms, the natural history of the disease has been poorly defined until recently. With the current ability to define individuals at increased risk for type 1 diabetes based on high-risk HLA and islet autoantibodies, the understanding of the pre-diabetes period is improving.

The prospective studies from birth of children with increased risk for type 1 diabetes in TEDDY and the other studies listed in Table 14.2 have revealed that GADA, IAA, IA-2A, or ZnT8A may develop several years before the clinical diagnosis. The sequence of events preceding the diagnosis of overt type 1 diabetes would include the following:

1. Genetic predisposition.
2. Overt immunological abnormality, reflected in a first-appearing islet autoantibody but with normal glucose levels and no symptoms.
3. Development of a second or third islet autoantibody, still with normal blood glucose and no symptoms (type 1 diabetes stage 1).
4. Development of β-cell dysfunction and dysglycaemia, but no symptoms (type 1 diabetes stage 2).
5. Development of overt hyperglycaemia with detectable C-peptide (type 1 diabetes stage 3).
6. The final stage of insulin dependency, with loss of detectable C-peptide (Figure 14.2) [82].

The fact that type 1 diabetes develops in people of all ages must be considered when studying the natural history in children and adults. Early histological studies of pancreatic tissue of people who died shortly after the clinical onset of diabetes revealed that the pancreatic islets were altered by fibrosis, hyalinosis, atrophy, and infiltration of inflammatory cells [1]. The inflammatory lesion of the islets of Langerhans was described as *insulitis*, and quantitative studies of the pancreatic islets showed a specific loss of insulin-positive cells in association with the clinical onset of type 1 diabetes [1]. It was therefore suggested that the pathogenesis of type 1 diabetes involved autoimmune reactions directed towards the endocrine pancreas.

This notion was supported by leucocyte migration inhibition to pancreatic islet antigens [2]. Numerous studies have confirmed the presence of insulitis [83–85], however, despite the assumption that type 1 diabetes is a T-cell mediated disease, reproducible and standardised tests of blood T-cell reactivity against islet autoantigens or other specific autoantigens are yet to be fully established.

Islet autoantibodies as biomarkers

Islet autoantibodies have been studied longitudinally in a large number of first-degree relatives of people with type 1 diabetes until the clinical onset of type 1 diabetes [86–88]. The islet autoantibodies are not thought to be directly involved in β-cell destruction. For example, complement-mediated antibody-dependent cytotoxicity would require the autoantigen to be expressed on the β-cell surface [19,20]. A subset of autoantibodies to ZnT8 may fulfil the criteria for cell surface expression [89,90]. Further studies are needed to fully establish to what extent islet autoantibodies *per se* contribute to pathogenesis and risk for diabetes. The demonstration of islet autoantibodies years before the onset of clinical symptoms has made it possible to identify individuals at high risk for type 1 diabetes and to initiate therapeutic intervention trials. In particular, the number of islet autoantibodies seems to affect the rate of progression to clinical onset [39]. Children recruited and followed in three studies (DAISY, Colorado, n = 1962; DIPP, Finland, n = 8597; and BABYDIAB, Germany, n = 2818) were merged in a joint analysis [39]. The data showed that progression to diabetes at 10-year follow-up after islet autoantibody seroconversion varied with the number of islet autoantibodies: no islet autoantibodies was 0.4% (95% confidence interval [CI], 0.2–0.6%); a single islet autoantibody was 14.5% (95% CI, 10.3–18.7%); and multiple islet autoantibodies was 69.7% (95% CI, 65.1–74.3%) [39]. These results were further corroborated in 1815 first-degree relatives who were

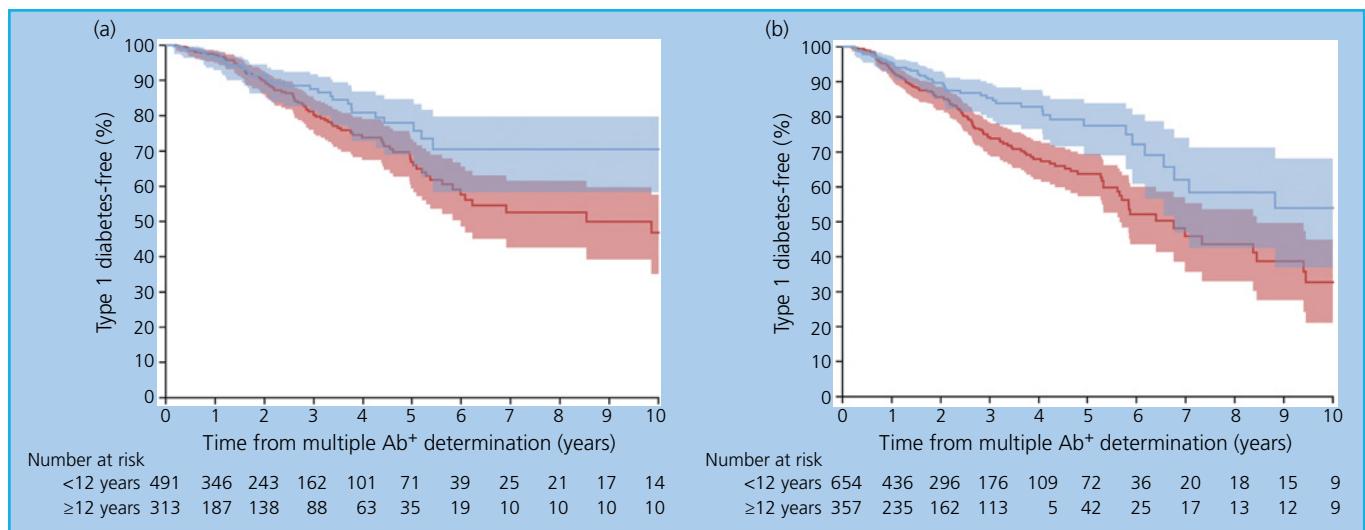

Figure 14.3 Type 1 diabetes-free cumulative incidence with 95% confidence interval (shaded area) in TrialNet participants with two (a) or more than two (b) islet autoantibodies. (a) In participants with two autoantibodies, there was a lower cumulative incidence among those older than 12 years of age (red) ($p = 0.0496$). (b) In participants with more than two autoantibodies, the cumulative incidence was markedly different between those younger than 12 years (red) and those older than 12 years of age (blue) ($p = 0.0008$). Source: Jacobsen et al. 2020 [91].

followed until diabetes diagnosis in the TrialNet Pathway to Prevention study (Figure 14.3) [91]. Participants younger than 12 years had a higher risk of progressing to clinical onset regardless of whether they had two autoantibodies only (panel a) or more than two autoantibodies (panel b) [91]. These data raise the question of whether islet autoantibody screening should be used in clinical practice. The effect of age and number of autoantibodies strongly suggests that the heterogeneity in progressing to clinical onset needs to be taken into account in secondary prevention clinical trials.

A first step was to use a meta-analysis to assess the evidence of an association between islet autoantibodies and the development of type 1 diabetes in a pooled population of both genetically at-risk individuals and people without a definite genetic background [92]. In the meta-analysis, 21 prospective cohort studies with 71 482 participants, who were followed for a median of 7 years and of whom 926 developed type 1 diabetes, evaluated the role of islet autoantibodies in prediction of type 1 diabetes progression. Compared to people without autoantibodies, those positive for any type or number of islet autoantibody had a marked risk for type 1 diabetes (risk ratio [RR] 150.42 [95% CI 87.34, 259.04]) [92]. People with multiple autoantibodies had a ninefold higher risk than those with a single islet autoantibody. This meta-analysis is raising the question of the place of screening the general population for islet autoantibodies, since the likelihood of individuals with multiple islet autoantibodies eventually developing type 1 diabetes is high.

A second step was the recent discovery that the aetiology of islet autoimmunity may represent two different endotypes, dependent on whether IAA appear first compared to GADA [28,30]. This raises the question of whether the first-appearing autoantibody is related to disease progression. In longitudinal sampling of IAA, GADA, and IA-2A in a cohort of 24 662 people combined from DAISY [16], DIPP [93], DiPiS [94], DEW-IT [75], and BABYDIAB [95], 2172 individuals fulfilled the criteria of two or more follow-up visits and autoantibody positivity at least once, while 652 progressed to type 1 diabetes during 15 years of follow-up (Figure 14.4). Continuous-time hidden Markov models [18] were used to let the data visualize the latent health state of the participants

during 5 years of follow-up. Three different trajectories were discovered from 11 latent states. TR1 represents those with multiple islet autoantibodies in the first sample. Only 40% remained diabetes free after 5 years. TR2 represents people with predominantly IAA as the first-appearing autoantibody. Diabetes-free survival was 62%. TR3 was people with GADA first who showed 88% diabetes-free survival after 5 years of follow-up. Progression rates within each trajectory could be refined by age, sex, and HLA-DR, thereby providing a clinically useful prediction of disease onset [18]. This type of approach with the aid of further machine learning and artificial intelligence may provide the means by which islet autoantibody analyses will become meaningful for the individual.

Genetic and environmental aetiology to initiate islet autoimmunity

Genetic aetiology

Longitudinal studies of newborn children at increased genetic risk either as a first-degree relative (father, mother, or sibling has type 1 diabetes) or by cord blood HLA typing have identified infants who developed a first islet autoantibody during the first year of life [13, 28, 30]. The first autoantibody was either IAA or GADA, rarely IA-2A or ZnT8A, but two or more autoantibodies occurred as blood sampling was not more frequent than three months apart. There was a strong association between HLA-DR4-DQ8 and IAA as the first β -cell autoantibody [28, 31]. GADA as a first islet autoantibody was associated with HLA-DR3-DQ2; indeed GADA-first was exclusive to homozygous HLA-DR3-DQ2 children [28, 31]. These observations suggest a paradigm shift in the understanding of the association between HLA and type 1 diabetes. The primary effect would be an association between HLA and the first-appearing autoantibody and not type 1 diabetes *per se*. The mechanism by which HLA contributes to the aetiological triggering of islet autoimmunity should be sought, as it may have nothing to do with loss of β cells, dysglycaemia, and diabetes [53, 96].

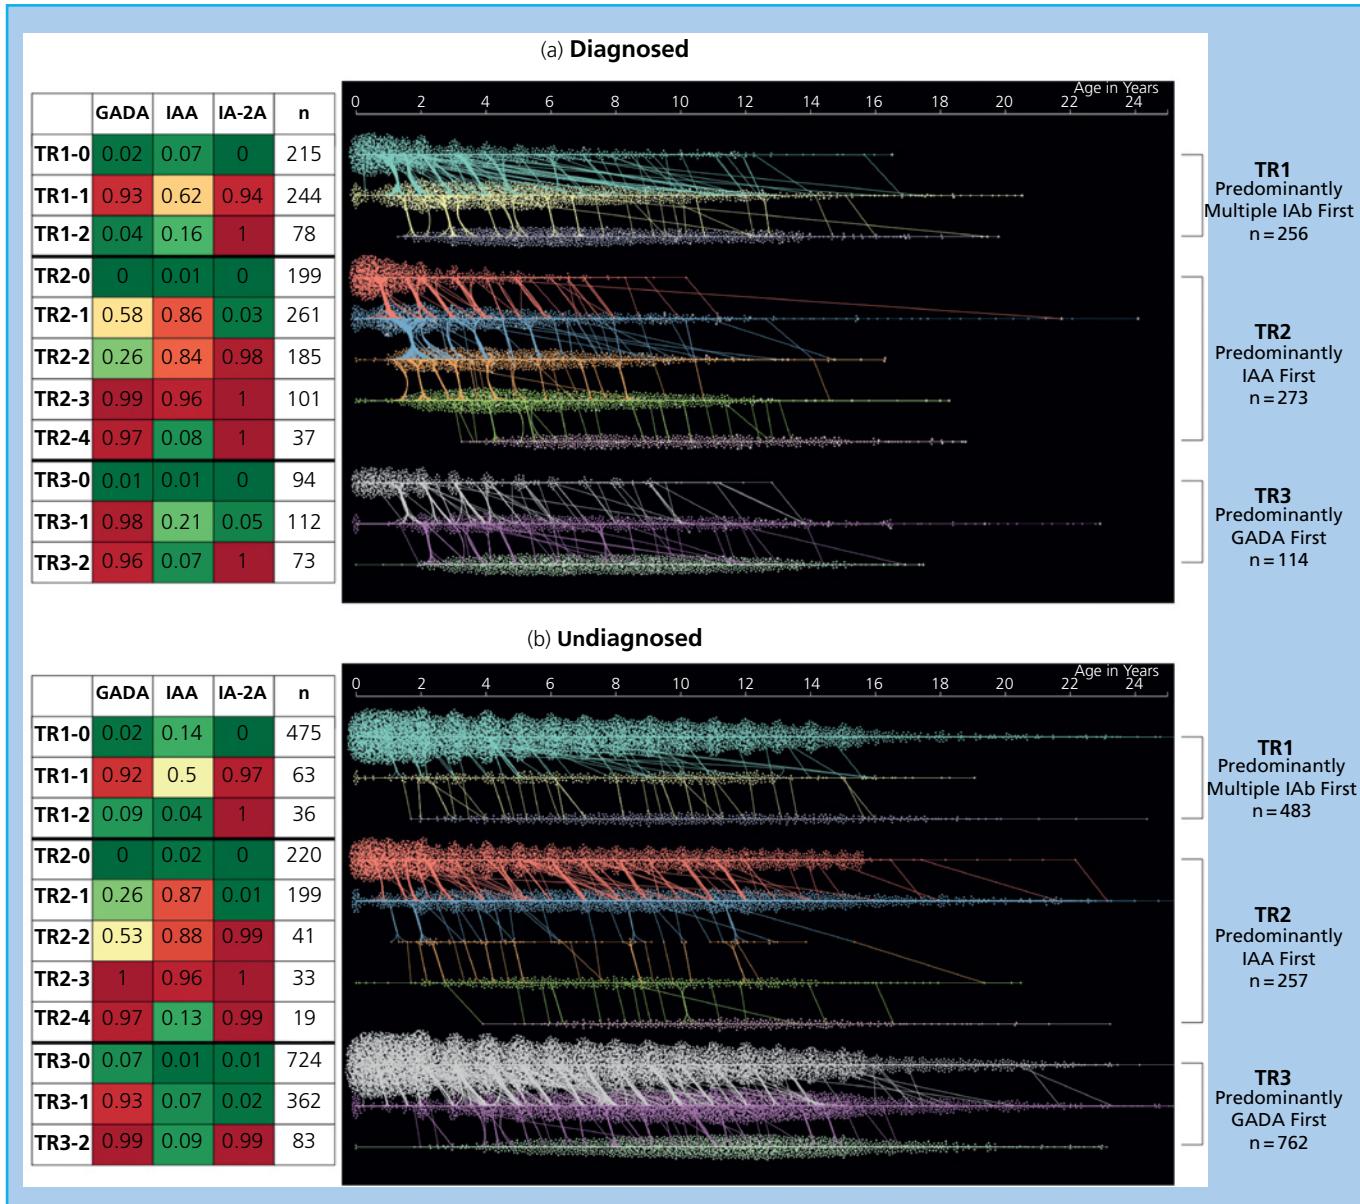

Figure 14.4 Three trajectories of data-driven islet autoantibodies towards stage 3 diabetes. A 11-state hidden Markov model discovered the three trajectories for (a) diagnosed (D, 643 individuals who were diagnosed with type 1 diabetes) and (b) undiagnosed (UD, 1502 individuals who remained not diagnosed with diabetes during follow-up). The data in the table to the left describe the 11 states as the probabilities for each islet autoantibody (glutamic acid decarboxylase autoantibody [GADA], insulin autoantibody [IAA], or islet antigen-2 autoantibody [IA-2A]) for each state (the heat map

indicate green for 0 and red for 1). Waterfall diagrams to the right show visits (dots) and the respective trajectory state over time in years (x-axis). Each person is depicted from the appearance of the first autoantibody and can then be followed from one state to the next in the waterfall. The three trajectories reveal themselves as TR1, predominantly multiple islet autoantibodies (IAb) as the first islet autoantibody (256 D, 483 UD); TR2, predominantly IAA first (273 D; 257 UD); and TR3, predominantly GADA first (11 D; 762 NP). P, progressors; NP, non-progressors. Source: Kwon et al. 2022 [18]. Licensed under CC BY 4.0.

The genetics of type 1 diabetes have been studied extensively during the past 50 years, especially since the mode of inheritance has remained uncertain. HLA represents ~50% of the familial risk of type 1 diabetes [97]. It should be noted that alleles in the HLA region, such as the HLA class II DR and DQ alleles, are in linkage disequilibrium, which means that among hundreds of alleles certain allele combinations are inherited as extended haplotypes. The reduced rate of recombination events in the HLA region is not understood and it complicates the dissection of which allele and protein product is mechanistically responsible for the association between HLA and the first-appearing islet autoantibody. A suitable example is the recently discovered tri-SNP (single-nucleotide polymorphism) in the first

intron of HLA-DRA [98,99]. The HLA-DRA protein, representing the A-chain of the DR heterodimer, does not vary between people. However, the recent finding suggests the presence of an intron polymorphism that may regulate the expression not only of HLA-DR, but also the DQ heterodimer [98,99].

The class II HLA-DR-DQ haplotype DR3-DQ2 (*DRB1*03-DQA1*0501-B1*0201*)/DR4-DQ8 (*DRB1*04-DQA1*03:01-B1*03:02*) confers the highest risk for type 1 diabetes [48]. The risk of the heterozygous DQ2/8 genotype for type 1 diabetes is complicated by the possibility that *DQA1*05:01-B1*03:02* and *DQA1*03:01-B1*02:01* haplotypes form heterodimer molecules in *trans* that contribute to risk by unique antigen-presenting capabilities [100]. The

HLA DQ2/8 genotype may therefore represent not only two but four potential antigen-presenting heterodimers. The DR3-DQ2/DR4-DQ8 genotype was found in more than 95% of individuals with type 1 diabetes younger than 30 years of age compared to 25–30% of the general population [101]. The HLA DR3-DQ2 and DR4-DQ8 haplotypes, alone or in combination, may therefore be regarded as necessary but not sufficient for aetiology currently measured as the risk of developing a first-appearing islet autoantibody (Figure 14.2). In children developing a second islet autoantibody, the risk that the pathogenesis will end up in clinical onset has been estimated as 70% within 10 years [32,39].

HLA DR-DQ genes are transcribed and translated into the α and β transmembrane chains that pair to form a heterodimer (Figure 14.5). The heterodimer creates a peptide-binding region between the α - and β -chains. The peptide-binding region has pockets to bind

amino acid residues, but it is the physicochemical nature of the peptide-binding region that dictates the binding of peptides from exogenous and endogenous protein antigens (Figure 14.5). The peptide-binding region with bound peptide is the ligand, the trimolecular complex, for the T-cell receptor (TCR). The genetic aetiology of islet autoimmunity is reflected by the amino acid residues coded for by different DRB1* [102] and DQA1*-DQB1* for either risk [103,104] or protection [104,105]. Amino acid residues associated with islet autoimmunity were α 1, α 44, α 157, α 196 on the DQ A-chain, and β 9, β 30, β 57, β 70, β 135 on the DQ B-chain. These motifs capture all known susceptibility and resistant type 1 diabetes associations. Three motifs, DCAA-YSARD (representing DQ2.5), DQAA-YYARD (representing DQ8), and DQDA-YYARD (representing DQ8.1), accounted for the structures needed to develop islet

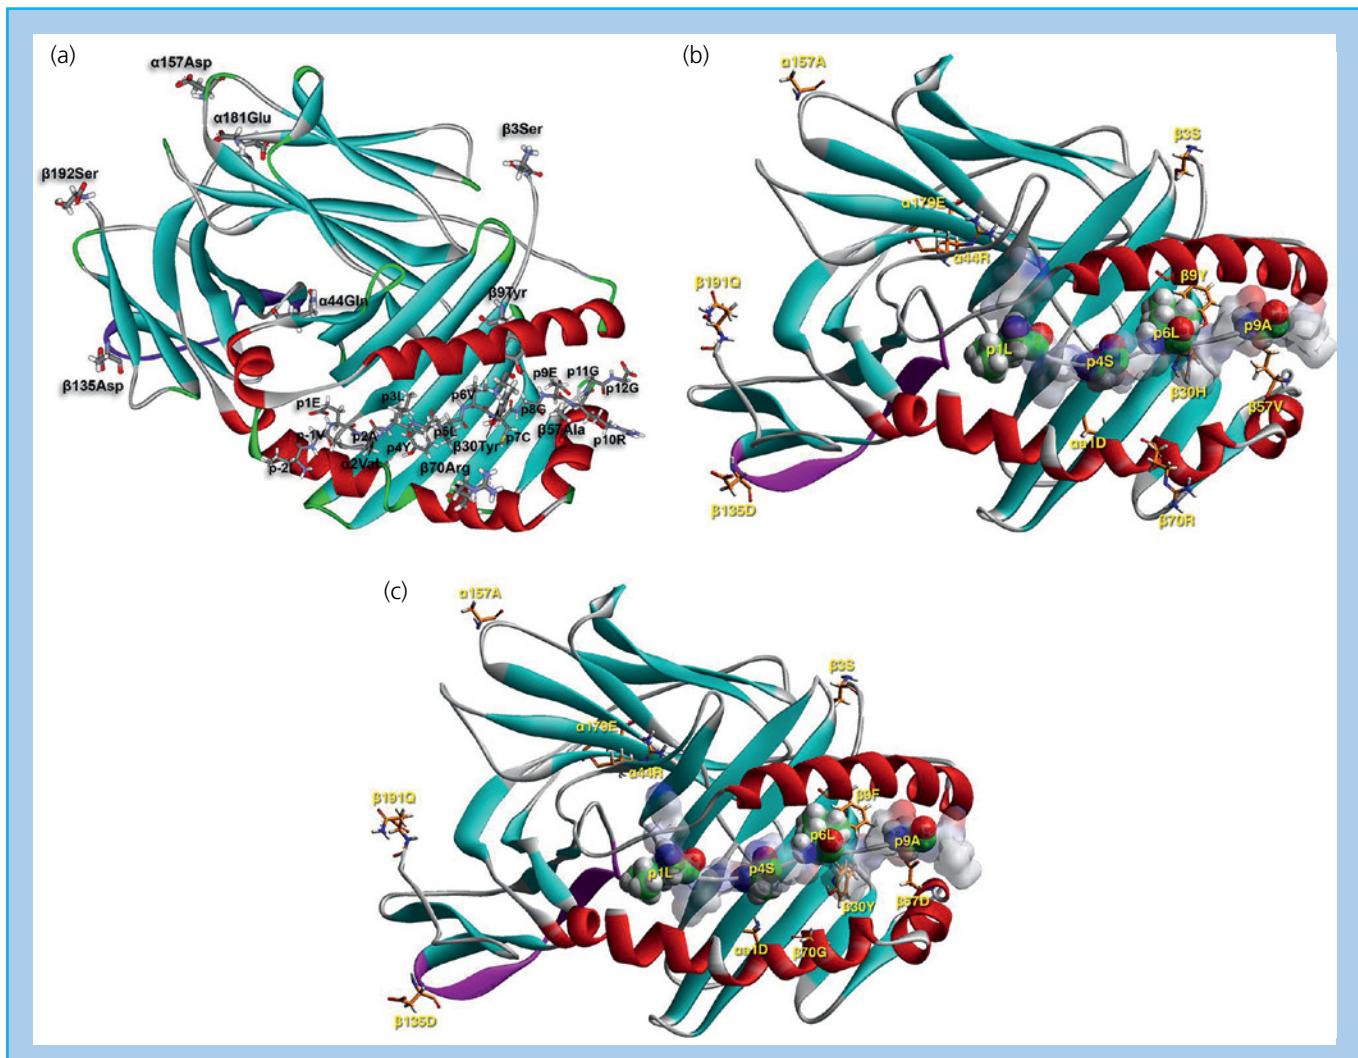

Figure 14.5 Molecular illustrations of insulin peptides bound to (a) human leucocyte antigen (HLA)-DQ heterodimers at risk (DQ8 with insulin B11–24); (b) neutral risk (DQ6.4 with insulin B5–15); and (c) protection (DQ6.2 with insulin B5–15). (a) is based on a crystallized complex while (b) and (c) are based on molecular simulations. The HLA-DQ-insulin peptide complexes are shown in their secondary structure formation (α -helix in red; β -sheet in turquoise; β -turn, random coil, or any other form in grey). The β 134–148 CD4-binding stretch is shown in purple. The HLA-DQ amino residues in both the A- and B-chains are shown in stick form (atom colour convention: carbon, grey; oxygen, red; nitrogen, blue; sulfur,

yellow; hydrogen, white). The insulin peptide is shown in stick form in (a) (thinner sticks, with the same colour convention), and in space-filling form in (b) and (c) with the p1Leu, p4Ala, p6Leu, and p9Ala anchor residues opaque. The remaining residues are non-transparent surfaces coloured by atom charge (red, negative; blue, positive; partial charges coloured with shades in between), in order to appreciate the positioning and orientation of the different amino acid residues. The trimolecular complexes depicted in (a–c) from risk to protection are clearly different in appearance to indicate that T-cell receptors on CD4+ T cells will differ markedly in binding characteristics to go from risk to protection.

autoimmunity and risk for type 1 diabetes. Ten motifs were significantly associated with resistance to type 1 diabetes [104]. The nine amino acid residues were within or near anchoring pockets of the peptide-binding region ($\alpha 44$, $\beta 9$, $\beta 30$, $\beta 57$, and $\beta 70$); one was the N-terminal of the alpha chain ($\alpha 1$), one in the CD4-binding region ($\beta 135$), one in the putative cognate TCR-induced $\alpha\beta$ homodimerization process ($\alpha 157$), and one in the intra-membrane domain of the alpha chain ($\alpha 196$) (Figure 14.5). These motifs are critical to the understanding of the mechanisms by which immunological tolerance is broken and islet autoimmunity is allowed to develop. The structure and physicochemical property of the highest-risk HLA class II molecules have been specified and the question that remains to be answered is what peptides will form a trimolecular complex that interact with CD4+ T cells able to trigger islet autoimmunity.

The concomitant inheritance of both HLA and non-HLA high-risk alleles and haplotypes appears to increase the risk of type 1 diabetes significantly through synergistic association of their single risks. In individuals with type 1 diabetes, DQ8(*DQA1*0301-B1*0302*) is mostly inherited with variants of *DRB1*04*, especially *DRB1*04:01*, *DRB1*04:04*, *DRB1*04:05* or *DRB1*04:02*, but not *DRB1*04:03* or *DRB1*04:07*. *DRB1*04:01* confers a higher risk than *DRB1*04:04*, while *DRB1*04:03* or *DRB1*04:07* is negatively associated with type 1 diabetes [106, 107]. The limited genetic differences between these alleles are reflected in the structure of the heterodimeric proteins formed by the DRA-coded A-chain and the DRB1-coded B-chain. The peptide-binding groove attains physicochemical characteristics that differ between the heterodimers despite a limited number of amino acid substitutions [102, 108]. These amino acid substitutions may account for most of the *DRB1*04* contribution to type 1 diabetes risk. Further studies are needed to establish the way genetic polymorphisms within the HLA region are related to the binding of peptides and subsequent antigen presentation that can be linked to the risk of developing a first autoantibody as a biomarker of the initiation of islet autoimmunity.

The most common protective haplotypes are DQ6(*DQA1*01:02-B1*06:02* and *DQA1*01:02-B1*06:03*) and also *DQA1*01:01-B1*05:03* and *DQA1*02:02-B1*03:03* [106, 107]. Furthermore, other HLA class II (such as DPB1) and class I alleles have also been associated with type 1 diabetes and the search for new associations is continuing (for a review, see [107]).

The genetic aetiology is further complicated by a large number of genetic variants found to be associated with type 1 diabetes in whole-genome association studies [97, 109]. From studies of more than 60 000 people, 78 genome-wide significant regions were reported [109]. A subset of these type 1 diabetes-associated genetic variants was enriched particularly in CD4+ effector T cells. It will be important to analyse the non-HLA genetic variants for the aetiology and triggers of islet autoimmunity. Type 1 diabetes-associated common genetic variants have therefore been combined in a genetic risk score approach to make use of all the genetic information in order not only to dissect the heterogeneity of diabetes, but also the aetiology and pathogenesis of the disease. A genetic risk score was developed to distinguish monogenic diabetes from type 1 diabetes [110] or type 1 diabetes from type 2 diabetes [111]. Using 41 [112], 61 [113], or 67 [114] genetic risk variants, risk scores were developed not only to classify type 1 diabetes, but also to identify neonates with a significant risk of developing a first islet autoantibody and then progressing to clinical onset. The polymerase chain reaction (PCR) testing used is cost-effective and the type 1 diabetes genetic risk score should prove useful both in neonatal screening for children at high risk of type 1 diabetes as well as for disease classification.

Environmental aetiology

There is a long history between environmental triggers and type 1 diabetes. The first case linking type 1 diabetes to an acute viral infection was reported in the late nineteenth century when the onset of type 1 diabetes appeared to be precipitated by a mumps infection in a child [115]. Many similar reports of the clinical onset of type 1 diabetes after an acute viral infection followed [116, 117]. Taken together, these reports suggest a relation between the clinical onset of type 1 diabetes and several viruses, including rubella, mumps, coxsackievirus B, rotavirus, cytomegalovirus, and Epstein–Barr virus [117]. The true relation between these viral diseases and the clinical onset of type 1 diabetes remains conjectural. It is not until recently when longitudinal studies of children at genetic risk for type 1 diabetes have made it possible to distinguish viruses that may be aetiologically and trigger islet autoimmunity from viruses that affect the pathogenesis prior to clinical onset. This distinction was made in the DAISY study, with the observation that progression from islet autoimmunity to type 1 diabetes may increase after an enterovirus infection characterized by the presence of viral RNA in blood [47]. Virus aetiology will therefore be considered only when data are reported prior to islet autoimmunity; that is, prior to the appearance of a first islet autoantibody (Figure 14.2).

Virus aetiology

Indication of virus infection prior to seroconversion includes reports by questionnaires, by direct demonstration of virus RNA or DNA by PCR, or by analysing virus antibodies as a measure of exposure. Self-reported lower respiratory tract infections in young children were associated with an increased risk of islet autoimmunity [79, 118, 119]. The IFIH1 (common SNP rs1990760) gene, interferon-induced helicase C domain-containing protein 1, was associated with the frequency of enterovirus RNA in blood [120]. Enterovirus RNA in blood did not predict islet autoantibodies, but tended to be detected at islet autoantibody seroconversion [121]. In the DIPP study (Table 14.2), stool sample enterovirus RNA using reverse transcription PCR (RT-PCR) and genotype sequencing showed that children developing islet autoantibodies had more enterovirus infections than control children. Infections occurred more than one year before the first detection of islet autoantibodies; ~50% were coxsackie A virus [122]. In the TEDDY study (Table 14.2), a large-scale investigation of known eukaryotic DNA and RNA viruses in faecally shed viruses were found to be related to islet autoimmunity. Prolonged rather than short-duration enterovirus B infections increased the risk for islet autoimmunity, in particular IAA first, in young children. In addition, early-life human mastadenovirus C infection, as well as an association with the coxsackievirus B-adenovirus receptor (CXADR), was independently correlated with a first-appearing islet autoantibody, predominantly IAA first [45]. These data were indirectly supported by enterovirus B-neutralizing antibodies in the DIPP study (Table 14.2). These antibodies are surrogate markers of coxsackie B infection in serum samples collected before and at the appearance of islet autoantibodies. Only coxsackie B1, but no other coxsackie B infections, was associated with IAA as the first-appearing autoantibody. As none of the coxsackie B antibodies was associated with the appearance of GADA, coxsackie B1 infection may contribute to the initiation of IAA-first associated islet autoimmunity [46]. The mechanisms by which persistent infection induces an autoimmune response are not understood. It may be speculated that children with HLA-DQ8 have an underperforming immune response to coxsackie B, which would explain the prolonged shedding. The neutralizing virus antibodies

may be low level or poor binders. Coxsackie B has amino acid sequence homologies to islet autoantigens [123] and molecular mimicry cannot be excluded as a possible explanation of the relationship between prolonged virus infection and the appearance of IAA.

Biomarkers of triggers

There is a paucity of studies investigating the immune response to viral infections in children with an increased genetic risk of developing islet autoimmunity and type 1 diabetes. The timing is critical and it cannot be excluded that the pattern of an autoimmune response is comparable to that of an immune response to a virus (Figure 14.6). The essential cellular reactions to establish an immune response eventually also leading to the formation of immunoglobulin (Ig)G antibodies are completed within three weeks or ~21 days. The timing of the human immune response has been detailed in studies of naturally occurring infections, such as SARS-CoV-2 [124], but more often after vaccination [125–127], and in evaluating the immune response to neoantigen bacteriophage phi X 174, a T-cell-dependent antigen [128]. Dissecting the immune response to a potential virus, such as coxsackie B, to trigger islet autoimmunity may require more frequent blood sampling than is currently achieved in longitudinal studies of children followed from birth (Table 14.2). A blood sample was at best obtained every third month. Omics biomarkers including whole-genome sequencing, epigenomics, transcriptomics, metabolomics, plasma cytokines, single-cell sorting, and single-cell sequencing will be needed to probe human immunity [125, 129]. Data from whole-blood transcriptomics in the TEDDY and DIPP studies confirmed age-associated gene expression changes in healthy infancy [130, 131], but also showed age-independent changes particularly in natural killer (NK) cells prior to either IAA first or GADA first [132]. Serum fatty acids (pentadecanoic acid, heptadecanoic acid, stearic acid, and conjugated linoleic acid), but also other factors such as amino acids and vitamin C and D [133], increased the risk for a first islet autoantibody [49, 134]. In fractionated CD4+ and CD8+ T cells and unfractionated peripheral blood mononuclear cells in the DIPP study, mRNA sequencing prior to seroconversion showed upregulation of interleukin 32 (IL-32) in activated T cells and NK cells [135]. Studies of the immune response prior to the first-appearing islet autoantibody should increase the possibility of developing novel biomarkers for the mechanisms that trigger islet autoimmunity.

Figure 14.6 Magnitude and timing of an immune response to a common virus. It is suggested that the timing of the cellular and humoral reactions would potentially be the same for a virus that triggers islet autoimmunity. The virus may be in circulation for about 7 days. It is neutralized because of the combined immediate action of natural killer (NK) cells and interferons. Antigen-presenting cells that engulf virus-infected host cells present virus antigens on HLA class II heterodimers to be captured by the T-cell receptors of CD4+ T cells. The CD4+ T helper cells will help to activate cytotoxic CD8+ T cells and B cells. The former kill virus-infected cells, while the latter generate virus antibodies. It cannot be excluded that the islet autoimmunity response follows a similar pattern after a virus infection.

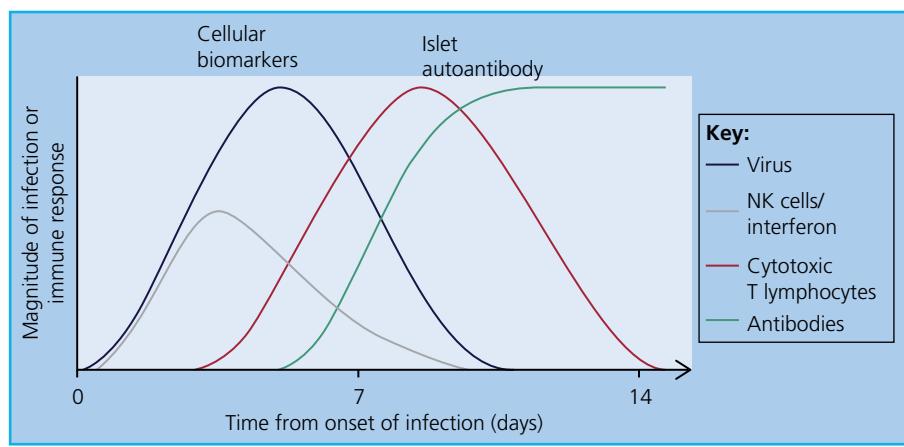

Pathogenesis

The pathogenesis of type 1 diabetes is strongly associated with IAA, GADA, IA-2A, and ZnT8A biomarkers (Table 14.1). These pathogenic markers are useful to predict progression to clinical onset, but also to classify type 1 diabetes once diabetes has been diagnosed. HLA does not seem to influence the tempo of the disease process when progressing from a first to a second islet autoantibody [53, 136]. Stage 1 is reached when two or more islet autoantibodies have developed (Figure 14.2). The role of the HLA class II molecules in the immune response is to convey cell-cell interactions between T-helper (CD4+) lymphocytes and antigen-presenting cells (APCs) or B lymphocytes. The CD4+ T cell provides help to cytotoxic T lymphocytes (CD8+) as well as to B lymphocytes. It is assumed that these basic immune response mechanisms contribute to the appearance of a second, third, or fourth autoantibody.

We need to consider which factors contribute to progression from multiple autoantibodies without dysglycaemia (stage 1) and multiple autoantibodies with dysglycaemia (stage 2) to clinical onset (stage 3). First, the number of islet autoantibodies accelerates progression to stage 3 (Figure 14.3) [39, 137]. In children with persistent autoantibodies, higher IAA and IA-2A, but not GADA, levels increase the risk for stage 3 [138]. Several risk scores have been developed to predict the time to stage 3 among people with multiple islet autoantibodies [114, 139–141]. Islet autoantibodies are becoming widespread biomarkers of autoimmune type 1 diabetes in stage 1 or 2 (Figure 14.3), but need to be combined with β -cell function tests such as oral or intravenous glucose tolerance tests or continuous glucose monitoring [142–145]. Glycated haemoglobin (HbA_{1c}) was a specific but not sensitive early indicator for stage 3 type 1 diabetes diagnosed by glucose tolerance tests or asymptomatic hyperglycaemia [146, 147]. We need additional biomarkers, perhaps C-peptide and plasma glucose, to predict the time to clinical onset better in anticipation of treatment that will halt the pathogenesis at either stage 1 or stage 2 [148, 149].

Cellular autoimmunity

Stage 1 and stage 2 cellular autoimmunity has been examined in the peripheral blood in relation to the observations in the pancreas. Pancreas specimens from organ donors found to have one (pre-stage 1) or multiple islet autoantibodies (stage 1 or stage 2) have

been studied [150–152]. Stage 1 pancreas had no abnormalities. Stage 2 pancreases from individuals with multiple autoantibodies and confirmed increased HLA risk showed mononuclear cell infiltrates (insulitis) in a smaller fraction of islets (<5%) and comprised predominantly CD3+ CD8+ T cells [152]. Insulin immunocytochemistry showed reduced staining and such pseudo-atrophic islets were present in multiple small foci scattered throughout the pancreatic tissue.

Single and multiple autoantibody-positive donors had relative β -cell area comparable to that of people without autoantibodies. Combining clinical features, genetic risk score, plasma C-peptide, and islet autoantibodies modelled insulitis in the absence of histological definition [150]. Factors that allow transmission from stage 1 to stage 2 and initiate insulitis remain to be identified. The identification of β -cell autoantigen-specific T lymphocytes has been challenging and the development of standardized assays of T lymphocytes specific to islet autoantigens (insulin, GAD65, and IA-2) is still difficult to achieve. Soluble HLA class II tetramer assays to assess autoantigen-specific T lymphocytes should prove useful to follow individuals transitioning between stages 1, 2, and 3 [153]. Peripheral blood cellular biomarkers may include neutrophils [154], regulatory T cell (Treg) enumeration [155], NK cell signatures [132], transcriptomic analysis of peripheral blood mononuclear cells [156], RNA sequencing of single sorted cells [157], and possibly HLA class I restricted pancreatic islet antigen peptide-specific CD8+ T cells [158]. Cellular biomarker analyses would require standardized T-cell tests that are yet to be achieved [159]. Longitudinal studies of children transitioning between stage 1, stage 2, and Stage 3 will be critical to define specific cellular factors that reflect the pathogenesis.

Humoral autoimmunity

The four major autoantigens (Table 14.1) are used in standardized assays to detect and quantify autoantibodies. The Islet Autoantibody Standardization Program (IASP) is a collaborative effort aimed at improving the performance of assays for autoantibodies that mark the pathogenesis and the concordance between laboratories [27]. The utility of islet autoantibodies has been further advanced by the European Medicines Agency (EMA), which has issued a positive qualification opinion for islet autoantibodies as enrichment biomarkers for type 1 diabetes prevention trials [160, 161].

There is a comprehensive literature on which autoantibody is thought to have the highest predictive marker for clinical onset (stage 3) [148, 162]. Although the number of islet autoantibodies is related to risk for type 1 diabetes [32, 39], additional features of the respective autoantibodies need to be considered:

- *Insulin* represents the autoantigen that has the lowest inter-laboratory consistency in the IASP workshops [163]. Proinsulin autoantibodies remain to be fully characterized [164].
- *GAD65* has been tested after truncation of the N-terminal end, which increases the predictive value for type 1 diabetes compared to full-length GAD65 [27, 165–167].
- *IA-2* is present in at least two major forms, IA-2 and IA-2 β . Autoantibodies to either isoform add to the ability to predict the clinical onset of type 1 diabetes [168–171]. An antigenic determinant within the N terminus of IA-2, IA-2ec autoantibodies was detected in individuals with type 1 diabetes and in a subgroup of adults with autoimmune diabetes [172].

- *ZnT8* has a major polymorphism at position 325, allowing the detection of ZnT8A variants dependent on whether tryptophan (W), arginine (R), or glutamine (Q) is present on position 325 [38, 173–176]. Most laboratories analyse both the W and R variants simultaneously and the ZnT8A predictive value is given as a combination of the two variants.

Serum samples from individuals with newly diagnosed type 1 diabetes are often tested to detect additional autoantigens. The importance of autoantibodies against additional autoantigens may improve the positive predictive value for type 1 diabetes. These autoantigens are often referred to as *minor autoantigens*, as they are usually detected at a frequency of <25% in new-onset type 1 diabetes. Tetraspanin-7 (glima38) was confirmed as an autoantigen by demonstrating binding to autoantibodies in type 1 diabetes [177, 178]. Other minor autoantigens include ICA12/SOX13 [179–181], VAMP2 [182], NPY [183], carboxypeptidase H [184], ICA69 [185], and INS-IGF2 [186].

Biomarkers of pathogenesis

HLA does not seem to be important to the pathogenesis and processes leading from stage 1 and 2 to clinical onset at stage 3 (Figure 14.2) [32, 53]. Genetic factors contributing to the pathogenesis include genes related to T-cell function (Table 14.3). Genetic risk scores, which consider genetic factors related to both aetiology and pathogenesis, have proved useful in determining the risk for individuals with autoantibodies of progressing to clinical onset regardless of whether they have first-degree relatives with diabetes or belong to the general population [111–113].

Diabetes diagnosis

The criteria for diagnosing diabetes are discussed in Chapter 2 and apply to all types of diabetes [189]. Genetic markers, such as HLA genes or any particular SNP, are of no value at the time of the diagnosis of diabetes nor during the subsequent management of people with type 1 diabetes. Typing for genetic markers and the use of genetic risk scores may become clinical practice for people who cannot be clearly classified as having type 1 diabetes or type 2 diabetes.

Islet autoantibodies are not used in routine diagnosis of diabetes, but are now recommended by the European Association for the Study of Diabetes and American Diabetes Association for people with clinical features of new-onset type 1 diabetes, as standardized islet autoantibody tests may help classify diabetes in adults, particularly where there are clinical features that overlap between type 1 diabetes and type 2 diabetes [190].

Screening for islet autoimmunity and diabetes

The understanding that HLA DR3-DQ2 and DR4-DQ8 haplotypes confer an increased risk for type 1 diabetes made it possible to use PCR-based typing methods for a very large number of newborn children to be followed for islet autoantibodies and subsequent diabetes [14, 56, 69, 70]. At-birth screening for increased genetic risk using genetic risk scores [112] has initiated primary prevention trials with oral insulin [191].

Screening schoolchildren for islet autoantibodies has been advocated as a means to prevent diabetes ketoacidosis at the time of

Table 14.3 Examples of genetic factors related either to the aetiology of islet autoimmunity or to pathogenesis leading to clinical onset of type 1 diabetes.

Genes related to aetiology			Reference
HLA-DQ8	IAA first	Antigen presentation	[28]
HLA-DQ2	GADA first	Antigen presentation	[28]
SH2B3	Islet autoimmunity	Immune adaptor protein	[187, 188]
PTPN22	Islet autoimmunity	Protein tyrosine phosphatase	[187]
PPIL2	Islet autoimmunity	Peptidylprolyl isomerase like 2	[187]
ERBB3	Islet autoimmunity	Erb-B2 receptor tyrosine kinase 3	[188]
INS	IAA first	Insulin gene regulatory	[187, 188]
TTC34/PRDM16	IAA first	Zn finger transcription factor	[187]
RBFOX1	GADA first	RNA binding protein	[187]
Related to pathogenesis			
INS	Type 1 diabetes	Insulin gene regulatory	[187]
RNASET2	Type 1 diabetes	Extracellular ribonuclease	[187]
PLEKHA1	Type 1 diabetes	Pleckstrin homology domain containing, family A	[187]
PPIL2	Type 1 diabetes	Peptidylprolyl isomerase like 2	[187]

GADA, glutamic acid decarboxylase autoantibody; IAA, insulin autoantibody.

clinical onset [55, 192–194]. The possibility of identifying people with multiple islet autoantibodies who could be recruited in secondary prevention trials is well established by screening first-degree relatives [149, 193, 195, 196]. Secondary prevention studies in individuals with autoantibodies have been carried out with parenteral insulin [195], oral insulin [196, 197], nasal insulin [198], GAD-alum [199], and teplizumab [149] (Chapter 76). None of the trials reached the study end-points to delay the clinical diagnosis except a trial with teplizumab. Individuals who were HLA-DR3 negative,

HLA-DR4 positive, or Znt8A negative who were treated with teplizumab had fewer diabetes diagnoses than those treated with placebo [149]. The efforts to screen for islet autoantibodies in the general population as well as among first-degree relatives, perhaps in combination with improved genetic risk scores [111, 113], should help identify participants for secondary prevention trials, especially since the EMA issued a positive qualification opinion for islet autoantibodies as enrichment biomarkers in type 1 diabetes prevention trials [161].

Key points

- People with type 1 diabetes classically present early, require continuous insulin treatment, and carry autoimmune markers, such as antibodies to glutamic acid decarboxylase (GAD).
- There are other types of diabetes with a phenotype that is similar to type 1 diabetes presenting with ketoacidosis, such as fulminant type 1 diabetes after viral infections or immune checkpoint inhibitor-induced diabetes.
- Other atypical forms of diabetes may have heterogeneous aetiologies, including maturity-onset diabetes of the young (MODY) and other forms of monogenic diabetes due to mutations of mitochondria or amylin or pathways implicated in pancreatic β -cell biology.
- Some people may present with ketosis-prone diabetes that reverts to a clinical course resembling type 2 diabetes after amelioration of glucotoxicity with partial recovery of pancreatic β -cell function.
- The correct diagnosis of these disorders is clinically important owing to their different clinical courses, prognosis, and management.

Diabetes is characterized by chronic hyperglycaemia due to varying degrees of insulin deficiency and resistance resulting in generalized vasculopathy in multiple body systems [1]. Insulin is the only hormone that can lower blood glucose and is key in maintaining a normal range of blood glucose between 4 and 8 mmol/l (70–160 mg/dL), irrespective of fasting and prandial states. Effective insulin activity requires insulin synthesis, processing, and secretion from a developed islet as well as peripheral action of insulin on target tissues. Effective glucose sensing is the first step of triggering insulin secretion [2], which is a highly energy-dependent process requiring normal mitochondrial function. Once hyperglycaemia develops, abnormal islet metabolism, especially that of mitochondria as the key organelle in generating energy, can lead to further impairment of insulin secretion [3]. Insulin is co-secreted with amylin, which is a key component of pancreatic amyloidosis. It has been hypothesized that hyperinsulinaemia and hyperamylinhaemia, especially in the presence of insulin resistance, may contribute towards the decline in β -cell function [4]. These cellular events can interact to set up a vicious cycle of hyperglycaemia, insulin resistance, progressive insulin insufficiency, and worsening hyperglycaemia.

Genetic variants affecting these metabolic pathways can present as monogenic forms of diabetes, often associated with atypical presentation in young and normal- or low-weight individuals with a family history of diabetes [3,5]. Interactions of these pathways,

modulated by cardiometabolic and inflammatory factors, can result in different trajectories in deterioration in β -cell function. Depending on the genetic predisposition, β -cell capacity, precipitating causes, and severity of hyperglycaemia, clinical presentation of diabetes can be ketotic or non-ketotic, with considerable inter-individual and intra-individual variation [6].

Apart from autoimmune type 1 diabetes, there are other causes of severe insulin deficiency that provide important insights into the pathogenesis of diabetes. Fulminant type 1 diabetes, albeit uncommon, can present at any age, characterized by rapid onset of diabetic ketoacidosis (DKA) within days, often preceded by a viral illness. These individuals typically do not have islet autoantibodies, but have very low C-peptide levels and require long-term insulin therapy [7]. More recently, the introduction of immune checkpoint inhibitors as an anti-cancer treatment has led to the recognition of autoimmune disease including type 1 diabetes as a rare adverse drug reaction [8]. These associations have revealed the complex immunomodulating roles of cytotoxic T lymphocytes (CTL), natural T-regulatory (Treg) cells, programmed death 1 (PD1) receptors, and PD1 ligands (PDL-1), which interact within a spectrum of diseases including chronic infections, cancer, and autoimmunity. While dysregulation of one of these pathways may result in a disease state (e.g. cancer), which can be modified by therapeutic manipulation, perturbation of these complex networks may result in autoimmune disease, such as type 1 diabetes [9,10].

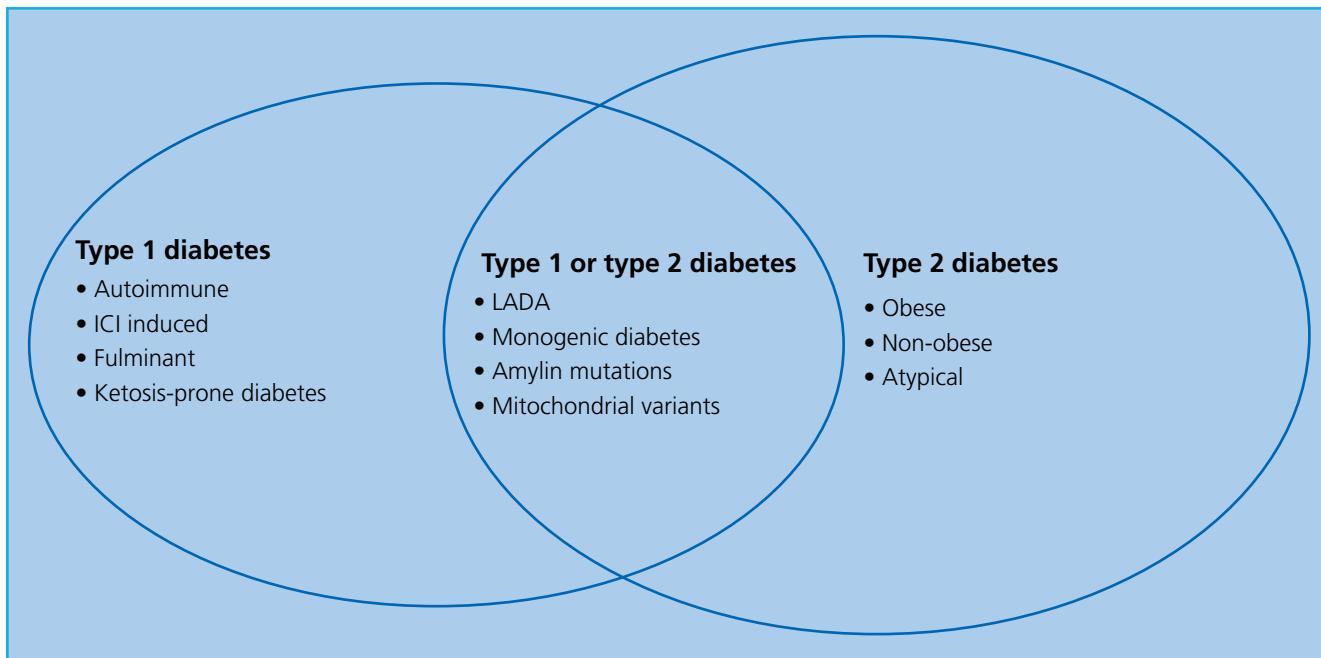

Figure 15.1 The considerable overlap between the phenotypes of type 1 diabetes and type 2 diabetes caused by complex aetiologies. Subtypes of diabetes with ketotic presentation include classic autoimmune type 1 diabetes, ketosis-prone diabetes, fulminant type 1 diabetes, and immune checkpoint inhibitor (ICI)-induced type 1 diabetes. Other subtypes of diabetes such as latent autoimmune diabetes in adults (LADA), rare variants

implicated in monogenic diabetes, as well as rare and common variants implicated in other pathways associated with energy metabolism including but not limited to amylin and mitochondrial pathways might have both type 1 diabetes or type 2 diabetes presentation, depending on the co-occurrence of other familial and non-familial factors, giving each individual a unique profile that forms the basis of precision care.

Against this background, in this chapter we provide an overview of the pathogenesis, clinical features, and treatment of these atypical forms of diabetes (Figure 15.1).

Ketosis-prone diabetes

In 1980, Winter et al. first described a cohort of 129 African American young people with acute ketotic presentation, of whom 12 individuals subsequently did not require insulin and followed a clinical course resembling type 2 diabetes. These individuals were mainly young men with obesity presenting with acute hyperglycaemia and ketosis requiring insulin therapy in the acute stage. However, once acute hyperglycaemia was ameliorated, the clinical course was more akin to that of type 2 diabetes, with preserved insulin function and adequate glycaemic levels by oral glucose-lowering drugs [11].

This type of ketosis-prone diabetes or *flatbush diabetes* was relatively common in African American populations, but had also been reported as an important clinical entity in Asian and Indian populations [6]. Many of these individuals did not have human leucocyte antigen (HLA)-related genotypes or autoantibodies typical of autoimmune type 1 diabetes. Some of these individuals had obesity with insulin resistance [12]. Not uncommonly, the acute hyperglycaemic event was precipitated by sepsis made worse by consumption of sugar-sweetened beverages for thirst quenching. While the exact mechanisms underlying the initial ketotic presentation remained unknown, lipo-glucotoxicity and acute inflammatory conditions, such as infection, might compromise the β -cell function, which might already have been reduced due to other predisposing factors such as genetic causes or obesity, leading to metabolic decompensation [6].

Autoimmune diabetes in adults

In the early 1980s, among people of white European ancestry, over 90% of all individuals with diabetes diagnosed young were considered to have classic type 1 diabetes due to autoimmune islet destruction with acute ketosis and absolute insulin deficiency [13]. Autoantibodies against pancreatic islet antigens, such as glutamic acid decarboxylase (GAD), are markers for type 1 diabetes. In the early 1990s, Zimmet et al. first described a form of adult-onset autoimmune diabetes, albeit with phenotypes resembling type 2 diabetes, so called latent autoimmune diabetes in adults (LADA). In 2019, the World Health Organization (WHO) formally recognized this form of diabetes and renamed it as a slowing evolving immune-mediated diabetes of adults under the classification category of a hybrid form of diabetes, although the nomenclature of LADA is still widely used [14–16]. Individuals with LADA often carry other autoantibodies associated with coeliac disease and adrenal and thyroid disorders, suggesting it is part of a spectrum of autoimmune diseases [17]. More recent studies indicate that LADA might be a hybrid of type 2 diabetes and autoimmune diabetes. Individuals with LADA have a high frequency of both type 1 diabetes-susceptibility genotype and type 2 diabetes-susceptibility genotypes, suggesting that these aetiologies were not mutually exclusive [18, 19]. In the UK Prospective Diabetes Study (UKPDS), approximately 10% of individuals with type 2 diabetes had GAD autoantibodies, the majority of whom eventually progressed to insulin dependency [20, 21].

Depending on the selection criteria of clinical definition, age of diagnosis, ethnicity, and assay methodologies, the prevalence of LADA in individuals with type 2 diabetes might vary considerably. Reports from other ethnic groups suggested an estimated 10% prevalence of LADA in adult populations with a clinical presentation

of type 2 diabetes [20, 22]. In a prospective cohort of Chinese adults with young-onset diabetes, 8.1% of individuals had GAD autoantibodies suggestive of LADA. Compared to their counterparts without GAD autoantibodies, individuals with LADA were highly responsive to insulin treatment with a reduction of glycated haemoglobin (HbA_{1c}) of 2.3% (25 mmol/mol) versus 0.7% (7 mmol/mol) in individuals without LADA at 12 months. Although individuals with LADA had fewer cardiometabolic risk factors and were less likely to have cardiovascular events than their counterparts with a type 2 diabetes presentation, they were three times more likely to develop end-stage kidney disease than those with a type 1 diabetes presentation [23]. The levels of GAD autoantibodies correlate with pancreatic β -cell function. Individuals with high GAD autoantibody titre had more rapid decline in β -cell function as measured using homeostasis model assessment (HOMA2-B) and were more likely to reach β -cell failure [24].

The prompt diagnosis of LADA is clinically important, since early use of insulin was often needed to improve glycaemic levels to prevent accelerated loss of β -cell function [25]. Impaired β -cell response is often evident at diagnosis and early use of insulin might reduce the adverse effects of glucotoxicity on β cells. However, there is no evidence that early insulin implementation has any effects on the risk of late diabetes complications [26, 27]. Limited evidence suggests that treatment with sulfonylureas was associated with more rapid progression to β -cell failure, whereas treatment with dipeptidyl-peptidase 4 inhibitors might be protective [28, 29].

Apart from clinical suspicion, HLA studies might distinguish LADA from classic type 1 diabetes. In white European populations, LADA was associated with HLA DQA1-DQB1*0102(3)-*0602(3)/X, which was uncommon in individuals with typical type 1 diabetes [30]. In a consensus statement from an international expert panel, measurement of C-peptide levels as a proxy for endogenous pancreatic β -cell function was recommended to guide diagnosis and management in LADA. For C-peptide levels <0.3 and >0.7 nmol/l, individuals should be managed as type 1 diabetes and type 2 diabetes, respectively. For those in the grey zone (C-peptide ≥ 0.3 and ≤ 0.7 nmol/l), insulin should be considered in combination with other therapies to attenuate the progression of β -cell failure [31].

Fulminant type 1 diabetes

In 2000, a novel subtype of type 1 diabetes, known as fulminant type 1 diabetes, was first reported in Japan [32]. According to the Japan Diabetes Society [33], fulminant type 1 diabetes was characterized by acute destruction of β cells with rapid progression to hyperglycaemia and DKA. The pathogenesis of this disease remained to be clarified, but involvement of HLA genes and viruses has been implicated. The disease affects all ages and both sexes, including pregnant women, albeit most individuals were middle-aged men. Hence, the difference in age distribution between fulminant type 1 diabetes and autoimmune type 1 diabetes is one of the discriminating features between the two conditions.

Individuals with fulminant type 1 diabetes typically have short duration of hyperglycaemic symptoms with an average of four days, preceded by common cold-like and gastrointestinal symptoms. DKA is accompanied by near-normal HbA_{1c} despite very high plasma glucose levels, compatible with acute development of hyperglycaemia. There is seasonal variation in presentation supportive of a viral aetiology. The acute presentation of DKA is accompanied by

abnormal exocrine function with increased serum levels of pancreatic enzymes (e.g. lipase, elastase-1, amylase), absent C-peptide levels, but virtually no detectable autoantibodies against constituents of pancreatic β cells. Many individuals with fulminant type 1 diabetes were reported in Japan, although sporadic cases have also been reported in other Asian countries including Korea, the Philippines, and China [34]. Given the high fatality rate of undiagnosed and untreated DKA, medical practitioners should be aware of this rare presentation, which requires intensive management, with many individuals requiring long-term insulin therapy [7].

Autoimmune type 1 diabetes and immune checkpoint inhibitors

The host immune system plays a key role in biological surveillance and defence against external and internal stressors. Among the many immune mediators, there is cross-talk between CTL and Treg lymphocytes, which results in the release of various pro-inflammatory and anti-inflammatory cytokines in response to different antigens. Although a full review of the subject is beyond the scope of this chapter, dysregulation of this immune-modulating system may result in a spectrum of conditions including chronic infection, autoimmunity, and cancer. Chronic stimulation of CTL could lead to progressive loss of cytokine production and cytotoxicity, so called T-cell exhaustion, which might promote cancer development and chronic viral infection with reduced clearance of viral load. In contrast, continuing activity of autoreactive cytotoxic cells could mediate the destruction of host tissues resulting in autoimmune diseases [9]. The immune checkpoints, PD-1 receptor and its ligand PDL-1, are immunoreceptors widely expressed in many tissues. They form part of the feedback of the cytotoxic pathway to reduce the risk of autoimmunity. Thus, while PD-1 agonists have been used to suppress adverse immune responses for the treatment of autoimmune diseases, allergy, and transplant rejection, PD-1 inhibitors have been used to augment the immune response for treatment of cancer and infectious diseases [35].

Since the introduction of PD-1 and PDL-1 inhibitors as immune-checkpoint inhibitors for treating multiple types of cancer, there have been increasing numbers of case reports of autoimmune disease as a drug-related adverse reaction. A recent systematic review and meta-analysis summarized the clinical course of 71 individuals presenting with type 1 diabetes after the initiation of immune-checkpoint inhibitor therapy. The mean age of these individuals was 61.7 years, with 55% being men and melanoma being the most frequent cancer (53.5%). Other cancer types included lung, head and neck, renal cell, and urothelial carcinoma. The median time to onset of type 1 diabetes was 49 days, with DKA presentation in 76% of the individuals. The mean HbA_{1c} was 7.8% (62 mmol/mol) at presentation. All individuals had insulin deficiency and required permanent exogenous insulin treatment, with half of the individuals having autoantibodies associated with type 1 diabetes. These latter individuals had more rapid onset and higher incidence of DKA than those without auto-antibodies [10].

There are close associations among diabetes, cancer, and chronic infection, with type 1 diabetes being rare and type 2 diabetes and cancer being common in non-Europid populations living in areas endemic for low-grade infections [36]. These intriguing observations associated with autoimmunity and immune-checkpoint inhibitors should motivate more studies to examine the interplay

among these immune-modulating pathways in both type 1 diabetes and type 2 diabetes and their associated aetiologies (e.g. acute or chronic infections) as well as subphenotypes (e.g. cancer and autoimmune disease). From a clinical practice perspective, the increasing use of immune-checkpoint inhibitors in different cancer conditions should alert healthcare professionals regarding this potential drug-related severe adverse event in the context of diabetes.

Young-onset diabetes, maturity-onset diabetes of the young, and monogenic diabetes

In people of white European descent, over 90% of individuals with diabetes diagnosed in childhood or adolescence had classic type 1 diabetes from autoimmune islet destruction with acute ketosis and absolute insulin deficiency [13]. In non-Europid populations, including those from Mexico, India, China, and the rest of Asia, classic, ketosis-prone type 1 diabetes is relatively uncommon in young adults diagnosed with diabetes. In Chinese individuals with young-onset diabetes (diagnosed before the age of 40 years), only 10% had classic type 1 diabetes. Despite the non-ketotic presentation, individuals with young-onset diabetes often required earlier insulin treatment than those with late-onset disease, while some responded well to oral anti-diabetes drugs [36]. This phenotypic heterogeneity calls for more precise diagnosis and classification to guide anti-diabetes treatment for reducing the risk of complications. In the case of monogenic diabetes with high penetrance, genetic counselling and cascade screening may be necessary for early detection and intervention among carriers of risk conferring-variants (Chapter 20) [37].

Maturity-onset diabetes of the young

Monogenic diabetes is caused by mutation in a single gene (Chapter 20). Maturity-onset diabetes of the young (MODY) is the most common form of monogenic diabetes. According to the American Diabetes Association, MODY is defined as presentation before the age of 25 years with a strong family history suggestive of autosomal dominant inheritance. It is characterized by absence of β -cell autoimmunity and sustained pancreatic β -cell function [5, 38]. In the early 1990s, some of the MODY genes were first discovered in Asian family-based cohorts of young-onset diabetes in pursuit of the underlying cause due to the low prevalence of autoimmune type 1 diabetes in these young individuals [39]. These early findings together with several large cohorts in Europe have provided the basis of the current knowledge in the field of MODY. The use of family-based linkage analysis and sequencing technology has discovered biological pathways implicated in the neogenesis, differentiation, and maturation of pancreatic β cells as well as intracellular signalling mechanisms underlying insulin sensing, synthesis, secretion, and processing as important causes of MODY [40].

Around 40 subtypes of monogenic diabetes have been identified, with variants in 14 genes being best described in the literature. These include six genes encoding proteins that, respectively, correspond to MODY subtypes 1–6: hepatocyte nuclear factor (*HNF*) 4 α (*HNF4* α); glucokinase (*GCK*); HNF1 α (*HNF1* α); pancreatic and duodenal homeobox 1 (*PDX1*); HNF1 β (*HNF1* β); and neurogenin

differentiation 1 (*NEUROD1*). Another eight genes have been identified as possibly causative in MODY subtypes 7–14, including Kruppel-like factor 11 (*KLF11*); carboxyl ester lipase (*CEL*); paired box-containing gene 4 (*PAX4*); insulin (*INS*); B-lymphocyte kinase (*BLK*); adenosine triphosphate (ATP)-binding cassette; sub-family C (CFTR/MRP) member 8 (*ABCC8*); potassium channel, inwardly rectifying subfamily J, member 11 (*KCNJ11*); and adaptor protein, phosphotyrosine interaction, PH domain, and leucine zipper containing 1 (*APPL1*) [5]. There is now a trend to replace the old nomenclature of MODY1 and MODY 2 with *HNF4* α -MODY or *GCK*-MODY for better clarity. Most of the monogenic diabetes genes are transcription factors implicated in pancreatic β -cell development, structure, and function, such as *Pax6*, *Nkx2-2*, *Nkx6-1*, and *Pax-4* [41, 42]. Others are transmembrane channels implicated in insulin secretion, such as Kir6.2 (*KCNJ11*) and SUR1 (*ABCC8*) [5, 38, 43]. These rare variants in transcription factors typically cause significant insulin insufficiency and hyperglycaemia, with strong familial inheritance and full penetrance (Figure 15.2).

Recently, more mutations associated with monogenic diabetes have been identified [44] and the list is expected to grow with the increasing availability of DNA sequencing. Some mutations are extremely rare or associated with syndromic features (e.g. deafness, visual impairment, development abnormality). Rare variants aside, genome-wide association studies have revealed a high frequency of common variants of some MODY genes, especially in Asian populations, including *HNF1* α , *HNF1* β , *GCK*, and *PAX4*. These genetic variants might interact with other genetic, environmental, or life-style factors to increase the risk of diabetes or related traits [42, 45–47]. These results are in keeping with epidemiological analysis indicating the important role of abnormal β -cell biology in the pathogenesis of type 2 diabetes in Asian populations undergoing rapid transition, with obesity as a major risk factor [48].

Given the mixed phenotypes, it can be challenging to distinguish individuals with MODY from the large number of individuals with type 1 diabetes or young-onset type 2 diabetes. It is estimated that more than 80% of cases of MODY are not diagnosed or are misclassified in clinical practice [49, 50], not least because the costs of genetic analysis can be prohibitive for widespread screening for mutations in individuals with diabetes. In 2008, a consensus group recommended clinical criteria for MODY testing that included onset of diabetes below 25 years, parental history of diabetes, non-insulin dependence (for *HNF1* α - and *HNF4* α -MODY), and fasting plasma glucose of 5.5–8.0 mmol/l and $\text{HbA}_{1c} < 8\%$ (64 mmol/mol) for *GCK*-MODY [51]. These criteria have high specificity but low sensitivity, with other forms of familial monogenic diabetes yet to be discovered. By extending the screening criteria to individuals diagnosed under the age of 30 years or with C-peptide positivity after three years of diagnosis (random or glucagon-stimulated C-peptide ≥ 0.2 nmol/l), more positive cases have been diagnosed [52]. Common variants near the *HNF1* α gene influence the levels of high-sensitivity C-reactive protein (hsCRP) in healthy populations [53] and low levels of hsCRP may distinguish *HNF1* α -MODY from type 1 diabetes and type 2 diabetes with increased sensitivity up to 90% when combined with clinical criteria [54].

In cohorts with clinical features of MODY and depending on additional selection criteria, such as C-peptide or autoimmune markers to prioritize diagnostic testing, the proportions of young individuals with monogenic diabetes might range from less than 10% to more than 50% [5, 38]. In most cohorts, over 70% of confirmed individuals with MODY had mutations in *HNF1* α , *GCK*, and *HNF1* β . In a consecutive cohort of unrelated Chinese

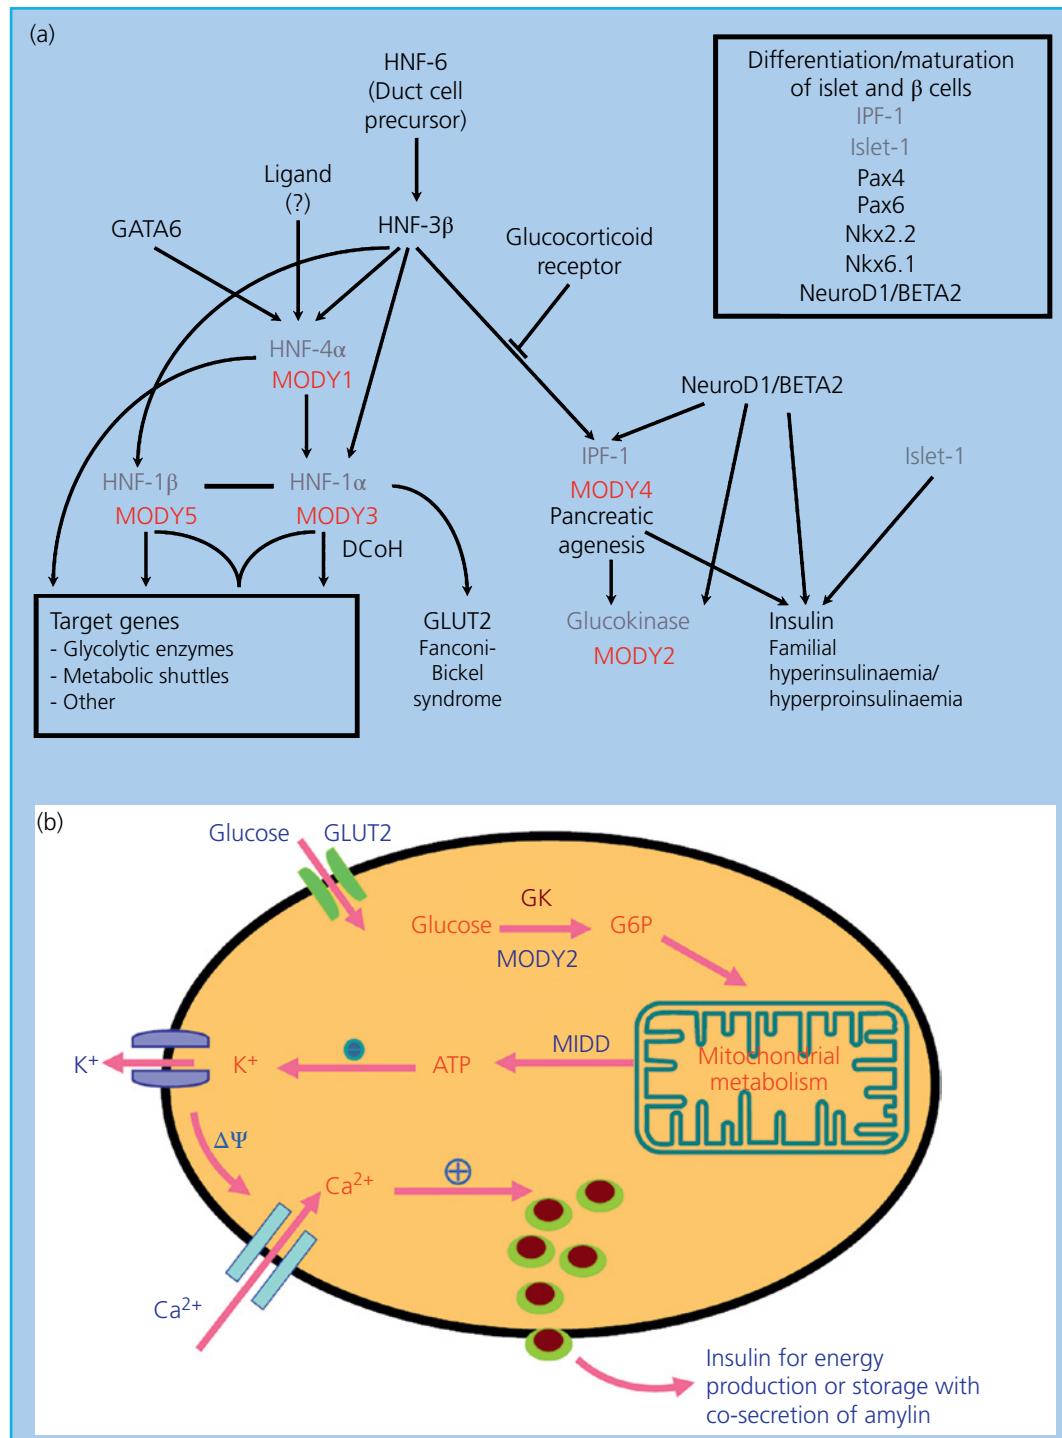

Figure 15.2 (a) The cascade of transcription factors involved in pancreatic development as well as neogenesis, differentiation, and maturation of pancreatic β cells. Maturity-onset diabetes of the young (MODY) includes subtypes with mutations in transcription factors, namely MODY 1 with mutations of hepatic nuclear factor (HNF-4 α); MODY 3: HNF-1 α ; MODY 4: insulin promotion factor (IDF-1); MODY 5: HNF-1 β ; MODY 6: neurogenic differentiation 1 (NeuroD1); and MODY 7: carboxyl ester lipase (CEL). Other genes include glucokinase, the glucose sensor (MODY 2), glucose transporter 2 (GLUT2), and additional transcription factors such as GATA, the family of PAX genes, Nkx 2.2 and Nkx 6.1, and neurogenin-3 (Neurog3). These genes interact at different stages to control islet cell development and regulate glucose sensing and insulin secretion in order to maintain a normal range of blood

glucose of 4–8 mmol/l at all times, irrespective of fasting and prandial states. (b) The multiple steps involved in regulation of insulin secretion, commencing with sensing of ambient blood glucose level by glucose transporter 2 (GLUT2), glycolysis by glucokinase (GK), and adenosine triphosphate (ATP) production by mitochondria. The generated ATP particles then close the potassium channels, leading to membrane depolarization and opening of calcium channels. The intracellular calcium influx is associated with translocation of insulin- and amylin-containing vesicles to the cellular surface for exocytosis. During these processes, transcription factors are also activated, resulting in insulin gene transcription and production to replenish the insulin-containing vesicles to ensure continuous insulin supply for rapid release on demand. MIDD, maternal-inherited diabetes and deafness.

individuals with type 2 diabetes diagnosed before the age of 40 years, 5–10% had *GCK* or *HNF1α* mutations [55]. There are relatively few MODY cohorts in African, Arabic, or Latin American populations. Given the known differences in genetic, ecological, and cultural factors, different patterns of MODY might be expected [5, 38]. Recently, a work group has reported good discriminatory performance of MODY risk calculators, although their applicability in non-Europid populations remains uncertain [56].

There are few cohort studies on monogenic diabetes in the USA and an estimated 95% of cases might be misdiagnosed as type 1 diabetes or type 2 diabetes [38]. In the latest analysis of a multiethnic cohort of young people under the age of 20 years with a clinical diagnosis of type 2 diabetes, whole-exome sequencing was performed to discover genetic variants associated with MODY genes classified as likely pathogenic (LP) or pathogenic (P) according to current guidelines [57]. Among 3333 participants, 93 (2.8%) carried an LP/P variant in *HNF4α* ($n = 16$), *GCK* ($n = 23$), *HNF1α* ($n = 44$), *PDX1* ($n = 5$), *INS* ($n = 4$), or *CEL* ($n = 1$). Compared with those with no LP/P variants, young people with MODY had a younger age at diagnosis and lower fasting C-peptide levels. They were also less likely to have hypertension and had higher high-density lipoprotein (HDL) cholesterol levels. Among these 2.8% of young people with clinically diagnosed type 2 diabetes, the diagnosis of MODY through sequencing would have changed clinical management in 89% of them. However, there were no clinical criteria that could reliably separate MODY from other forms of diabetes, which calls for new tools and algorithms to select individuals for genetic testing.

Accurate diagnosis of MODY has implications for choices of treatment. Typically, GCK-MODY is characterized by mild fasting hyperglycaemia and might not necessitate treatment. Individuals with MODY due to *HNF4α* and *HNF1α* mutations are sensitive to sulfonylureas. These individuals also respond well to incretin-based therapy with dipeptidyl peptidase 4 inhibitors and glucagon-like peptide 1 receptor agonists [5, 58]. Many individuals with transcription factor MODY eventually require insulin due to progressive β-cell failure, often due to factors such as delayed diagnosis, long disease duration, and suboptimal glycaemic levels with ongoing glucolipotoxicity and inflammation [59].

Timely recognition of MODY also influences antenatal care, as maternal–offspring genotype concordance or discordance affects the pregnancy outcome. Using GCK-MODY as an example, intensive insulin treatment in an affected mother during pregnancy might result in low birth weight of affected offspring, who require a higher fasting plasma glucose to trigger insulin secretion. By contrast, high fasting hyperglycaemia in an affected mother might lead to high birth weight in an unaffected offspring due to fetal hyperinsulinaemia [59, 60]. Although individuals with some MODY subtypes (e.g. GCK-MODY) run a mild clinical course and rarely develop complications, depending on the coexistence of other risk factors and genotypes, individuals with MODY might exhibit marked heterogeneity in terms of insulin insufficiency, complications, and treatment requirements, even among family members carrying the same variant [61, 62].

Precise diagnosis, classification, and treatment are particularly important in young individuals with type 2 diabetes presentation. In Chinese people, young-onset diabetes is associated with a 1.5–6-fold increased risk of hospitalization with acute or chronic complications, cardiovascular–renal complications, and premature death, in part due to long disease duration and poor risk factor management [63, 64]. The insidious nature of these symptoms might lead to delayed presentation with complications, while early diagnosis

Table 15.1 Clinical features, pathophysiology, and treatment implications of the 14 subtypes of maturity-onset diabetes of the young (MODY) due to rare mutations that often follow a Mendelian mode of inheritance with full penetrance.

Main defects in glucose metabolism	MODY gene mutation	Implications in choices of anti-diabetes treatment
Pancreatic islet and β-cell development	<i>HNF4α</i> <i>HNF1α</i> <i>PDX1</i>	Sulfonylureas Sulfonylureas Diet, oral anti-diabetes drugs, or insulin
	<i>HNF1β</i> <i>NEUROD1</i>	Insulin Oral anti-diabetes drugs or insulin
	<i>KLF11</i>	Oral anti-diabetes drugs or insulin
	<i>PAX4</i>	Diet, oral anti-diabetes drugs, or insulin
Glucose-sensing defect	<i>GCK</i>	Diet only, no need for any drugs
Insulin secretion defect	<i>BLK</i> <i>APPL1</i>	Diet, oral anti-diabetes drugs, or insulin Diet, oral anti-diabetes drugs, or insulin
Insulin gene defect	<i>INS</i>	Oral anti-diabetes drugs or insulin
Adenosine triphosphate (ATP)-sensitive potassium channel dysfunction	<i>ABCC8</i> <i>KCNJ11</i>	Sulfonylureas Oral anti-diabetes drugs or insulin
Pancreas endocrine and exocrine dysfunction	<i>CEL</i>	Oral antidiabetes drugs or insulin

through screening of family members on identification of an index individual might prevent these adverse outcomes [61, 65]. With the rising prevalence of young-onset diabetes especially in low- and middle-income countries [36], healthcare professionals need to appreciate the multiple aetiologies that might coexist in an individual with an atypical presentation of diabetes. In these individuals, precision diagnosis can have important implications for treatment selection, with some benefiting from early insulin treatment (e.g. LADA) and others from oral glucose-lowering drugs (e.g. MODY) (Table 15.1 and Figure 15.3).

Mitochondrial gene mutations

Mitochondria are important intracellular organelles in maintaining glucose homeostasis and energy balance. Mitochondria have their own genome and unlike nuclear DNA, which is protected by histones, mitochondrial DNA is more vulnerable to oxidative stress and environmental toxins. Superoxide radicals generated by the mitochondrial respiratory chain are major sources of damage to mitochondrial DNA. Older people with a positive family history of diabetes have a high frequency of mitochondrial mutations [66]. Due to its maternal inheritance, mitochondrial DNA is a well-known cause of a subtype of maternally-inherited diabetes mellitus [67].

In 1992, an A3243G mutation in the mitochondrial DNA coding for tRNA^{Leu(UUR)} (mt3243) was first reported. This mutation was

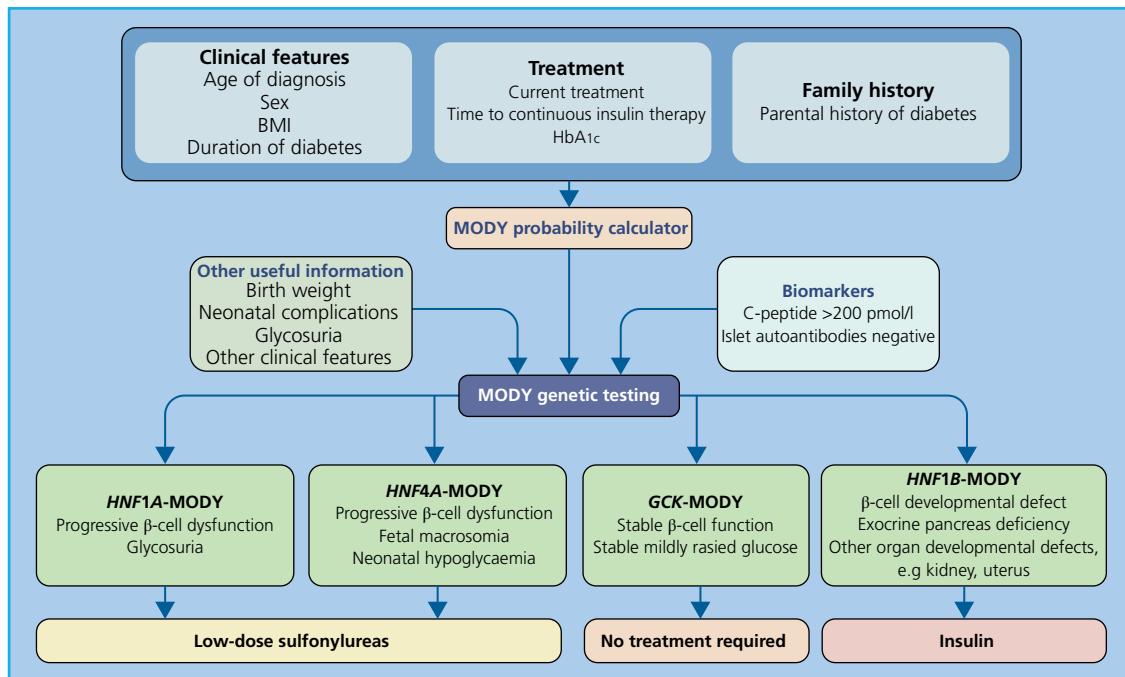

Figure 15.3 A proposed algorithm for identifying individuals with monogenic diabetes and targeted treatment. BMI, body mass index; HbA_{1c}, glycated haemoglobin; MODY, maturity-onset diabetes of the young, maturity-onset diabetes of the young. Source: Adapted from Hattersley and Patel 2017 [58].

found in individuals with type 1 diabetes and type 2 diabetes presentations, and is characterized by maternal inheritance and deafness [68]. The prevalence of this mutation has been reported to be 1–3% in Chinese individuals with diabetes with either ketotic or non-ketotic presentation [69–71]. Other point mutations associated with increased risk of diabetes include sites at 3316, 3394, and 14 577, as well as deletion and rearrangement in mitochondrial DNA [66].

In keeping with its candidacy as a *thrifty gene*, common polymorphisms of the mitochondrial DNA (T16189C) have been associated with increased risk of metabolic syndrome in Chinese people, after adjustment for age and body mass index, with a frequency of 44% compared with 33% in those without metabolic syndrome [72]. In a meta-analysis, Asian people without diabetes had a higher frequency of the T16189C variant than their European counterparts (31.0% versus 9.2%) [73]. Despite negative reports in European populations [73], there are consistent data showing a risk association of the T16189C variant with type 2 diabetes in Asian populations [74, 75]. There are major inter-ethnic differences in mitochondrial haplotypes, with different mitochondrial variants or haplotypes associated with type 2 diabetes in Indian [76], Turkish [77], and Chinese Uyghur [78] populations.

Given the pivotal roles of mitochondria in maintaining islet biology and energy metabolism, mitochondrial diabetes might be an important cause of diabetes in populations undergoing rapid transition in terms of energy consumption [79, 80]. Using transcriptomic and proteomic analyses, researchers had reported changes in multiple genes and proteins in non-obese, non-dyslipidaemic diabetes mouse islets with upregulation of glycolysis and gluconeogenesis pathways, downregulation of oxidative phosphorylation pathways, impaired glucose-induced NADH and ATP production, as well as reduced oxidative and glycolytic glucose metabolism. These data suggest that hyperglycaemia *per se* might induce metabolic changes in β cells that could markedly reduce mitochondrial metabolism and ATP synthesis to drive progressive failure of β cells in diabetes [3].

Taken together, in predisposed individuals, genetic or non-genetic factors that perturb glucose homeostasis might trigger and perpetuate a series of events culminating in persistent and worsening hyperglycaemia. These interlinking events emphasize the importance of maintaining euglycaemia to reduce the risk of onset and worsening of hyperglycaemia in predisposed individuals [3].

Pancreatic amyloidosis and other pancreatic diseases

Amylin, a 37-amino-acid polypeptide, is co-secreted with insulin by pancreatic β cells. It is the principal constituent of the amyloid deposits in the islets of Langerhans in type 2 diabetes [81, 82]. In autopsy series, pancreatic amyloidosis was associated with β-cell loss in both white European and Chinese individuals [83–85]. Using pancreatic specimens, Asian researchers found significant correlations between body mass index and volume of β cells [86], with amyloidosis, inflammation, and fibrosis as common pathological features [87]. Formation of intracellular islet amyloid polypeptide oligomers causes pancreatic β-cell loss with progressive hyperglycaemia [82]. Changes in metabolic milieu or genetic variants encoding proteins involved in amylin metabolism might lead to structural changes of amylin and increased oligomerization with β-cell death [88]. One example is the S20G variant of the amylin gene, which enhances cytotoxicity in one transformed cell line (COS-1) and amyloidogenicity *in vitro*. This genetic variant is found in 2–3% of Japanese, Chinese, and Pacific Islanders with diabetes. In Taiwanese Chinese, normoglycaemic carriers of the S20G variant have reduced early-phase insulin secretion. However, results of co-segregation analysis in family studies of the S20G variant were inconclusive, suggesting that this genetic variant is likely to be a risk-modifying factor rather than a major diabetes gene [4, 65].

In India, young-onset type 2 diabetes often overlaps with monogenic forms of diabetes, fibrocalculus pancreatic diabetes, and diabetes associated with malnourishment [89]. In Indian individuals with tropical calcific pancreatitis, the loss of endocrine function accompanying the exocrine damage might be an additional factor contributing to the clinical manifestation of diabetes in the presence of other stressors [90].

Interpretation of genetic variants in the era of sequencing

The increasing availability of DNA sequence data and access to sophisticated bioinformatic algorithms mean that an unbiased bioinformatics-based assessment of the predicted impact of a genomic variant is rapidly available. However, there are potential pitfalls of variant classification based on bioinformatics analysis alone. In a recent study using bioinformatic algorithms, 88 *likely pathogenic* monogenic diabetes variants were identified in 80 individuals (8.6%) from a cohort of 1019 individuals with type 1 diabetes for 50 or more years. Using the American College of Medical Genetics and Genomics and the Association for Molecular Pathology (ACMG/AMP) standards and guidelines, only 9 of these 88 variants were classified as likely pathogenic or pathogenic variants. Other published research studies with an over-reliance on *in silico* prediction tools also reported high levels (~90%) of false-positive likely pathogenic monogenic diabetes variants. Given the complex nature of diabetes with multiple aetiologies, additional information is needed to interpret the predicted effect on protein function. This includes knowledge regarding the gene-disease validity, mode of inheritance, appropriate allele frequency cut-off thresholds, most clinically relevant transcript, and specificity of disease-causing variant type for each gene [91].

In this context, a good understanding of human biology, epidemiology, and clinical medicine is essential in integrating the exponential

growth of information available from a single individual with or at risk of having diabetes. Given the importance of genetics in the pathogenesis of diabetes, using family members to ascertain co-segregation of novel genetic variants with diabetes and related traits is one approach where physicians can verify their clinical relevance. Moreover, additional aetiologies and disease-modifying factors need to be considered. Apart from autoimmune markers as well as common and rare variants of the nuclear and mitochondrial genome, other genetic, epigenetic, and non-genetic familial factors can be important. For example, epidemiological studies have reported increased risk of diabetes with haemoglobinopathies (e.g. thalassaemia traits) due to increased iron turnover with oxidative stress and β -cell dysfunction [92,93]. People with chronic hepatitis B and C infections have increased risk of diabetes due to low-grade inflammation [94,95]. Other non-modifiable factors, such as age, sex, and disease duration, as well as modifiable factors, such as cognitive-psychological-behavioural factors, management of cardiometabolic risk factors, concomitant medications, access to care, and timeliness in diagnosis and treatment to preserve β -cell function are important considerations in improving the precision of diagnosis and treatment (Figure 15.4) [1,36,37,44,96].

Conclusion

Until recently, autoimmune type 1 diabetes was considered to be the predominant form of diabetes in children and young adults. Clinical and molecular epidemiological analysis has discovered multiple genetic or acquired factors, which may affect islet and mitochondrial biology, with considerable overlap between type 1 and type 2 diabetes phenotypes. Detailed medical history taking, complete physical examination, and use of appropriate laboratory testing along with evaluation of autoimmune and genetic markers may help clinicians improve the precision of diagnosis and management of individuals with atypical diabetes for better outcomes.

Abnormalities of Insulin Secretion and β -Cell Defects in Type 2 Diabetes

Stefano Del Prato, Cristina Bianchi, and Giuseppe Daniele

Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy

Key points

- Type 2 diabetes is a heterogeneous, progressive disease caused by the interaction of genetic and environmental factors, which adversely affect β -cell function and tissue insulin sensitivity.
- Physiological regulation of insulin secretion is controlled through a sophisticated integrated process encompassing finely tuned feedback mechanisms between the β cell, plasma glucose and other nutrient levels, insulin sensitivity, incretin hormones, neuropeptides, and neuronal control.
- β -cell abnormalities are the main determinant of the rate of progression of type 2 diabetes. Worsening of the ability of the β cells to compensate for existing tissue insulin resistance sets the rate of progression of the disease.
- A predisposing genetic background is the most likely explanation for the evidence provided by multiple studies that β -cell function is altered well before the onset of overt type 2 diabetes.
- In predisposed normoglycaemic individuals, loss of first-phase insulin secretion and loss of glucose sensitivity, i.e. the ability of β cells to sense and respond properly to changes in glucose concentrations, represent the earliest abnormalities of β -cell function.
- An apparent reduction in β -cell volume of up to 60% has been found in people with pre-diabetes, with a further reduction in individuals with overt diabetes. The decrease in β -cell mass is the result of an increased rate of apoptosis, autophagy, and dedifferentiation. The increased β -cell death occurs without a compensatory increase in β -cell replication owing, at least in part, to the limited regenerative capacity of adult human β cells.
- Multiple factors contribute to the progressive loss of β -cell function and β -cell mass, including the characteristic alterations of the metabolic milieu of type 2 diabetes, i.e. hyperglycaemia, hyperlipidaemia, chronic β -cell stimulation, and impaired incretin effect.
- All factors that accelerate the decreased number and function of β cells promote common damage pathways, including oxidative stress, endoplasmic reticulum stress, inflammation, immune system activation, and amyloid deposition. These factors impair both the function and survival of β cells, although abnormalities of β -cell function seem to be predominant compared with the reduction in the number of insulin-secreting cells.
- Preserving β -cell function is key to ensuring long-term glycaemic management in people with type 2 diabetes.

Type 2 diabetes is a complex, progressive disease. In the past 40 years or so, several alterations involving different tissues have been identified as contributing to the development and progression of hyperglycaemia and concomitant metabolic disorders [1,2]. Of the many pathogenic mechanisms, insulin resistance and impaired β -cell function remain the hallmarks of the condition. Insulin resistance is almost universally present in people with type 2 diabetes and it is already apparent in predisposed individuals. However, normal glucose tolerance is maintained in the face of insulin resistance provided that the β cell remains capable of compensating for the increased secretory demand. This simple observation highlights how the defect of insulin secretion plays a central role in the development of glucose intolerance, conversion to diabetes, and progression of the disease. Insulin secretion, indeed, is key to the maintenance of glucose homeostasis.

Physiological insulin secretion

Insulin is secreted from the β cells of the pancreas. The insulin-producing cells are embedded in ~3 million islets of Langerhans

scattered throughout the exocrine pancreatic tissue, where they account for up to 60% of the entire islet cell population. The total β -cell weight of a normal-weight adult does not exceed 1 g. This minute β -cell mass contains sufficient insulin to ensure up to 8–10 days of hormone requirement [3]. Insulin is key for keeping daily plasma glucose concentration within a tight range in spite of wide fluctuations in carbohydrate intake (i.e. food ingestion) and demand (e.g. resting conditions vs physical activity). This implies tightly regulated, dynamic, and rapidly acting feedback between insulin secretion and plasma glucose concentration [4].

Glucose is actively transported inside the β cell in a linear manner with plasma glucose levels through the activity of glucose transporter 2 (GLUT2). Once inside the cell, glucose is promptly phosphorylated by glucokinase, allowing its entry into the glycolytic pathway ending with the generation of adenosine triphosphate (ATP), the main driver of glucose-induced insulin secretion. Increased cytosolic ATP levels cause the closure of ATP-sensitive K^+ channels and depolarization of the plasma membrane, causing the opening of the voltage-dependent Ca^{2+} channels and Ca^{2+} influx. The rise in intracellular Ca^{2+} concentration triggers the

exocytosis of insulin granules and the release of insulin (Figure 16.1). Therefore, glucokinase is the rate-limiting step for the glycolytic flux and represents the main glucose sensor in the β cell, although recent experimental work has suggested the existence of additional sensing systems, including heterodimers of sweet taste receptors [6].

Insulin secretion in response to glucose is biphasic in nature, with a short-lasting (a few minutes) first-phase increase in insulin secretion followed by a more sustained second-phase increase, which lasts as long as glucose levels remain elevated [7,8]. The biphasic response of insulin secretion reflects the dynamics of spatially and functionally distinct intracellular insulin granule pools. According to this view, first-phase insulin secretion reflects fusion to the cell membrane of pre-docked granules from a readily releasable granule pool [9]. This pool accounts for no more than 5% of the total granules in the cell. The increase in ATP concentration in the β cell on exposure to glucose facilitates movement of insulin granules and priming of exocytosis. The second phase of insulin secretion involves the recruitment of granules from a more distant and larger reserve pool as well as stimulation of *de novo* insulin synthesis [10]. This characteristic biphasic response of the β cell can be clearly appreciated using the hyperglycaemic clamp technique

depicted in Figure 16.2 [11]. A square wave of hyperglycaemia is obtained with this technique, which distinguishes the first phase of insulin secretion, which is generally dependent on the magnitude of the early increase in glucose levels, and the second phase. Although such a clear-cut distinction is not fully apparent with a more gradual glucose increase, the same sequence – that is, an early insulin response followed by a more sustained response – occurs after the ingestion of carbohydrates or a regular meal.

Insulin is secreted into the portal vein and exerts an immediate biological action on the liver. In the fasting state, portal insulin limits the supply of glucose from the liver into the systemic circulation to match the need of glucose-dependent tissues, primarily the central and peripheral nervous system and red blood cells. Basal insulin secretion is characterized by rapid oscillations with a 3–4-minute frequency [12]. In the absorptive state, insulin is secreted in proportion to the increments in plasma glucose levels on the entry of nutrients into the circulation following food digestion and absorption. The route of administration of glucose and other nutrients markedly influences insulin secretion. When glucose is administered via the gastrointestinal tract, a much greater stimulation of insulin secretion is observed compared with similar plasma glucose levels obtained with intravenous glucose infusion.

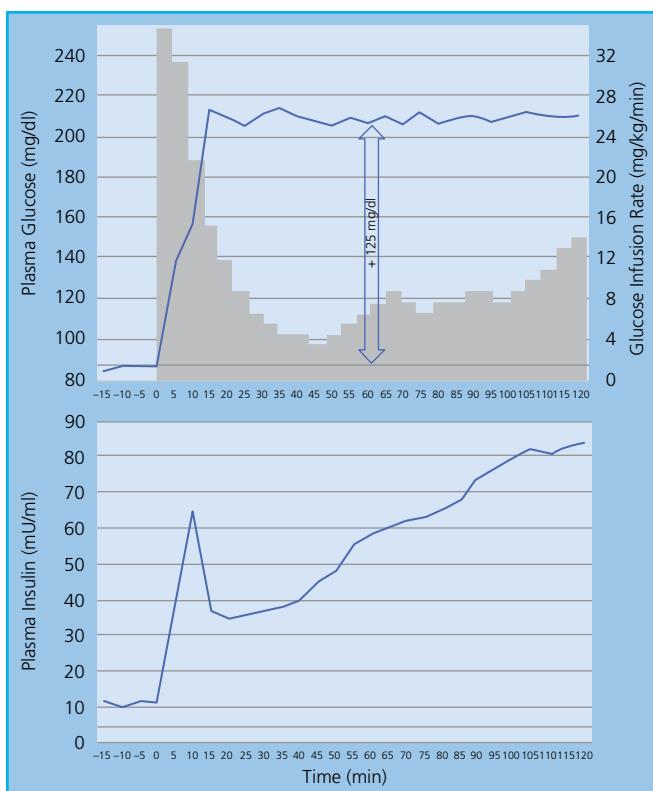

Figure 16.2 First- and second-phase plasma insulin response during hyperglycaemic clamp in healthy individuals. Plasma glucose is acutely raised +125 mg/dl (6.9 mmol/l) above baseline and maintained for the ensuing two hours. Plasma insulin concentration is measured at regular intervals. This difference in insulin secretion between intravenous and oral glucose administration is referred to as the *incretin effect* [13] and it is mediated by the release of gastrointestinal hormones. The major incretin hormones in humans are glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP) and these contribute to the maintenance of glucose homeostasis after meals [14]. Other gut hormones, such as cholecystokinin (CCK), contribute to the incretin effect, although the importance of these peptides is negligible under physiological conditions [15].

Insulin secretion is also stimulated by protein and fat ingestion [16]. Amino acids trigger insulin release and amplify insulin-secretory pathways by acting as a substrate for the tricarboxylic acid cycle and/or redox shuttles with subsequent generation of ATP, and through direct depolarization of the plasma membrane (Figure 16.1). The latter is the consequence of the transmembrane transport of positively charged amino acids via specific amino acid transporters and Na^+ cotransport. Lipids and free fatty acids play a crucial role in β -cell function and insulin release [5]. In the presence of nutrients, free fatty acids modulate insulin secretion through three distinct pathways:

- Tricarboxylic acid cycle/malonyl-coenzyme A (CoA) metabolic signalling.
 - Glycerolipid/free fatty acid cycling.
 - Direct activation of G-protein-coupled receptors (GPCRs) [5].
- Finally, many other factors, including neuropeptides and neuronal control, contribute to the modulation of insulin secretion through a sophisticated integrated process [5]. Stimulation of the

parasympathetic nervous system increases insulin secretion [17] while sympathetic stimulation exerts an inhibitory effect [18].

The pancreatic islets of Langerhans are more than just the home of the insulin-producing β cells. They contain several additional endocrine cell types, most notably glucagon-producing α cells and somatostatin-producing δ cells, which coordinate their activity in response to changes in glucose and other nutrients and modulate β -cell activity through a paracrine crosstalk between the three major endocrine cell types of the islet [19]. At the systemic level glucagon functionally opposes the glucose-lowering effects of insulin, yet it stimulates insulin secretion through the glucagon receptor (GCGR), a class B GPCR related to the incretin receptors. Glucagon essentially acts in an incretin-like fashion amplifying glucose-stimulated insulin secretion. The glucagon paracrine effect is necessary for full insulin secretion in response to glucose stimulation [20]. Pancreatic δ cells provide feedback control of neighbouring α and β cells through local circulation and the interstitial compartment. These interactions are essential for precise control and coordination of insulin and glucagon secretion. In addition to their paracrine activation by urocortin 3, δ cells receive selective inputs from multiple hormones, neurotransmitters, and nutrients, and integrate these into appropriate feedback modulation of insulin and glucagon secretion [21]. Though the contributions of α and δ cells to glucose-stimulated insulin secretion are often hard to evaluate in humans, the breakdown of these paracrine connections contributes to dysregulation of insulin- and glucagon-secretory responses in diabetes.

Insulin secretion is mainly modulated in rapid feedback with plasma glucose levels, but a long-term adaptation can also occur through changes in the number of β cells, as indicated by the progressive increase in β -cell mass occurring from birth to adulthood. Expansion of β -cell mass tends to become negligible after the age of 20–30 years [22, 23], yet an increase may occur under conditions of increased insulin demand such as obesity [24, 25] and pregnancy [26].

More details on the regulation of insulin secretion are available in Chapter 7, but from this brief discussion of the physiological regulation of insulin secretion, it should become apparent how abnormal insulin secretion in type 2 diabetes may arise from defective β -cell function, reduced β -cell mass, or a combination of the two.

Natural history of β -cell failure

Because of its fine regulation, assessment of insulin secretion *in vivo* requires complex methodological approaches and sophisticated modelling analysis [27, 28]. Homeostasis model assessment B (HOMA-B) is a model-derived parameter reflecting β -cell function in the basal state [29]. This measure has been instrumental in describing the natural history of β -cell dysfunction in type 2 diabetes in the UK Prospective Diabetes Study (UKPDS) [30]. Individuals with type 2 diabetes already have significantly reduced β -cell function at the time of diagnosis. Moreover, β -cell function declined in an almost linear manner during the 10-year follow-up of the study, irrespective of pharmacological treatment. Because of such a linear relationship, the defect in β -cell function was extrapolated to antedate the development of hyperglycaemia by many years. The Belfast Diet Study used the same HOMA-B parameter to describe β -cell dysfunction [31]; individuals who eventually developed diabetes

already had an intrinsic 40–60% reduction in β -cell function at the outset, while over time two phases were identified:

- Phase A, which precedes overt diabetes and is characterized by a slow, constant decline of β -cell function (~2% per year).
- Phase B, characterized by a much faster decline (~18% per year), more commonly occurring with the development of diabetes.

This view is of interest because it reflects three conditions that, in recent years, have received growing experimental support: (i) genetic predisposition; (ii) early β -cell dysfunction; and (iii) factors that accelerate the rate of loss of β -cell function.

Genetic predisposition

More light has been shed in recent years on the genetic predisposition to type 2 diabetes (Chapter 12; Figure 16.3). Early linkage and candidate gene analyses and, more recently, genome-wide association studies (GWAS) have identified many genetic variants associated with increased risk of developing type 2 diabetes, although most have limited size effects that seldom exceed 10–15% [32]. The only exception is represented by variants of the *TCF7L2* gene encoding for a transcription factor involved in the Wnt- β catenin signalling pathway [33]. In particular, the T allele of the genotypes of the single-nucleotide polymorphism (SNP) rs7903146 confers a greater risk of developing type 2 diabetes in all populations so far evaluated [33], except for the Pima [34]. More interestingly, the

same genotype is associated with impaired *in vivo* [34,35] and *ex vivo* [35] insulin secretion. The *TCF7L2* genetic variants may exert both direct and indirect effects on the β cell. Thus, the increased *TCF7L2* expression found in human pancreatic islets carrying the risk allele T was inversely correlated with glucose-stimulated insulin release [35]. Moreover, people carrying the risk alleles have impaired potentiation of insulin secretion in response to GLP-1 infusion [36]. In summary, the *TCF7L2* genetic variants may be associated with reduced insulin secretion in response to both glucose and incretin hormones. Other studies have reported reduced expression of the *TCF7L2* gene in type 2 diabetes pancreatic islets along with impaired insulin secretion and β -cell survival [37].

A reduced early insulin response to both oral and intravenous glucose and greater susceptibility to diabetes have been reported for carriers of the single-nucleotide polymorphism (SNP) rs10830963 in the melatonin receptor gene (*MTNR1B*) [38,39]. These individuals have increased melatonin receptor expression in β cells, which may lead to increased melatonin binding and reduced cyclic adenosine monophosphate (cAMP)/cyclic guanosine monophosphate (cGMP) generation, accounting for impaired insulin secretion.

Other gene variants that have been associated with impaired insulin action include the G/G variants of calpain-10 gene (*CAPN10*) and *KCNJ11*. The G/G variant of SNP-43 of *CAPN10* is associated with impaired insulin response to glucose in people

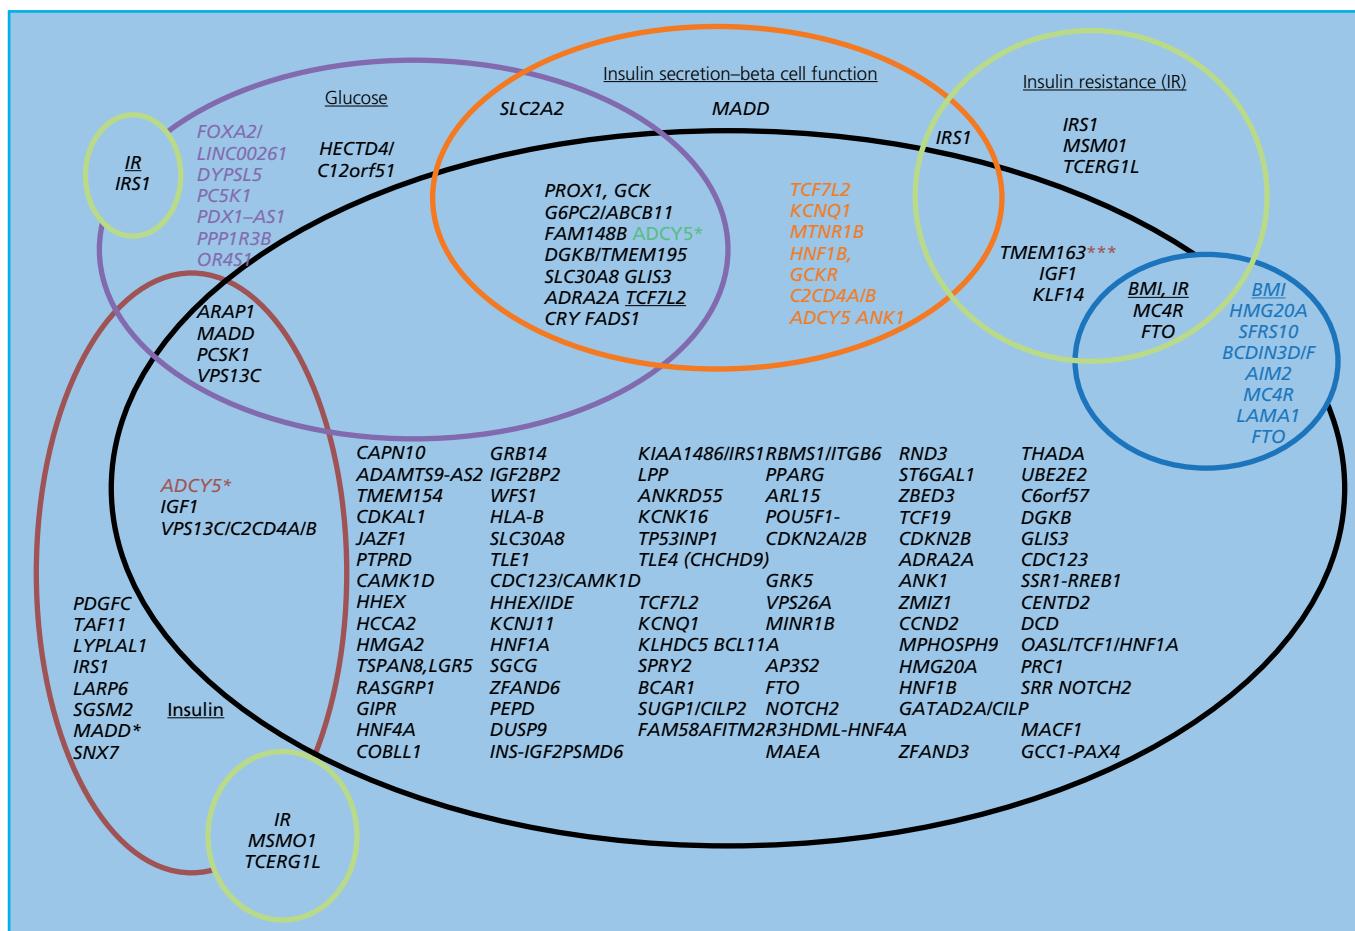

Figure 16.3 Type 2 diabetes and glycaemic trait-associated variants. The variants are represented by gene names here, which could indicate that the location is present either in the gene or in the vicinity of the gene. The white circle represents type 2 diabetes and the gene names in black in that circle represent variants only associated with type 2 diabetes. The overlapping circles indicate additional reporting associations for that variant. Source: Prasad and Groop 2015 [32]. Creative Commons Attribution License (CC BY).

without diabetes [40]. Variants of the *KCNJ11* gene may result in gain of function of the ATP-sensitive potassium channels, resulting in impaired depolarization of the β -cell membrane and altered insulin release, although such an effect becomes more apparent when the β cell is under stress conditions (i.e. glucotoxicity) [41].

Many other genes, including *HHEXZ/IDE*, *GIPR*, *PROX1*, *DGKB*, *CDKAL1*, *SLC30A8*, *CGK*, and *CDKN2A/2B*, have been associated with abnormal insulin secretion [42–59]. It is of interest that the majority of the gene variants so far associated with type 2 diabetes exert their main effect on insulin secretion, which worsens significantly with an increase in the two-hour plasma glucose level, even in people with normal glucose tolerance (i.e. two-hour plasma glucose <140 mg/dL; 7.8 mmol/L) [60,61]. In both lean individuals and those with obesity and two-hour plasma glucose levels of 120–140 mg/dL (6.7–7.8 mmol/L), β -cell function is already reduced by 60% compared with those with a two-hour plasma glucose level of <100 mg/dL (5.6 mmol/L) (Figure 16.4) [61]. The abnormalities of β -cell function become fully apparent when the insulin-secretion rate is plotted against prevalent plasma glucose levels [61,62]. This analysis clearly shows how β cells of people with a predisposition to diabetes secrete less insulin than healthy individuals for the same glucose stimulus [62]. This abnormality is often referred to as

impaired glucose sensitivity [63] and it is better defined when mathematical modelling approaches are applied [64].

Early β -cell dysfunction

Loss of first-phase insulin secretion is an early feature of β -cell dysfunction. Individuals with isolated impaired fasting glucose show a decrease in first-phase insulin-secretory response to intravenous glucose and early-phase insulin response to oral glucose [65]. The late-phase insulin response after an oral glucose tolerance test is less severely impaired than in people with impaired glucose tolerance who have severe defects in both early- and late-phase insulin responses. First-phase insulin secretion plays an important role in priming the liver to inhibit endogenous glucose production in response to glucose or nutrient ingestion [66,67]. Therefore, the defect in early-phase insulin secretion in impaired fasting glucose and impaired glucose tolerance results in inadequate suppression of hepatic glucose production and contributes to an excessive early rise in plasma glucose in response to an oral glucose load. In people with impaired glucose tolerance, the combination of deficient second-phase (late-phase during oral glucose tolerance test) insulin secretion and peripheral insulin resistance translates into less efficient glucose disposal. As a result, after the ingestion of a glucose load, plasma glucose concentration will continue to increase after the initial 60 minutes to remain elevated after 120 minutes. The loss of first-phase insulin not only contributes to impaired hepatic glucose metabolism [68], but also is an independent predictor of the development of type 2 diabetes [69,70].

In summary, the natural course of β -cell function suggests that the acute insulin response and glucose sensitivity play a major role in determining glucose tolerance [71]. Longitudinal studies of the Pima relating changes in insulin sensitivity and acute insulin response have clearly demonstrated that it is the worsening of the latter rather than the development of insulin resistance that marks the progression from normal glucose tolerance to impaired glucose tolerance and, eventually, type 2 diabetes [72].

The extent to which these functional abnormalities are also linked to loss of β -cell mass is still a matter of discussion [73], but β cells can undergo various changes, a phenomenon known as β -cell plasticity [74]. Recent evidence has shown how in people with pre-diabetes, under the increased demand imposed by insulin resistance, islets and exocrine cells become extraordinarily plastic [75]. Although an increased β -cell workload is a risk factor for hyperglycaemia, in most individuals there is an adaptive increase in insulin and proinsulin secretion with no apparent β -cell failure [76]. Rather, insulin resistance in these individuals induces an increase in the β -cell area, as observed in pancreas samples obtained from people without diabetes [77]. Neogenesis from duct cells and/or trans-differentiation from α cells are likely explanations for the changes in β -cell mass observed in people with insulin resistance.

Assessment of β -cell mass is largely dependent on methodological approaches [78], but several reports claim that an apparent reduction in β -cell volume of up to 60% is present in individuals with pre-diabetes [24,79,80]. The decrease in β -cell mass has been traditionally attributed to an increased rate of apoptosis [24,25,78,81,82] and, to a lesser extent, autophagy [83]. An increase in β -cell death occurs without a compensatory increase in β -cell replication owing, at least in part, to the limited regenerative capacity of adult human β cells [22,84]. Along with these mechanisms, β -cell dedifferentiation, rather than cell death, accounts for the loss of β cells in the pancreatic islet of individuals with diabetes [85,86]. Figure 16.5 summarizes the mechanisms involved in β -cell plasticity.

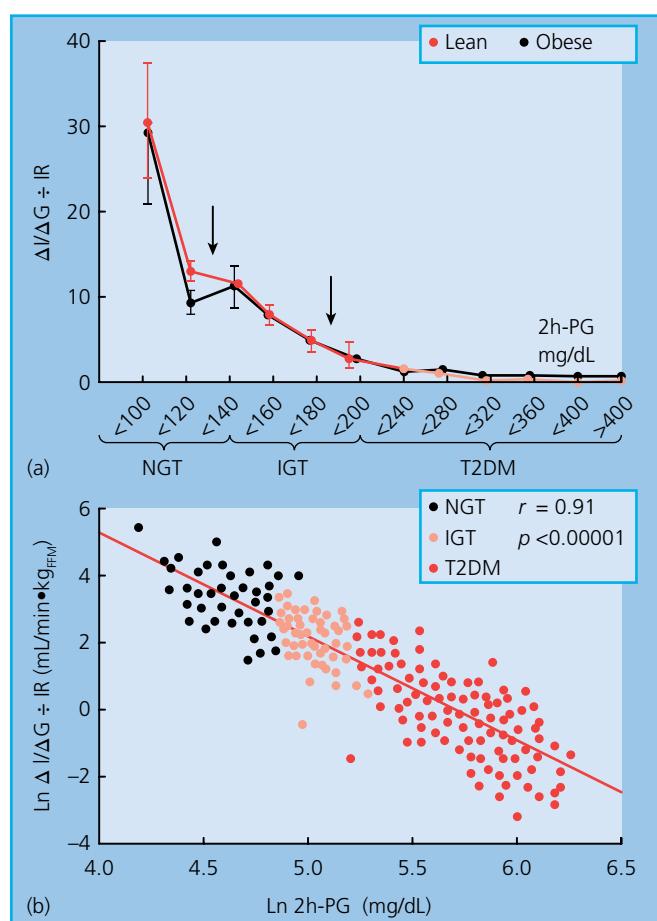

Figure 16.4 Relationship between the insulin secretion/insulin resistance index ($\Delta I/\Delta G$ factored by the severity of insulin resistance measured with the euglycaemic insulin clamp) and (a) the fasting plasma glucose (FPG) and (b) the two-hour plasma glucose (two-hour PG) concentration (log–log scale). Figure 16.5 Schematic representation of the hypothetical scenario of islet plasticity. Islet plasticity is the capacity of the islet to modify its morphology and function according to different metabolic conditions. A potential explanation of the present scenario is as follows: when insulin resistance increases insulin demand, islet plasticity guarantees a twofold increase in β cells, whose origins are still debated, but some hypotheses are trans-differentiation from centroacinar and duct cells (duct red cells and centroacinar violet cells), replication (red cell Ki67+), and neogenesis from an unknown source (white to red cell); a twofold increase in the α cells

trans-differentiated into insulin-producing cells (yellow double-positive cells); and a fivefold increase in the α cells via neogenesis, with a consequent increase of a potential glucagon-like peptide 1 (GLP-1) source (white to green cell). As with any compensatory mechanism, in a chronic condition it is bound to fail. The exhausted β cells undergo dedifferentiation (Dedef; a resting state, red to grey cells), the double-positive cell switches back into the original α cell (yellow cells to green cells), and the overstressed β cells trans-differentiate into α cells (red cell to green cell). Gcg, glucagon; Ins, insulin. Source: Mezza et al. [74].

Factors that accelerate the rate of loss of β -cell function; how insulin secretion progressively worsens after development of type 2 diabetes

Impaired insulin secretion and insulin-secretory capacity are the major determinants for the development of type 2 diabetes. Neither hyperglycaemia nor glucose intolerance develops in insulin-resistant individuals provided that sufficient insulin is secreted from β cells to compensate for the insulin resistance. β -cell dysfunction progresses over time and continues to worsen after diabetes has developed [30,31]. Multiple factors contribute to the progressive loss of β -cell function and mass, the most important being the direct consequences of the altered metabolic milieu characterizing type 2 diabetes.

Hyperglycaemia

Many *in vivo* and *in vitro* studies have shown that chronic elevation of glucose concentrations impairs β -cell function (and insulin action), a phenomenon known as *glucotoxicity*. Conversely, improved glycaemic levels, both under experimental conditions and in clinical studies, have been associated with improved β -cell function [87]. The main mechanisms accounting for the negative effect of high glucose are activation of oxidative stress, the consequence of increased glucose oxidation in the mitochondria, mitochondrial dysfunction, and overproduction of reactive oxygen species (ROS) [88]. In type 2 diabetes pancreatic islets, markers of

oxidative stress, are significantly increased [88] compared with normal islets and inversely related to glucose-stimulated insulin secretion. In contrast, overexpression of antioxidant factors reduces the level of markers of oxidative stress and increases β -cell responsiveness to insulin [88,89]. The β cell is particularly susceptible to the negative effect of oxidative stress owing to an intrinsic low expression of antioxidant enzymes and reduced DNA repair capacity [90].

Increased glucose availability is also associated with activation of the glycolytic pathway in β cells and with excessive formation of fructose-6-phosphate, with subsequent increased flux through the hexosamine pathway. *in vitro* studies have clearly shown how hexosamine pathway activation interferes with the expression of genes involved in β -cell regeneration and differentiation [91] and triggers apoptosis [92].

Therefore, chronic exposure to hyperglycaemia can affect both β -cell function and mass, although such an effect is likely to be more prominent when exerted on a predisposed β cell, since in healthy individuals 72 hours of hyperglycaemia do not impair β -cell function [93].

Hyperlipidaemia

Obesity is a common condition in people with type 2 diabetes and is one of the main causes of the progressive increase in the global prevalence of the disease [94]. Obesity, and concomitant insulin resistance, are often associated with dyslipidaemia,

increased circulating leptin concentrations, and chronic inflammation [95].

Leptin receptors are expressed in β cells, and their activation directly inhibits insulin secretion [96]. Moreover, leptin inhibits insulin gene expression and affects proliferation, apoptosis, and β -cell size [96]. Expansion of adipose tissue is associated with increased cytokine release [97]; tumour necrosis factor- α and interleukin (IL)-6 affect both β -cell function and survival [98]. Moreover, apoptosis can stimulate the innate immune system with mobilization of T cells and macrophages [99]. Under stress conditions, such as those generated by excessive stimulation by glucose and free fatty acids, the concentrations of pro-inflammatory factors are increased in the pancreatic islets [100,101] where they can trigger Fas-dependent apoptosis through activation of nuclear factor kB (NFkB). Plasma free fatty acid concentrations are commonly increased in people with type 2 diabetes and contribute to sustained insulin resistance [102] as well as impaired β -cell function [103], a phenomenon also known as *lipotoxicity*. The effects of free fatty acids on β -cell function are complex, as they are also physiological modulators of insulin secretion. Hence, under fasting conditions, an increase in plasma free fatty acids becomes essential for the maintenance of basal insulin levels and to ensure a normal insulin response to glucose [104]. Nonetheless, the toxic effect of free fatty acids can be easily demonstrated *in vitro*: even a short exposure of human pancreatic islets to an excessive free fatty acid concentration is sufficient to impair glucose-stimulated insulin release [105]. High free fatty acids levels contribute to β -cell dysfunction through intracellular accumulation of triglycerides as a response to activation of the sterol regulatory element binding proteins (SREBPs) [106], or by increased expression of uncoupling protein 2, which regulates cellular ATP production [107]. The impact on β -cell function is paralleled by a cytostatic effect due to the activation of caspase-mediated apoptosis [108]. Free fatty acids also induce the expression of nitric oxide (NO) synthase, causing marked NO overproduction. When NO production is restrained by inhibitors of inducible NO synthase, insulin secretion is significantly ameliorated [109]. NO also contributes to apoptosis through the activation of c-Jun N-terminal kinase (JNK), p38 mitogen-activated protein kinase (MAPK), and Akt inhibition [110]. Elevated free fatty acid levels exert a detrimental effect on insulin gene expression as well as the expression of transcription factors that may be directly involved in the differentiation process of β cells from ductal cells [111]. Moreover, exposure of mouse islets to palmitate impairs insulin exocytosis through alteration of the tight complexes of Ca^{2+} channels with the secretory granules. Along with these mechanisms, free fatty acids activate endoplasmic reticulum stress, alter autophagy, and sustain β -cell dedifferentiation. Free fatty acids can induce endoplasmic reticulum stress through perturbations affecting endoplasmic reticulum folding capacity, leading to misfolded protein overload [112]. Excess of lipids can result in dysregulated autophagy, as indicated by an increase of autophagic vacuoles and autophagosomes, and can lower lysosomal-associated membrane protein 2 and cathepsin expression [83]. Experimental data show that challenging the β cell with free fatty acids results in a recapitulation of the typical β -cell alterations occurring in type 2 diabetes. Exposure of β cells to free fatty acids causes a depletion of forkhead box protein 1 (Foxo-1), a transcription factor responsible for the integration of nutrient- and hormone-generated signals [86]. This depletion is associated with the activation of dedifferentiation markers, suggesting that lipotoxicity

may contribute to the loss of insulin-producing cells in the pancreatic islet.

In summary, like chronic hyperglycaemia, lipotoxicity can accelerate the progressive loss of β -cell function and mass. However, such an effect seems to be more apparent when the two conditions coexist, as commonly occurs in individuals with type 2 diabetes. For this reason, it may be more appropriate to refer to the combination of these effects as *glucolipotoxicity* [113]. The adverse metabolic milieu may also affect gene expression through epigenetic mechanisms. For instance, increased methylation of the PGC1- α gene promoter has been reported in pancreatic islets from cadaveric donors with type 2 diabetes; the greater the degree of methylation, the lower is the expression of the protein and the lower the glucose-stimulated insulin release [114].

Chronic β -cell stimulation

Chronic hyperglycaemia is associated with persistent β -cell stimulation and insulin biosynthesis. This process requires activation of the endoplasmic reticulum, which is responsible for the biosynthesis and folding of newly synthesized insulin (Figure 16.6) [116]. Because of glucolipotoxicity, the endoplasmic reticulum folding capacity is impaired, causing accumulation and aggregation of unfolded proteins, a condition known as endoplasmic reticulum stress [117]. Up to a certain point, this stress can be compensated via the so-called *unfolded protein response*. This adaptive and protective pathway, however, can become ineffective if endoplasmic reticulum stress is persistent and may lead to the generation of proapoptotic signals. Several studies have documented endoplasmic reticulum stress in *ex vivo* pancreatic islets of cadaveric donors with type 2 diabetes [115,118]. In these islets, endoplasmic reticulum stress is marginally increased if they are incubated in the presence of normal glucose concentration. In contrast, exposure to higher glucose levels causes greater endoplasmic reticulum stress than in islets from cadaveric donors without diabetes (Figure 16.6) [115]. These findings suggest a greater susceptibility to proapoptotic mechanisms in the diabetic β cell. In summary, increased and persistent insulin secretion can contribute to β -cell dysfunction and survival through insulin protein misfolding in the endoplasmic reticulum.

Chronic stimulation of β cells also results in an increase in the synthesis of islet amyloid polypeptide (IAPP). This peptide is co-localized with insulin secretory granules [119] and its production parallels that of proinsulin. IAPP can form aggregates and fibrils [120], leading to the deposition of amyloid plaque that triggers an inflammatory response [121], recruitment of macrophages [122], and apoptosis [123]. The mechanism through which IAPP forms amyloid and results in β -cell damage is not completely understood. Amyloid deposition has been found in other hypersecretory conditions, such as obesity without diabetes [124] and insulinoma [125], with no apparent negative impact on β -cell function. One possible explanation for this paradox is that the negative effect of amyloid may require concomitant glucolipotoxicity. In line with this hypothesis is the observation that pancreatic islet amyloid can be found in up to 90% of people with type 2 diabetes [126] and that the degree of deposition correlates with the duration and severity of the disease [127].

Impaired incretin effect

GLP-1 and GIP are physiological factors involved in β -cell function and survival [128] and they are the main players in the incretin effect [14]. This effect is characteristically lost in type 2 diabetes,

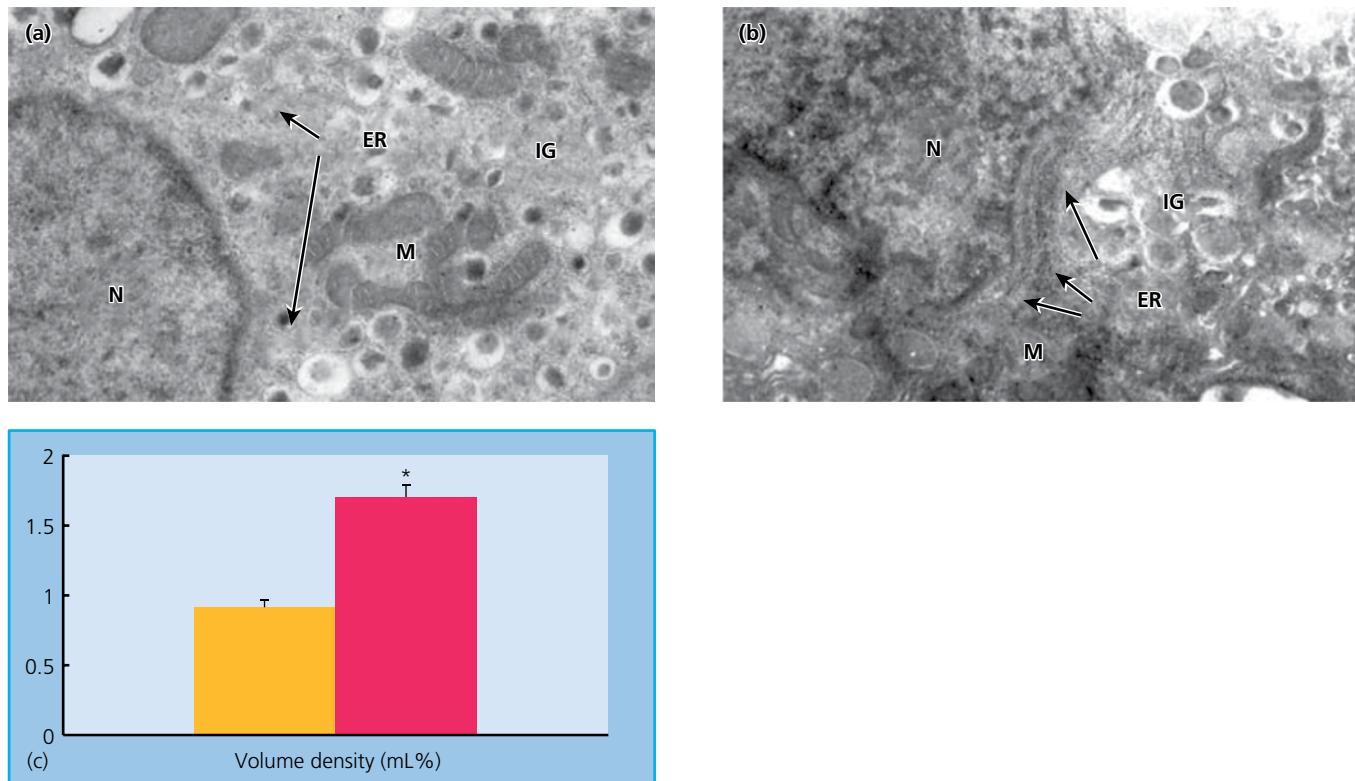

Figure 16.6 (a, b) Electron microscopy images showing the endoplasmic reticulum (ER) in (a) non-diabetic β cells and (b) type 2 diabetes β cells. The ER components (arrows) are scarcely visible in non-diabetic cells and more apparent in type 2 diabetes cells. Magnification $\times 10\,000$. IG, insulin granules; M, mitochondria; N, nucleus. (c) The ER density volume was significantly higher in type 2 diabetes β cells (red box) than non-diabetic β cells (yellow box). * $p < 0.05$ (Student's t -test for unpaired data). Source: Marchetti et al. 2007 [115]. Reproduced with permission of Springer.

although it is still a matter of discussion whether this alteration is a primary defect or an acquired one [129]. In both cases, the loss of the incretin effect results in poor potentiation of the insulin release in response to the ingestion of a meal and excessive post-prandial glucose excursion [130]. Whether this defect can also contribute to loss of β -cell mass is unclear, at least in humans, but pre-clinical studies have provided evidence for an effect of GLP-1 in reducing apoptosis and stimulating β -cell regeneration and differentiation in experimental murine models [131].

GLP-1 is mainly secreted by the L cells of the lower intestine, but GLP-1 can also be synthesized by the α cells of the pancreatic islet [132,133]. These cells also express dipeptidyl peptidase 4 (DPP-4), the peptidase responsible for GLP-1 inactivation [134]. GLP-1 production is increased in pancreatic islets from cadaveric donors with type 2 diabetes [133], whereas DPP-4 activity is reduced [134]. The extent to which these mechanisms may ensure an *in vivo* increase in local GLP-1 levels is difficult to ascertain, but the increase in intra-islet GLP-1 availability could be seen as an attempt to protect the β cells [135].

therapies may exert on the preservation of β cells. Potential protective effects have been claimed with the use of DPP-4 inhibitors [136,137], GLP-1 receptor agonists [138,139], and pioglitazone [140]. GLP-1 receptor agonists protect β cells from lipotoxicity by increasing cell defences [141], reducing inflammatory response [142], and preventing autophagy inhibition [143]. Glitazones can reduce oxidative stress [144], inflammation, and endoplasmic reticulum stress [145] associated with lipotoxicity. Incubation of pancreatic islets of individuals with type 2 diabetes in the presence of therapeutic concentrations of metformin increases insulin content and the number and density of mature insulin granules, improves glucose-induced insulin release, and reduces apoptosis along with normalization of several markers of oxidative stress [146]. Weight reduction and physical activity may exert a favourable effect on β -cell function of people with type 2 diabetes. Fat accumulation has been found in intrapancreatic adipocytes of these individuals [147] and its reduction with a very low-calorie diet is associated with a recovery of first-phase insulin secretion [148]. Exercise can also elicit a decrease of pancreatic fat, but can also enhance IL-6. Administration of IL-6 or elevated IL-6 concentrations in response to exercise stimulate GLP-1 secretion from intestinal L cells and pancreatic α cells, improving insulin secretion and glycaemia in experimental animals [132].

In *ex vivo* studies, concern has been expressed with respect to the effects of sulfonylureas on the β cell. *In vitro* experiments have shown increased β -cell apoptosis [149], although some difference

may exist among different sulfonylureas. In isolated human pancreatic islets, glibenclamide but not repaglinide activates β -cell apoptosis [149]. Other observations have indicated a reduced insulin content in pancreatic islets incubated in the presence of glimepiride, glibenclamide, and chlorpropamide, although no change in insulin release in response to glucose was observed with glimepiride [150]. In cultured β -cell lines, no activation of apoptosis was found with gliclazide treatment along with some antioxidant effect noted in human pancreatic islets [151].

The real impact of these findings is still unclear. In the clinical setting, the durability of the glucose-lowering efficacy of sulfonylureas is claimed to be poorer than with other anti-diabetes agents [152]. These findings are in keeping with animal studies showing that chronic glibenclamide treatment causes loss of insulin-secretory capacity due to β -cell hyperexcitability [153]. However, the same studies also revealed rapid reversibility of this secretory failure, arguing against β -cell apoptosis or other cell death induced by sulfonylureas. In contrast, these findings support earlier observations showing *in vivo* restoration of β -cell response to sulfonylureas, once sustained sulfonylurea therapy was discontinued [154].

In summary, on the development of overt hyperglycaemia, several factors, including chronic hyperglycaemia, obesity, increased free fatty acid availability, persistent stimulation of β cells, and, potentially, the use of specific drugs, may contribute to the acceleration of the decline in insulin-secretory capacity of individuals with type 2 diabetes and progression of the disease. These accelerating factors promote common damage mechanisms, including oxidative stress, endoplasmic reticulum stress, inflammation, and immune system activation (Figure 16.7) [155]. Because of these mechanisms, a vicious cycle develops by which the ability of the β cells to cope with hyperglycaemia and insulin resistance becomes weaker and the impact of the accelerating factors becomes greater. These factors

impair both the function and the survival of the β cells, although the relative contribution of the two remains to be established.

β -cell dysfunction: exhaustion or insufficient mass?

β -cell dysfunction and loss of β -cell mass both contribute to the pathogenesis of hyperglycaemia in type 2 diabetes. At the time of diagnosis of type 2 diabetes, the β -cell mass is already reduced by 30–40% [24, 79–81]. This loss of insulin-producing cells has been traditionally viewed as the result of the activation of apoptosis and other cell-death mechanisms. More recently it has been appreciated that metabolic stressors can induce dedifferentiation and/or trans-differentiation. Through dedifferentiation mature β cells can revert to a more progenitor-like stage and lose insulin-secretory capacity. This phenomenon has been extensively documented in experimental models of insulin resistance [156] and also reported in a study in individuals with type 2 diabetes [157]. Under similar metabolic stressful conditions, the β cell can also convert to different hormone-expressing cells, as shown by genetic lineage-tracing analysis carried out in experimental models [158]. Such an accurate analysis is not feasible in humans, yet the finding that these cells may spontaneously trans-differentiate in ductal cells has generated interest in therapeutic reprogramming in diabetes [159].

Whatever the mechanisms involved, the decreased number of cells is unlikely to account for the distinctive defect in insulin secretion that characterizes type 2 diabetes even before the time of diagnosis. Experimental data have shown that, at least in rodents, no disturbances in glucose homeostasis arise provided that the β -cell mass remains >20% [160]. In humans, diabetes

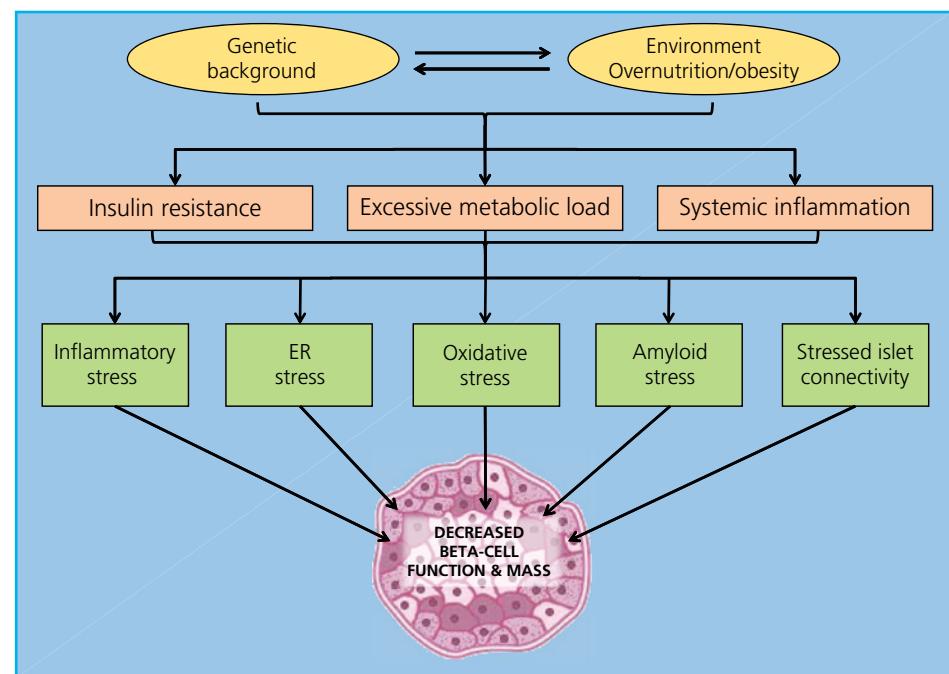

Figure 16.7 Mechanisms of β -cell damage in type 2 diabetes. Environmental factors and genetic backgrounds interact to activate stress processes that contribute to functional abnormalities and also progressive loss/dedifferentiation of β cells. ER, endoplasmic reticulum. Source: Adapted from Halban et al. 2014 [155].

develops when the β -cell area declines by ~65% [161]. The suggestion that the reduction in β -cell mass may not be sufficient *per se* to result in glucose intolerance is supported by the simple observation that a large overlap exists between the β -cell mass of individuals with and without diabetes (Figure 16.8) [162]. Moreover, hemi-pancreatectomy performed in normal individuals for the purpose of pancreas donation is not followed by major disturbances in insulin secretion [163]. The β -cell mass may also be a misleading measurement as one may argue whether it is the number of β cells (or cell area) or the insulin content per cell (and therefore the total insulin content in the pancreas) that is of importance. Relevant to this issue is the finding that the β -cell mass declines with the duration of the disease, although the insulin content per cell tends to increase [162]. The progressive loss of β cells in diabetes is likely to be the consequence of even a mild elevation of plasma glucose levels and concomitant increased secretory demand sustained by insulin resistance, particularly if these mechanisms operate on a genetically predisposed β cell. Consistent with this view are animal experiments showing how a 60% pancreatectomy in dogs does not result in an alteration of insulin secretion unless the plasma glucose levels are modestly increased by intravenous glucose infusion [163]. These results are also in keeping with the few available human studies. In people without diabetes, scheduled for pancreaticoduodenectomy surgery, despite comparable functional mass and fasting glucose and insulin levels at baseline, only pre-existing defects in β -cell function (reduced first-phase insulin secretion and glucose sensitivity) predicted the risk of developing hyperglycaemia after partial pancreatectomy (Figure 16.9), a model of acute β -cell mass reduction, suggesting that these functional alterations could be pivotal to the pathogenesis of type 2 diabetes [77].

This observation does not imply that loss of β -cell mass is less important than β -cell function. In fact, reduction of β -cell mass is the trigger that reveals the pivotal role of first-phase insulin secretion in predicting the appearance of impaired glucose metabolism after partial pancreatectomy [164]. Moreover, in healthy people with no family history of diabetes, a 72-hour glucose infusion resulting in constant elevation of post-absorptive plasma glucose

levels just above 110 mg/dl (6.1 mmol/l) was associated with a potentiation of both first- and second-phase insulin secretion rather than an impairment [93]. In contrast, when normo-tolerant first-degree relatives of individuals with type 2 diabetes were infused with fat emulsions to increase circulating free fatty acid levels, a marked impairment of insulin secretion became apparent [165] (Figure 16.10).

Such a rapid worsening of insulin secretion is unlikely to be due to a sudden reduction in the number of β cells; rather, this is much more congruent with a further impairment of the mechanisms responsible for glucose sensing and insulin response. Finally, the results of bariatric surgery in people with diabetes provide stronger support for the primacy of impaired β -cell function rather than loss of β cells. Even in individuals with type 2 diabetes with long-standing duration of the disease, the surgical procedure is followed by an almost immediate improvement of β -cell function associated with simplification, if not withdrawal, of pharmacological glucose-lowering therapy [166–168]. β -cell dysfunction may also be the result of the loss of islet organization. As mentioned, insulin secretion is pulsatile in nature, with a slow ultradian periodicity (<140 minutes) and a high-frequency periodicity [169]. These oscillations require sophisticated coordination of the secretory activity of the individual β cells dispersed through the ~1 million pancreatic islets present across the pancreatic tissue. Such connectivity recognizes several mechanisms operating in concert, including neural circuits, gap junctions, activity of primary cilia, and paracrine signalling [55]. Recently it has been suggested that, along with genomic imprinting [170], lipotoxicity may disrupt the incretin effect on this connectivity [171], possibly through downregulation of connexin 36, a component of gap junctions [172].

A further element that could contribute to impaired β -cell function has been recently identified in the functional heterogeneity of insulin-producing cells within a single islet. Recent data have indicated the existence of β cells that differ one from another by morphology, distribution, function, connectivity, and gene expression profile [173]. This heterogeneity refers also to islet electrical excitability and connectivity, which is altered early in the natural history of diabetes [174].

In conclusion, the available evidence indicates the existence of multiple abnormalities accounting for β -cell dysfunction in type 2 diabetes that seem affect primarily function more than β -cell mass. The recent appreciation that β -cell dedifferentiation and/or trans-differentiation rather than apoptosis may account for reduced functional β -cell mass [175] speaks against the old concept of β -cell exhaustion and opens to the possibility of recovering proper insulin secretion through reprogramming. This view also fits with the observation that β -cell dedifferentiation enhances degranulation [176] and that experimental insulin granules can be restored through a decrease in blood glucose [177] and insulin secretion recovered even in islets from individuals with type 2 diabetes [178].

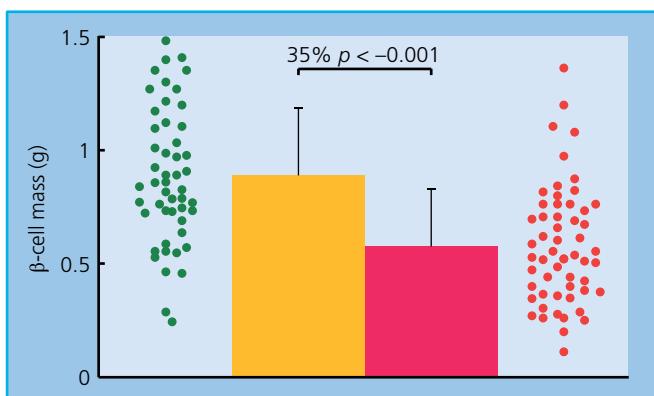

Figure 16.8 β -cell mass in the pancreas of people without (left) and with type 2 diabetes (right). Data are presented for individual values as scatterplots and mean values \pm SD (standard deviation) as columns. Although on average the β -cell mass is about 40% less in people with type 2 diabetes, there is some degree of overlap between the two groups. Source: Rahier et al. 2008 [162]. Conclusion

β -cell dysfunction is an early feature in the natural course of type 2 diabetes and plays a critical role in the development of glucose intolerance and progression of the disease. This distinctive

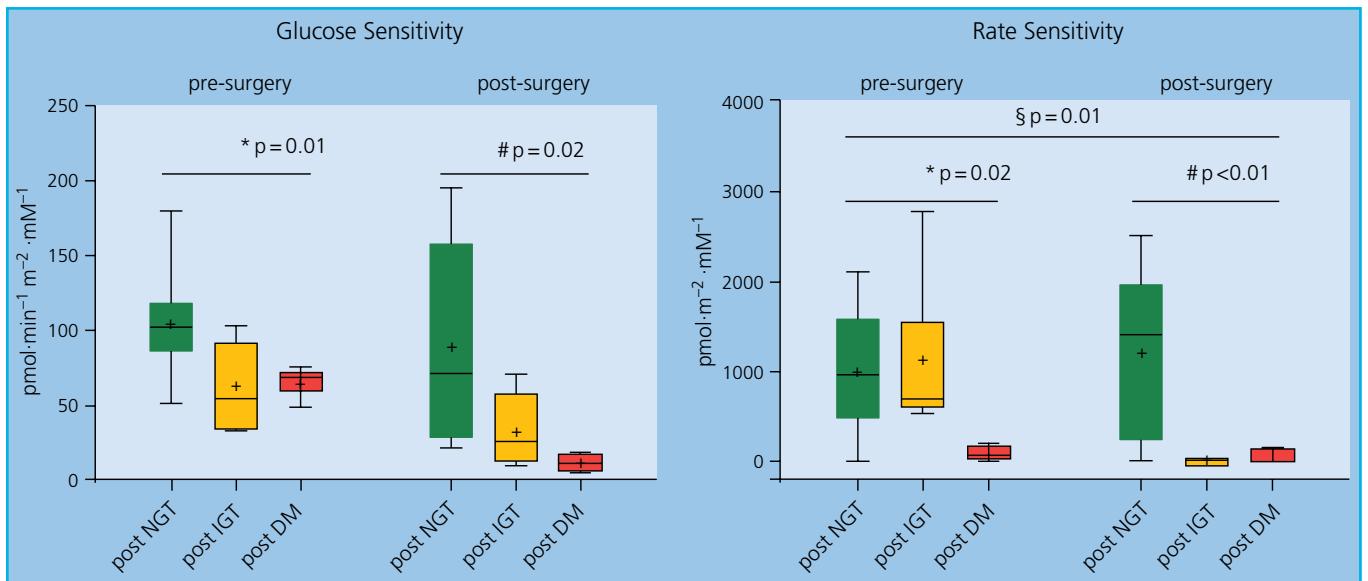

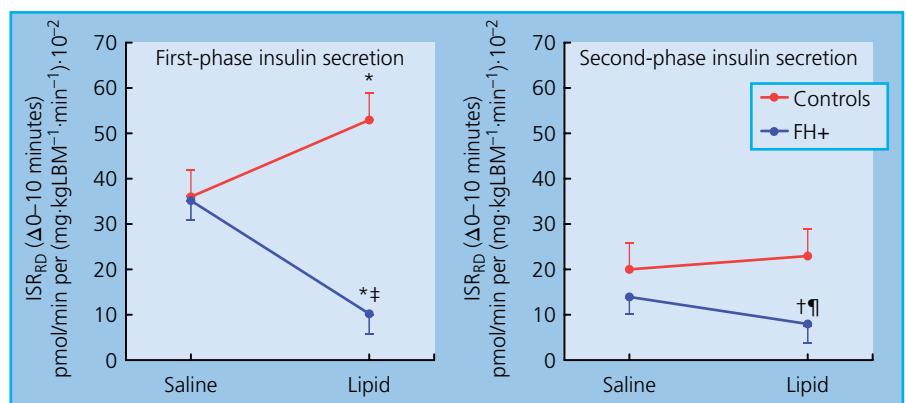

Figure 16.9 Oral glucose tolerance (OGTT)-derived glucose sensitivity (a) and rate sensitivity (b), i.e. measures of β -cell function, before and after partial pancreatectomy, categorized on the basis of glucose tolerance after surgery: normal glucose tolerance (NGT, green box); impaired glucose tolerance (IGT, orange box); and diabetes (DM, red box). The relationship between variables was derived by linear regression analysis. Variables were regressed against glucose tolerance status by

using (a) pre-pancreatectomy values and (b) post-pancreatectomy values adjusted for pre-pancreatectomy values. *p < 0.05 before surgery; #p < 0.05 after surgery; §p < 0.05 before surgery adjusted for after surgery. alteration recognizes a genetic background, with several genetic variants specifically associated with impaired β -cell function and survival. In people predisposed to diabetes and in those with prediabetes, both a reduction in β -cell mass and, to a greater extent, impaired insulin secretion are fully apparent. A minimal increase in fasting plasma glucose levels is already accompanied by a typical loss of first-phase insulin secretion. Obesity, development of hyperglycaemia and dyslipidaemia (in particular increased plasma free fatty acid concentrations), and chronic overstimulation of insulin secretion can activate pathogenic mechanisms (glucolipotoxicity, oxidative stress, inflammation, endoplasmic reticulum stress,

epigenetic modifications, amyloid deposition) that can accelerate the progression of β -cell impairment. The same mechanisms activate apoptosis, dedifferentiation, and possibly trans-differentiation, and alter autophagy. Concomitant insufficient β -cell regeneration or differentiation results in a reduction of functional β -cell mass. This process is a progressive, though potentially reversible, process. Therefore, preservation of β -cell function is key to preventing deterioration of glucose tolerance and development of diabetes. Moreover, tight control of the accelerating factors may slow the progression of the disease and result in more durable glycaemic levels over the years.

Key points

- Insulin resistance is a major factor in the pathogenesis of type 2 diabetes, but it can be also observed in type 1 diabetes.
- Impaired insulin-stimulated muscle glycogen synthesis, due to defects in glucose transport, is the key contributor to whole-body insulin resistance.
- Ectopic fat storage leads to increases in plasma membrane sn-1,2-diacylglycerol content, which in turn activates novel protein kinase Cε in muscle, liver, and adipose tissue, leading to phosphorylation of the insulin receptor on threonine¹¹⁶⁰, causing inhibition of insulin receptor kinase activity and insulin resistance.
- Reduced mitochondrial function is a predisposing factor for ectopic lipid deposition, increased plasma membrane sn-1,2-diacylglycerol content, and insulin resistance.
- Macrophage-induced adipose tissue lipolysis promotes increased hepatic gluconeogenesis, hepatic insulin resistance, and fasting hyperglycaemia in suboptimally managed diabetes by increasing hepatic acetyl-coenzyme A content, which in turn activates pyruvate carboxylase activity and increased glycerol conversion to glucose.

Definition and measurement of insulin resistance in humans

The sensitivity to insulin results from its biological effects in the insulin-responsive tissues, predominantly skeletal muscle, liver, and adipose tissue. Impaired insulin sensitivity, also termed insulin resistance, is generally defined as reduced glucose clearance in skeletal muscle, impaired suppression of glucose production by the liver, and decreased rates of lipolysis in adipose tissue or by decreased combined action on whole-body glucose disposal (Figures 17.1 and 17.2).

In 1936, Himsworth [3] provided the first protocol for the standardized *in vivo* determination of insulin sensitivity from the glycaemic response on intravenous insulin application. Decades later, the hyperinsulinaemic-euglycaemic clamp test [4–6] became the gold standard for measuring whole-body insulin sensitivity *in vivo* and for identifying insulin-resistant people [7, 8]. This steady-state method relies on constant insulin and glucose concentrations, which disrupt the physiological feedback loop between blood glucose concentrations and insulin secretion. The glucose infusion rates required to maintain a defined level of glycaemia will then reflect whole-body insulin sensitivity, given as the *M*-value [5]. Combined with other techniques, including indirect calorimetry,

isotopic tracer dilution, and nuclear magnetic resonance (NMR) spectroscopy of muscle, liver, and brain, the clamp allows the assessment of oxidative and non-oxidative glucose metabolism, systemic, and even tissue-specific fluxes of glucose and other metabolites under *in vivo* conditions. In contrast to the steady-state clamp test, other techniques such as the intravenous [9] or oral [10] glucose tolerance tests [7, 8] describe parameters of insulin action, such as the *S_i* or oral glucose insulin sensitivity (OGIS) values, from modelling of the dynamic changes of plasma glucose and insulin concentrations over time. These tests can also provide measures of insulin secretion and kinetics during the same experiment.

As these techniques are time consuming and laborious and require experienced personnel, simpler tests have been developed for assessing insulin sensitivity in epidemiological studies. The commonest indices, homeostasis model assessment (HOMA-IR, HOMA-B) [11] and QUICKI [12], are calculated from fasting plasma glucose and insulin or C-peptide concentrations [13]. The general limitation of this approach results from the fact that the liver is responsible for providing fasting plasma glucose [14]. Under these conditions, 60% of glucose is utilized in non-insulin-dependent tissues, such as the brain, and to a lesser extent in insulin-sensitive tissues, such as muscle and liver [15]. The insulin resistance indices obtained during fasting therefore do not correlate closely with clamp-derived glucose disposal [16, 17]. Finally, these

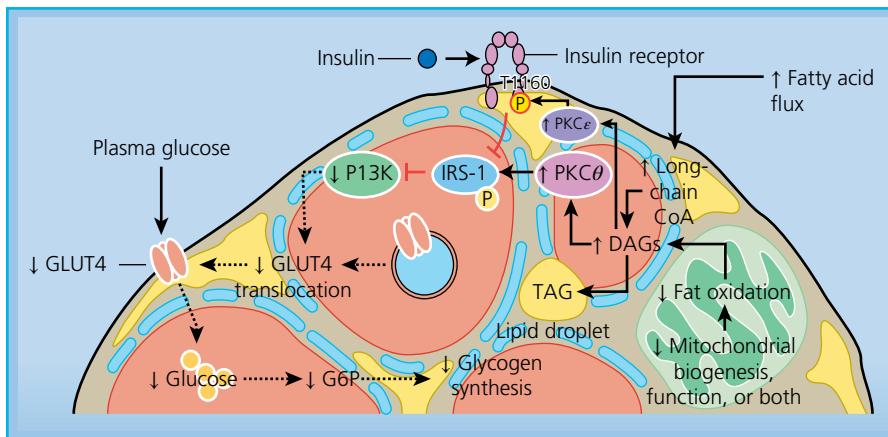

Figure 17.1 Cellular mechanism of insulin resistance in human skeletal muscle. Augmented lipid availability, mainly increased fatty acid flux, raises the intramyocellular pool of the long-chain fatty acyl (CoA) pool, which fuels mitochondrial oxidation or serves to synthesize diacylglycerols (DAGs) for storage as triglyceride (TAG) lipid droplets. When fatty acid delivery and uptake exceed the rates of mitochondrial long-chain fatty acyl-CoA oxidation and incorporation of DAGs into TAGs, the intramyocellular DAG content transiently or chronically increases. Specifically, increases in plasma membrane sn-1,2-DAGs lead to activation of novel protein kinase C (nPKC) isoforms (PKC ϵ and PKC θ). Translocation of the PKC ϵ to the membrane leads to phosphorylation of the insulin receptor on threonine¹¹⁶⁰

(T1160), leading to inhibition of insulin receptor kinase (IRK) activity, whereas activation of PKC θ leads to increased serine phosphorylation of insulin receptor substrate 1 (IRS-1) on critical sites (e.g. Ser¹¹⁰¹), which in turn blocks insulin-stimulated tyrosine phosphorylation of IRS-1 and the binding and activation of phosphatidylinositol 3-kinase (PI3K). Both of these events result in reduced insulin-stimulated recruitment of glucose transporter type 4 (GLUT4) units to the membrane, leading to impaired insulin-stimulated glucose uptake and phosphorylation to glucose-6-phosphate and ultimately decreased insulin-stimulated glycogen synthesis. Figure 17.2 Cellular mechanism of insulin resistance in the human liver. An imbalance of intrahepatocellular fluxes gives rise to increases in plasma membrane sn-1,2-diacylglycerols (sn-1,2-DAGs), when DAG synthesis, from both fatty acid re-esterification and de novo lipogenesis, exceeds the rates of mitochondrial oxidation of long-chain fatty acyl-coenzyme A (CoA) and/or the rates of sn-1,2-DAG incorporation into triglycerides (TAGs) and lipid droplets. Increases in plasma membrane sn-1,2-DAGs leads to translocation and activation of protein kinase C ϵ (PKC ϵ) to the plasma membrane, where it binds to the insulin receptor and phosphorylates it on threonine¹¹⁶⁰ (threonine¹¹⁵⁰ in mice), which in turn leads to inhibition of IRK activity and downstream insulin signalling events. In turn, phosphorylation of glycogen synthase kinase 3 (GSK3) increases, while that of

forkhead box subgroup O (FOXO) decreases. This results in inhibition of glycogen synthase activity and thereby lowering insulin-stimulated glycogen storage, and in FOXO-mediated gene transcription of the gluconeogenic enzymes (e.g. phosphoenolpyruvate carboxykinase [PEP-CK] and glucose-6-phosphate), with decreased insulin suppression of hepatic gluconeogenesis. It is also important to note that untargeted phosphoproteomic studies have identified many other proteins that are phosphorylated by activation of PKC ϵ besides the insulin receptor, such as p70S6K, which will also cause insulin resistance downstream of the insulin receptor [2]. indices can be used for describing insulin sensitivity in recent-onset diabetes [18], but may not be valid in long-standing diabetes when the physiological relationship between circulating glucose and insulin or C-peptide is disrupted.

Insulin resistance as a risk factor for type 2 diabetes

Insulin resistance may occur independently of inadequate insulin secretion and be a prerequisite for incident type 2 diabetes [19–22]. The direct evidence for a time-dependent association between insulin sensitivity and deterioration of glucose tolerance preceding type 2 diabetes comes from comparison of population trajectories of fasting and post-glucose challenge plasma glucose concentrations with HOMA-S and insulin secretion (HOMA-B) in people developing or remaining free of diabetes in the longitudinal Whitehall II study [23]. This study found that individuals had 29% lower HOMA-S but 13% greater HOMA-B values at 13 years before the onset of diabetes. HOMA-S decreased linearly until about five years before diagnosis and with an even steeper slope during the last five years prior to diagnosis. Thus, insulin resistance represents an early abnormality, which is compensated by augmented β -cell function for a long time before the insulin–glucose feedback loop fails. Insulin resistance not only predicts type 2 diabetes, but also correlates with cardiovascular disease and outcomes [24, 25].

The most important factors predicting type 2 diabetes are male sex, increasing age, overweight, and obesity [26]. Insulin resistance is frequent in people with the so-called metabolic syndrome, which, in addition to visceral obesity, comprises dyslipidaemia, hypertension, and dysglycaemia. Hyperuricaemia, arteriosclerosis, microalbuminuria, platelet hyperaggregation, and antifibrinolysis, sleep apnoea, and male hypogonadism have also been associated with this syndrome. The risk of type 2 diabetes is also markedly higher in first-degree relatives of individuals with type 2 diabetes and in women with a history of gestational diabetes mellitus or polycystic ovary syndrome, all of whom are mostly insulin resistant [16, 17, 27–30]. These associations raise the question of whether chronic insulin resistance represents an inherited or an acquired abnormality. Despite the fact that a family history of type 2 diabetes raises the risk of type 2 diabetes in relatives, even the combination of all currently known genes associated with diabetes adds little to the prediction of type 2 diabetes based on sex, age, and body mass index [26]. Marked differences exist at the clinical onset of diabetes: clustering based on five variables including HOMA-IR identified, aside from autoimmune diabetes, four endotypes of type 2 diabetes, with one characterized by severe insulin resistance [18, 30]. At diagnosis, this endotype also shows the most pronounced liver steatosis and low-grade inflammation, whereas the other endotypes exhibit increasing insulin resistance over the next five years [18].

Dietary and physical activity interventions that improve insulin resistance markedly reduce the incidence of type 2 diabetes [31], underscoring the predominant role of lifestyle in both the pathogenesis of insulin resistance and the progression of type 2 diabetes. Several metabolic factors related to lifestyle associate with or predict insulin resistance and type 2 diabetes. These factors are mainly related to lipid metabolism, such as plasma concentration of non-esterified fatty acids [32], serum triacylglyceride-to-serum high-density lipoprotein (TAG/HDL-C) [33, 34], and ectopic fat content in skeletal muscle (intramyocellular triacylglycerols [TAGs])

[35–37] or in the liver (hepatocellular lipid content) [38, 39]. In addition, red meat intake was among the best predictors of type 2 diabetes in a large epidemiological study [40] and plasma concentrations of amino acids also predict type 2 diabetes [41].

Altered secretion patterns of cytokines, mainly derived from adipose tissue, and elevation of circulating pro-inflammatory markers such as C-reactive protein may predict insulin resistance and type 2 diabetes [42, 43]. Adiponectin is the only anti-inflammatory cytokine with lower circulating levels before the onset of type 2 diabetes [44], while concentrations of others, such as interleukin-1 receptor antagonist (IL-1RA), transforming growth factor β 1 (TGF- β 1) and growth differentiation factor-15 (GDF-15) are increased [45] and indicate the presence of a compensatory, but eventually futile, counter-regulation of pro-inflammatory stimuli. Although all metabolic and inflammation-related variables circulate systemically and may cause effects in several tissues simultaneously, insulin resistance may sequentially affect certain insulin-responsive tissues, such as skeletal muscle, liver, and adipose tissue.

Insulin resistance in skeletal muscle

^{13}C -NMR spectroscopy permitted for the first time non-invasive, direct assessment of rates of insulin-stimulated muscle glycogen synthesis *in vivo*. Using this approach, it was found that muscle glycogen synthesis accounts for ~90% of insulin-stimulated whole-body glucose disposal and for virtually all the non-oxidative glucose disposal in healthy insulin-sensitive humans [46]. People with type 2 diabetes exhibit a 60% reduction in insulin-stimulated muscle glycogen synthesis, which represents the main abnormality underlying their insulin resistance [46, 47]. Similarly, after the ingestion of mixed meals, the increase in muscle glycogen synthesis was ~30% lower in people with type 2 diabetes despite doubled serum insulin concentrations compared with insulin-sensitive individuals [48, 49]. Applying combined $^{13}\text{C}/^{31}\text{P}$ NMR spectroscopy to directly measure the time course of intracellular concentrations of key metabolites in the pathway of muscle glycogen synthesis (intramyocellular glucose, glucose-6-phosphate, and glycogen) revealed diminished increases in glucose-6-phosphate [50] and intramyocellular glucose concentrations [47] in skeletal muscle of type 2 diabetes during hyperinsulinaemia (Figure 17.1). This indicates that an abnormality in insulin-stimulated glucose transport via glucose transporter 4 (GLUT4) is the main abnormality responsible for muscle insulin resistance in people with type 2 diabetes and/or obesity and in insulin-resistant first-degree relatives of people with type 2 diabetes [51]. Further studies to delineate the mechanism by which insulin resistance affects recruitment of GLUT4 have indicated that upstream defects in the insulin signalling cascade are responsible for the impaired GLUT4 translocation [1, 52].

It has been suggested previously that hyperglycaemia may cause these abnormalities by a mechanism summarized as *glucose toxicity* [53, 54], which seems to be supported by similar impairments of insulin-stimulated glycogen synthesis and glucose-6-phosphate increases in skeletal muscle in individuals with suboptimally managed type 1 diabetes [55, 56]. However, since insulin-resistant but normoglycaemic humans, such as lean relatives of people with obesity or older people with type 2 diabetes exhibit identical effects, mechanisms other than glucose toxicity have to explain the insulin resistance in the skeletal muscle of these groups [51, 57–59].

Most insulin-resistant but normoglycaemic humans feature dyslipidaemia with elevated very low-density lipoproteins (VLDLs), TAGs, and/or fatty acids, which also predict not only type 2 diabetes [32, 60–62] but also cardiovascular mortality [63]. Excess lipid storage in the form of obesity has long been associated with insulin resistance, but ¹H-NMR studies provided evidence for an even stronger relationship between intramuscular [64] and intramyocellular TAG content and muscle insulin resistance than for body fat content [37, 64–66]. Intramyocellular TAG concentrations can be measured non-invasively by ¹H NMR spectroscopy and increased concentrations have been termed ectopic lipid accumulation or metabolic obesity. The observation of augmented ectopic lipid deposition in insulin-resistant states infers that intracellular TAGs or lipid metabolites could mediate the effect of circulating lipids on insulin action (Figure 17.1). From early pre-clinical studies, Randle explained the impaired glucose metabolism in type 2 diabetes by an interaction with fatty acids, termed the *glucose-fatty acid cycle* [67]. This hypothesis postulated that fatty acid oxidation first raises the mitochondrial concentration ratio of acetyl-coenzyme A (acetyl-CoA)/CoA, which would inhibit the pyruvate dehydrogenase (PDH) complex. The subsequent rise in citrate would inhibit phosphofructokinase-1 and raise glucose-6-phosphate, which would then inhibit hexokinase and finally increase intracellular glucose concentrations and reduce muscle glucose uptake. In contrast, short-term elevations of plasma TAGs and fatty acids resulted in marked muscle insulin resistance, but a blunted rise in intramyocellular glucose and glucose-6-phosphate, as measured using ¹³C/³¹P NMR spectroscopy during insulin stimulation in healthy humans. Lipid-induced muscle insulin resistance in humans thereby results from reduction of insulin-stimulated glucose transport into the muscle cells, with subsequently impaired glucose phosphorylation and decreased insulin-stimulated glycogen synthesis [52, 68, 69] (Figure 17.1). Thus, lipids cause insulin resistance in humans via direct inhibition of glucose transport, but not via inhibition of the PDH complex [52, 70, 71]. Some studies [72, 73], but not others [74], suggest that lipid-induced insulin resistance may be more pronounced in men than in women, which would support the known greater diabetes risk for men.

Increases in intramyocellular TAGs are an even better predictor of insulin resistance in muscle and liver than circulating plasma fatty acids [37]. Indeed, lipid-induced insulin resistance is reflected by impaired insulin signalling via reduced tyrosine phosphorylation of insulin receptor substrate-1 (IRS-1) [52, 75], IRS-1-dependent phosphatidylinositol 3-kinase (PI3K) activation, and serine phosphorylation of Akt [76]. This could result from accumulation of intramyocellular long-chain acyl-CoA (LCFA-CoA), diacylglycerols (DAGs), or ceramides [77] (Figure 17.1). Studies on transgenic and knockout animal models provide compelling evidence that fatty acid elevation increases intramyocellular LCFA-CoA, CoA, and DAGs, but not ceramide content, along with stimulation of TAG synthesis by DAG O-acyltransferase-1 (DGAT-1) and of protein kinase C-θ (PKCθ), with subsequent serine phosphorylation of IRS-1 via the serine-threonine kinase cascade [78, 79]. However, studies employing other animal models showed that the ceramide pathway could also be involved in lipid-induced insulin resistance [80–82]. Several studies in humans reported conflicting results, likely due to differences in the design, cohorts, and analytical methods [73, 83, 84]. A recent study shed more light on the time course of events of lipid-induced insulin resistance by performing serial biopsies in humans during lipid infusion and comparing the results obtained from biopsies from

insulin-resistant individuals with obesity or type 2 diabetes [74]. Lipid infusion resulted in a transient increase in intramyocellular DAGs, followed by activation of PKCθ and increased phosphorylation of the serine¹¹⁰¹ residues of IRS-1, with subsequent inhibition of insulin signalling and insulin-stimulated muscle glucose disposal (Figure 17.1). Similar increases in myocellular DAGs and PKCθ activation were found in individuals with type 2 diabetes and obesity without lipid infusion. DAG subspecies containing C₁₈-acyl residues correlated best with insulin resistance in all conditions of insulin resistance, whereas total ceramides and their subspecies were not affected either by lipid infusion or in people with the insulin resistance of obesity and type 2 diabetes [74].

In addition to lipids, dietary excess of protein has been related to insulin resistance [85] and circulating branched-chain amino acids predict type 2 diabetes [86]. By analogy with fatty acids, short-term elevation of plasma amino acids reduces insulin-stimulated glucose-6-phosphate and glycogen synthesis [85] by activating the mammalian target of the rapamycin (mTOR)/p70 S60 kinase pathway, with subsequent serine phosphorylation of IRS-1 [87, 88]. This pathway would further favour ectopic lipid storage [89].

In conclusion, the lipid-induced insulin resistance or lipotoxicity hypothesis proposes that in the absence of a balance between fatty acid delivery and muscle TAG synthesis via DGAT-1 as well as oxidation in the mitochondria, lipotoxic species such as *sn*-1,2-DAGs will accumulate in the plasma membrane and activate PKCε/PKCθ in skeletal muscle [90]. This in turn will inhibit the insulin receptor kinase (IRK) activity (PKCε) and IRS-1-associated PI3K (PKCθ), leading to impaired insulin signalling and impaired insulin-stimulated glucose uptake. Any mechanism by which lipid delivery to the muscle is reduced, lipid oxidation is increased, and/or TAG synthesis is stimulated will likely reduce LCFA-CoA and plasma membrane *sn*-1,2-DAG concentrations and prevent lipid-induced muscle insulin resistance.

Consequently, decreases in muscle lipid oxidation could serve as another contributor to lipid accumulation in the skeletal muscle and thereby insulin resistance. Flux rates through muscle ATP synthase, reflecting basal mitochondrial phosphorylation, are ~40% lower in lean insulin-resistant first-degree relatives of individuals with type 2 diabetes than in insulin-sensitive but otherwise matched people [91]. During insulin stimulation, muscle ATP synthase flux doubled in insulin-sensitive humans, but was almost abolished in the offspring of people with type 2 diabetes [55]. Similarly, individuals with type 2 diabetes, but without obesity, featured ~25% lower mitochondrial phosphorylation rates in the basal (fasting) state [59, 92] and no increase during insulin stimulation, even in the presence of increased availability of glucose as a substrate [59, 92]. This may be due to reduced capacities of the electron-transport chain and/or the phosphorylation system [92] and/or reduced insulin-stimulated phosphate transport into the myocytes.

Ageing, an important risk factor of type 2 diabetes, associates with impaired biogenesis and accelerated apoptosis of mitochondria [93]. Non-obese older humans are not only frequently insulin resistant, but also feature higher intramyocellular TAG contents and ~30–40% lower rates of both muscle ATP synthase flux and tricarboxylic acid (TCA) cycle oxidation [94, 95]. Hence age-associated reductions in mitochondrial function may predispose older people to ectopic lipid accumulation and muscle insulin resistance [94], possibly owing to damage by accumulating reactive oxygen species (ROS). In line with this contention, similar reductions were reported for neural mitochondrial activity in healthy older individuals [96]. The hypothesis of age-associated

ROS-induced reductions in mitochondrial function contributing to age-associated muscle insulin resistance was further supported by findings in transgenic mice with overexpression of human catalase targeted to the mitochondria (MCAT mice) [97]. These mice were protected from age-associated abnormalities in muscle mitochondrial function and DAG/PKC θ -induced muscle insulin resistance, along with reduced mitochondrial oxidative damage, preserved muscle ATP synthesis, and adenosine 5'-monophosphate-activated protein kinase (AMPK)-induced mitochondrial biogenesis [98, 99]. Moreover, measurements of basal and insulin-stimulated rates of muscle PDH (V_{PDH}) flux relative to citrate synthase flux (V_{CS}) employing [$1-^{13}\text{C}$] glucose incorporation into glutamate relative to alanine in muscle biopsies from healthy, lean, old, and young humans revealed a blunted rise of insulin-stimulated V_{PDH}/V_{CS} fluxes in the old people, along with 25% lower muscle glucose uptake and 70% higher accumulation of intramyocellular TAGs [100]. These findings indicate a marked inability of mitochondria to switch from lipid to glucose oxidation during insulin stimulation. Recent assessments of V_{PDH}/V_{CS} ratios in soleus or quadriceps muscles revealed that mitochondrial substrate preference, often referred to as *metabolic inflexibility*, is not essential for the pathogenesis of insulin resistance in humans [90]. Taken together, combined acquired and age-associated reductions in features of mitochondrial function may promote intramyocellular lipid accumulation and insulin resistance in type 2 diabetes.

In addition to ageing *per se*, other metabolic factors such as hyperglycaemia and dyslipidaemia may impair mitochondrial function and thereby contribute to muscle insulin resistance. In this context, insulin-resistant individuals with type 1 diabetes have lower insulin-stimulated ATP synthase flux, which negatively relates to glucometabolic regulation [56]. Short-term lipid infusion also leads to lower muscle ATP synthase flux, but only on the onset of insulin resistance in healthy humans [101]. The reduced rates of insulin-stimulated ATP synthase flux were associated with impaired insulin-stimulated increases in muscle glucose-6-phosphate concentrations due to lower insulin-stimulated glucose uptake [101, 102]. Lipid lowering via inhibition of lipoprotein lipase (LPL) by acipimox improves insulin resistance independently of changes in oxidative capacity in type 2 diabetes [103]. These findings suggest that glucose- and lipid-induced abnormalities in muscle mitochondrial function are not primary events in the development of insulin resistance in common type 2 diabetes.

A series of studies addressed the role of mitochondrial function independently of age and glycaemic levels [90, 104]. Young, lean, but severely insulin-resistant first-degree relatives of people with type 2 diabetes were identified with 30% lower basal rates of muscle ATP synthase and TCA cycle fluxes compared to age- and body mass-matched insulin-sensitive individuals [90]. This abnormality of mitochondrial oxidative phosphorylation was found in the presence of 38% lower mitochondrial density, indicating that the reduction in mitochondrial function may be attributed to lower muscle mitochondrial content [105]. In contrast to previous reports on skeletal muscle of people with type 2 diabetes [106, 107], this was not explained by reduced expression of the peroxisome proliferator-activated receptor (PPAR) γ -coactivator 1 α (PGC1 α) [105], a key regulator of mitochondrial biogenesis. Likewise, in another cohort of first-degree relatives of individuals with type 2 diabetes, the stimulatory effect of exercise training on insulin sensitivity and ATP synthesis did not depend on common single-nucleotide polymorphisms (SNPs) of PGC1 α , but was modified by a G/G-SNP of the gene encoding NADH

dehydrogenase (ubiquinone) 1 β subcomplex (NDUFB6), a component of complex I of the mitochondrial respiratory chain [108]. The finding that the insulin resistance in relatives of individuals with type 2 diabetes is related to lower fasting and insulin-stimulated rates of muscle ATP synthesis in a similar fashion as in people with overt type 2 diabetes strongly underlines the role of inherited factors in the pathogenesis of insulin resistance and type 2 diabetes [59, 109]. Taken together, at least in this cohort of insulin-resistant first-degree relatives of individuals with type 2 diabetes, it is likely that a reduction in mitochondrial content, due to reduced mitochondrial biogenesis, is responsible for the reduced mitochondrial oxidative and phosphorylation activity and may be an acquired abnormality [110, 111]. Nevertheless, given the key role of mitochondrial activity in the regulation of fat metabolism in muscle cells [112–116], these data suggest that the reduced mitochondrial function may be an important predisposing factor that promotes plasma membrane *sn*-1,2-DAG accumulation in muscle cells and insulin resistance in muscle among people with insulin resistance whose parents have type 2 diabetes.

Insulin resistance in the liver

The liver plays a key role in the transition from the fasted to the fed state by its unique ability to switch rapidly from a glucose-producing organ to a glucose-storing organ. After ingestion of a mixed meal, the liver suppresses glucose production and takes up glucose for storage in the form of glycogen [117, 118]. In insulin-resistant individuals with type 2 diabetes, the excessive post-prandial hyperglycaemia results from impaired suppression of glucose production along with ~45% lower hepatic glycogen accumulation than in healthy people [49]. This cannot be explained simply by the impaired prandial insulin secretion, but rather results from other mechanisms such as defective insulin-stimulated flux through glycogen synthase, because this abnormality persists during hyperinsulinaemic-hyperglycaemic clamps, which maximally favour glycogen synthesis [49]. Insulin-mediated hepatic glycogen synthesis correlates inversely with ectopic lipid content in the liver not only in people with type 2 diabetes but also in those without, in line with a close link between hepatic lipid content and hepatic insulin resistance [49, 95]. Hepatic lipid accumulation, previously termed steatosis, is another form of ectopic lipid accumulation and is now included in the definition of non-alcoholic fatty liver disease (NAFLD). Steatosis relates closely to whole-body insulin resistance and is present in obesity, the metabolic syndrome, and women with a history of gestational diabetes or with type 2 diabetes [119, 120]. Although it has been discussed that NAFLD develops in the setting of or secondary to prevailing insulin resistance [121, 122], increased lipid availability *per se* could also induce hepatic TAG storage and insulin resistance [38]. This hypothesis is supported by human studies where short-term lipid infusions caused hepatic insulin resistance, as reflected by impaired insulin-mediated suppression of glucose production [123]. Animal models indicate that lipid intermediates such as plasma membrane *sn*-1,2-DAGs also inhibit insulin signalling in the liver, similarly to the mechanism of lipid-induced insulin resistance in skeletal muscle [1, 78, 84] (Figure 17.2). One study in particular, inducing selective hepatic steatosis in rats by a

three-day high-fat diet, found that hepatic insulin resistance corresponds to impaired tyrosine phosphorylation of IRS-2 and increased activities of PKC ϵ and c-Jun N-terminal kinase (JNK) 1, which act as serine/threonine kinases and can phosphorylate serine residues of IRS-2 [124]. One study of human liver biopsies detected increases in some PKC isoforms (ϵ , α , and ζ) in people with type 2 diabetes and obesity [125]. Another human liver biopsy studied found that stearoyl-CoA desaturase 1 (SCD1) activity and DAGs, but not ceramides, positively correlated with hepatic fat content [126]. Recent intraoperative liver biopsy studies provided evidence that increases in hepatic DAG content [127, 128] and PKC ϵ activity [127] correlate negatively with hepatic insulin sensitivity in individuals with NAFLD and obesity, thereby underlining a critical role of the DAG/PKC ϵ pathway also in hepatic insulin resistance in humans (Figure 17.2). More recently Petersen et al. demonstrated that PKC ϵ -induced phosphorylation of the insulin receptor on threonine¹¹⁶⁰ (threonine¹¹⁵⁰ in mice) was necessary for lipid-induced hepatic insulin resistance [129], and using a cell fraction method Lyu et al. demonstrated that it was the plasma membrane-bound *sn*-1,2-diacylglycerols that were responsible for the activation of PKC ϵ and that PKC ϵ is both necessary and sufficient for mediating lipid-induced hepatic insulin resistance [130]. This study also found that hepatic ceramide content did not consistently track with hepatic insulin resistance, suggesting that ceramides, like triglycerides, do not mediate hepatic insulin resistance.

Although NAFLD is most often associated with obesity, there are important exceptions where NAFLD and hepatic insulin resistance coexist in lean individuals [131, 132]. Healthy, young, lean Asian Indian men have a markedly greater risk of hepatic steatosis associated with hepatic insulin resistance than men of other ethnic groups [133]. Two polymorphisms (rs2854116 and rs2854117) in the apolipoprotein C3 (*ApoC3*) gene seem to predispose these individuals and lean men of Asian ethnic backgrounds to NAFLD and insulin resistance [134]. In these carriers of the APOC3 variant alleles (C-482T, T-455C, or both), higher fasting plasma apolipoprotein C3 and plasma TAG concentrations are 30% and 60% higher, respectively, than in wild-type homozygous humans. These findings can be explained in part by the inhibitory effect of apolipoprotein C3 on LPL activity, resulting in reduced plasma triglyceride clearance, leading to increases in post-prandial hypertriglyceridemia and increased post-prandial chylomicron remnants. This mechanism was validated genetically in transgenic mice with hepatic overexpression of human *ApoC3*, which were more prone to develop hepatic steatosis than their wild-type littermate counterparts when fed a high-fat diet [135]. This *ApoC3* gene–environment interaction has only been observed in male individuals, likely reflecting a protective effect of oestradiol on inhibition of LPL activity [136]. Furthermore, this *ApoC3* gene–environment interaction is not observed in individuals with obesity, in whom this relatively subtle gene–environment effect to promote hepatic steatosis in lean individuals is masked by the dominant effect of obesity and insulin resistance to promote NAFLD [137].

A genome-wide association study identified a missense mutation I148M within patatin-like phospholipase domain containing 3 (PNPLA3/adiponutrin) that is more prevalent in Hispanic individuals and associates with NAFLD [138]. The rs738409 polymorphism of PNPLA3 also leads to impaired TAG hydrolysis [139]. Although the association between this polymorphism and hepatic steatosis has been reproduced in other populations, there is no association with insulin resistance, with the limitation of these

studies that all the participants had obesity and were likely insulin resistant [140]. Individuals with the severe insulin-resistant diabetes endotype more likely carry the risk allele of this PNPLA3 polymorphism [141]. These individuals also feature markedly higher adipose tissue insulin resistance, suggesting a role of PNPLA3 for adipose tissue function [141]. Finally, alterations in other genes that regulate lipogenesis leading to lipodystrophy (e.g. *AGPAT2*, *PPAR γ*) [142] or lipolysis (e.g. perilipin, *ATGL*, *CGI-58*) [143] may also lead to ectopic lipid deposition and insulin resistance. Hence there is growing evidence that gene–environment interactions can predispose even lean individuals to hepatic insulin resistance, NAFLD, and type 2 diabetes. There are a few exceptions in which ectopic lipid content dissociates from insulin resistance. A mutation in the *ABHD5* gene with consecutive deficiency in the protein comparative gene identification 58 (CGI-58) leads to Chanarin–Dorfman syndrome [94, 96, 97], which is characterized by excessive lipid deposition in the liver, muscle weakness, and central nervous symptoms in the absence of insulin resistance. In this condition, DAGs are restricted to storage in lipid droplets (and not the plasma membrane) and thereby cannot promote PKC ϵ translocation to the plasma membrane, which is required for its binding to the insulin receptor and inhibition of IRK activity/insulin signalling in the liver.

Similar to skeletal muscle, people with type 2 diabetes but without obesity also show reductions in hepatocellular ATP concentrations as measured with non-invasive ³¹P NMR methods [144] compared with age-matched and young people without diabetes [145]. Hepatocellular ATP and inorganic phosphate levels differently change in type 2 diabetes and type 1 diabetes over the initial five years after clinical diabetes onset [146]. Even with adjustments for liver fat content, hepatic ATP concentrations correlated closely with hepatic insulin sensitivity, but not with whole-body insulin sensitivity. People with type 2 diabetes but without obesity also had 40% lower flux rates through hepatic ATP synthase, which relate to both peripheral and hepatic insulin sensitivity but negatively with body fat content [147]. Nevertheless, other features of hepatic mitochondrial function are not uniformly impaired in insulin-resistant humans [148–150]. Using high-resolution respirometry to quantify directly mitochondrial respiration in liver biopsies, it was found that, despite similar mitochondrial contents, people with obesity with or without steatosis had 4.3–5.0-fold higher maximal respiration rates in isolated mitochondria than lean people, whereas people with non-alcoholic steatohepatitis (NASH) featured 30–40% lower maximal respiration associated with greater hepatic insulin resistance [151] (Figure 17.3). These individuals also had higher degrees of mitochondrial uncoupling and leaking activity, together with augmented hepatic oxidative stress paralleled by reduced antioxidant defence capacity and increased inflammatory response. These findings suggest an adaptation of the liver at early stages of obesity-related insulin resistance, which is subsequently lost during the progression of NAFLD and insulin resistance. In line with this hypothesis, insulin-resistant individuals with steatosis and obesity had a sixfold greater increase in hepatic ATP concentrations than in lean insulin-sensitive individuals after ingestion of a single mixed meal [152].

Taken together, these findings suggest that loss of adaptation of hepatic energy metabolism to increased lipid flux from large visceral adipose tissue depots and/or adaptation-related hepatic oxidative stress could cause hepatic lipid accumulation and subsequent hepatic insulin resistance in the context of type 2 diabetes.

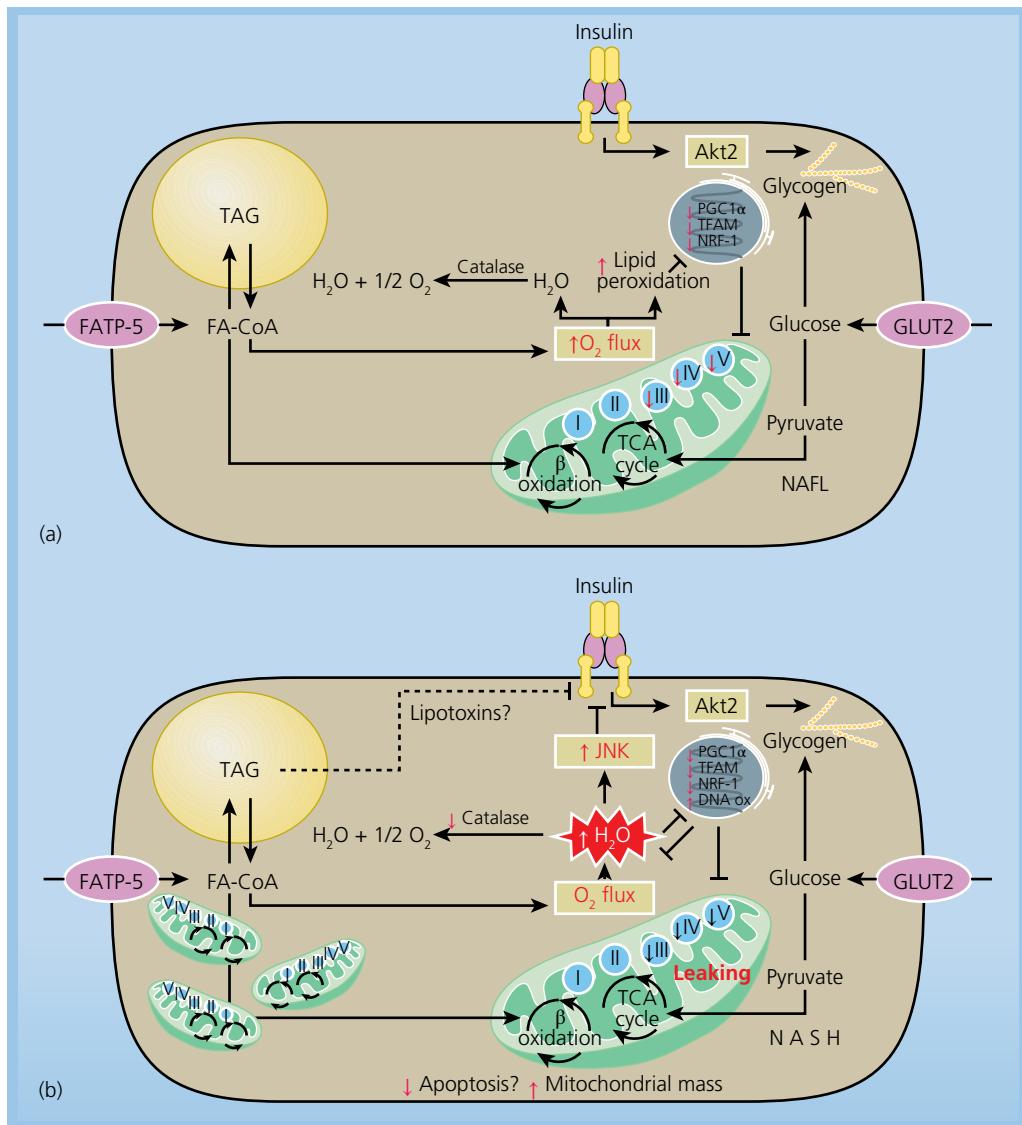

Figure 17.3 Hypothesis of adaptation of hepatic energy metabolism in the pathogenesis of non-alcoholic fatty liver disease (NAFLD) and progression of hepatic insulin resistance. (a) In states of obesity, increased fatty acid delivery upregulates hepatic mitochondrial oxidative capacity, which prevents excessive storage of triacylglycerols (TAGs), but promotes the accumulation of reactive oxygen species and lipid peroxides, which are scavenged by hepatic catalase activity. (b) During the

development of non-alcoholic fatty liver disease (NAFLD), the efficiency of mitochondrial coupling fails, which accelerates the generation of hydrogen peroxide (H_2O_2) in the face of decreasing catalase activity. Finally, oxidative stress decreases mitochondrial biogenesis, but increases leakage of mitochondria and activates c-Jun N-terminal kinase (JNK), which drives cellular inflammation and progression to steatohepatitis (NASH). Insulin resistance in adipose tissue

Adipose tissue is highly sensitive to the action of insulin on lipolysis in healthy humans, but not in states of insulin resistance and type 2 diabetes [153–155], which are also characterized by elevations in plasma concentrations of TAGs and fatty acids. These alterations will contribute to lipid-mediated effects on insulin sensitivity in other organs such as liver and skeletal muscle. By contrast, obesity and the metabolic syndrome have been linked to a state of so-called *subclinical inflammation*, arising from adipose tissue and leading to an imbalance of the secretion of adipocytokines with anti-inflammatory and insulin-sensitizing properties such as adiponectin and proinflammatory cytokines such as leptin, tumour necrosis factor- α , and interleukin-6 (IL-6), and many

others [156] (Figure 17.4). The latter adipocytokines may cause insulin resistance in liver and muscle by stimulating increased serine phosphorylation of IRS1 by activation of JNK1 and activation of I κ kinase β (IKK β)-nuclear factor- κ B (NF- κ B) kinase β , both of which are involved in chronic insulin resistance. Anti-inflammatory treatment, either acutely with acetyl salicylate or chronically with salsalate, promotes a modest improvement in glycaemic levels and insulin resistance in people with type 2 diabetes and obesity [157,158], indicating that activation of inflammatory pathways can contribute to obesity-associated insulin resistance and hyperglycaemia in type 2 diabetes. Endoplasmic reticulum stress may serve as another cause of cellular inflammation and insulin resistance via JNK activation [159,160]. In humans, weight loss following bariatric surgery

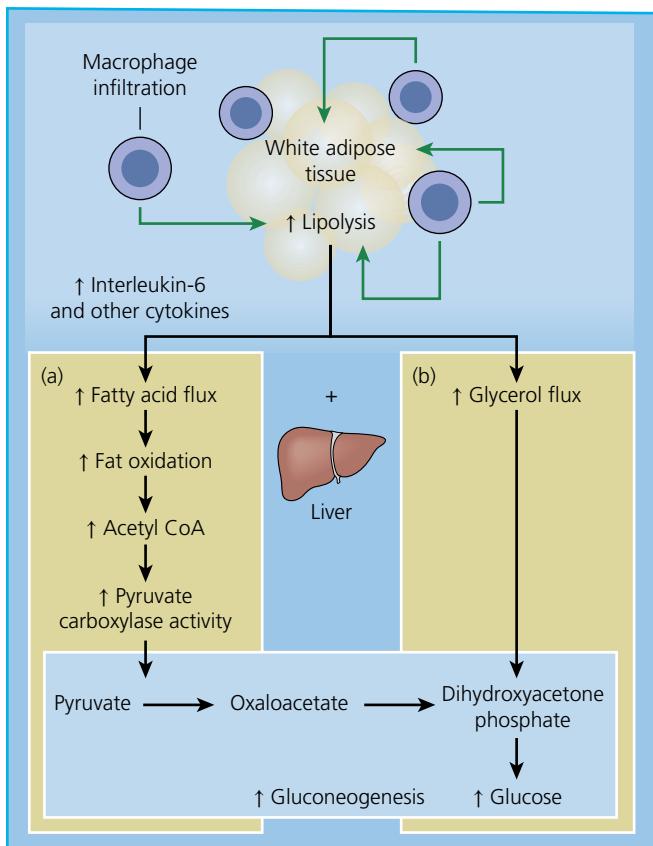

Figure 17.4 Hypothesis of macrophage-induced lipolysis in the pathogenesis of fasting hyperglycaemia and insulin resistance. During the development of obesity, macrophage infiltration of white adipose tissue results in increased lipolysis by release of macrophage-derived cytokines such as interleukin-6. Increased rates of lipolysis lead to accelerated rates of hepatic gluconeogenesis by two mechanisms. (a) First, increased fatty acid delivery to the liver leads to higher hepatic acetyl-CoA levels when its production through fat oxidation exceeds its rates of oxidation in the tricarboxylic acid cycle. This leads to increased pyruvate carboxylase activity. (b) Second, increased delivery of glycerol promotes its conversion to dihydroxyacetone (glyceraldehyde) 3-phosphate, which serves as a precursor of glucose. Source: Shulman 2014 [1]. improves insulin sensitivity [153, 157], which has been further associated with altered gut microbiota or hormone secretion [161] and also with reductions in endoplasmic reticulum stress. These hypotheses are currently under further investigation. Finally, chronically increased lipid availability may also cause mitochondrial and endoplasmic reticulum stress with release of ROS, which in turn activate proinflammatory NF- κ B [26]. Under these conditions, intracellular lipid metabolites (DAGs, ceramides, acyl-CoA) may also contribute to the resulting insulin resistance [71, 162, 163]. In support of the latter possibility, Lyu et al. recently demonstrated that increases in plasma membrane *sn*-1,2-DAGs and activation of PKC ϵ leading to insulin receptor threonine¹¹⁵⁰ phosphorylation were responsible for lipid-induced white adipose tissue insulin resistance following short-term high-fat feeding in rodent [130]. These findings underline the relevance of the plasma membrane *sn*-1,2-DAG/PKC ϵ /IRK T^{1160} pathway in mediating lipid-induced insulin resistance in multiple insulin-responsive tissues (liver, skeletal muscle, white adipose tissue).

Syndromes of lipodystrophy or lipoatrophy made it possible to study the roles of peripheral or visceral adipose tissues for insulin resistance and ectopic lipid deposition [131, 164–166]. Both inherited and acquired forms of generalized lipodystrophy are devoid of relevant amounts of adipose tissue and develop excessive hypertriglyceridaemia and ectopic fat deposition owing to fat overflow from the negligible triglyceride storage in adipocytes. Furthermore, these individuals have lower levels of inflammatory cytokines and leptin, resulting in hyperphagia [132]. Individuals with severe, generalized lipodystrophy have severe steatosis along with hepatic and muscle insulin resistance or even overt type 2 diabetes, which completely resolves after 3–8 months of leptin replacement therapy, as demonstrated previously in rodent models of lipodystrophy [78, 84]. Thus, visceral lipid content is likely more of a marker of hepatic steatosis rather than a causal player in the development of insulin resistance [132].

Although these findings also demonstrate that the important role of lipid-induced alterations at the onset of insulin resistance can be dissociated from inflammation, they do not exclude the operation of other mechanisms promoting the progression to impaired glucose tolerance and fasting hyperglycaemia. According to the canonical view, impaired pancreatic β - and α -cell function first leads to reduced hepatic activation of Akt and exclusion of forkhead box (FOXO1) from the nucleus of the hepatocyte, with consequent transcription-mediated hepatic gluconeogenesis [167]. Second, subclinical inflammation would diminish insulin action through secreted (adipo)cytokines, which subsequently interfere with insulin signalling and increase hepatic gluconeogenic protein transcription by activating the NF- κ B/JNK/ceramide pathways. Recently, an alternative mechanism has been proposed, by which macrophage-induced lipolysis may regulate hepatic gluconeogenesis independently of canonical insulin receptor signalling and thereby link subclinical inflammation to the onset of fasting hyperglycaemia [1, 168] (Figure 17.4). Using a novel *in vivo* metabolomics approach in rodent models, it was demonstrated that IL-6 and TNF- α , released from macrophages within adipose tissue, inhibit insulin-mediated lipolysis in white adipose tissue with augmented delivery of fatty acids and glycerol to the liver [169]. This resulted in increased hepatic acetyl-CoA concentrations, due to increased fatty acid β -oxidation, which stimulated hepatic gluconeogenesis through allosteric activation of pyruvate carboxylase as well as increased glycerol conversion to glucose in the liver by a substrate push mechanism. In line with these studies in rodents, insulin-resistant adolescents with obesity displayed increased circulating IL-6 concentrations and a more marked, 50% rise in IL-6 concentration in white adipose tissue, along with impaired insulin-mediated suppression of white adipose tissue lipolysis and endogenous glucose production compared with age- and body mass-matched insulin-sensitive humans. These studies collectively support the concept of an indirect action of insulin on hepatic glucose production via adipocytes [170, 171]. Some further observations underline that transcriptional control of hepatic gluconeogenesis cannot be due simply to direct insulin action on the liver to suppress glucose release. Insulin-mediated reduction in endogenous glucose production occurs rapidly, within minutes, even in individuals with type 2 diabetes [37], and there is a lack of any relationship between hepatic expression of gluconeogenic protein and fasting hyperglycaemia in humans with obesity, with and without type 2 diabetes [127].

Stepwise development of tissue-specific insulin resistance

The close association between obesity, ectopic fat accumulation, and insulin resistance makes it difficult to identify skeletal muscle, liver, or adipose tissue as the primary cause of insulin resistance. Indeed, ingestion of one energy-dense high-fat meal can cause simultaneous insulin resistance in these tissues both in humans and in mice [172]. Nevertheless, in humans the earliest development of insulin resistance most likely occurs in the adipose tissue [91, 173] (Figure 17.4). The observation of rapid reversibility of hepatic but not muscle insulin resistance with moderate weight loss in individuals with NAFLD, and leptin replacement in generalized lipodystrophy [132] and type 2 diabetes [131], is in agreement with this contention. As detailed earlier, the principal mechanism involves tissue-specific accumulation of plasma membrane *sn*-1,2-DAGs, which occurs owing to an imbalance between substrate influx and oxidation (mitochondrial activity) and/or synthesis of TAGs in insulin-responsive tissues. Accordingly, any situation that will disrupt the balance between delivery and removal of plasma membrane *sn*-1,2-DAGs to the muscle, liver, and white adipose tissue will lead to the accumulation of these lipid species, resulting in activation of PKC ϵ (as well as PKC θ in skeletal muscle) and insulin resistance. This likely explains the high prevalence of obesity-associated insulin resistance, where lipid delivery exceeds storage and oxidation, the impaired adipocyte storage capacity in lipodystrophy, and the decreased substrate oxidation in certain forms of inherited insulin resistance such as lean, insulin-resistant relatives of individuals with type 2 diabetes or in acquired insulin resistance occurring during ageing [140].

Evidence for the specific role of inefficient substrate oxidation during the onset of insulin resistance comes from the human model of lean, young, severely insulin-resistant relatives of people with type 2 diabetes, who are devoid of any other confounding factors such as obesity, hyperglycaemia, or subclinical inflammation. In these individuals, inherited abnormalities in muscle mitochondrial biogenesis and/or function can cause or at least contribute to muscle insulin resistance due to decreased mitochondrial fatty acid oxidation and subsequent accumulation of intracellular lipid metabolites (plasma membrane *sn*-1,2-DAGs) with diminished insulin signalling [105, 174]. The impaired adaptation of insulin sensitivity to exercise training in carriers of the rs540467 polymorphism of the *NDUFB6* gene in such relatives of people with type 2 diabetes is in line with this hypothesis [108]. Likewise, the rs2267668 A/G SNP in the *PPARD* gene and the Gly482Ser SNP in the *PGC1A* gene also have independent and additive effects on the effectiveness of aerobic exercise training to increase physical fitness and insulin sensitivity in humans at risk for type 2 diabetes [175]. Impaired mitochondrial function as assessed from ATP synthesis was also found in other non-obese groups at increased risk for type 2 diabetes, such as individuals with previous acromegaly [176] or gestational diabetes [120]. All these alterations in skeletal muscle metabolism would lead to lower rates of insulin-stimulated glucose disposal and accelerated rates of anaerobic glycolysis with release of lactate and alanine as substrates of hepatic gluconeogenesis.

Chronic overnutrition will increase the size of white adipose tissue and recruit macrophages to adipose tissue. Local inflammation of adipose tissue leads to macrophage-induced lipolysis with release of TAGs and fatty acids, which in turn elevate the white

adipose tissue-derived hepatic acetyl-CoA pool and drive hepatic gluconeogenesis. This mechanism could potentiate the transition from whole-body insulin resistance to impaired glucose tolerance and type 2 diabetes. Chronic increases in hepatic gluconeogenesis would then impair insulin secretion by the pancreatic β cells and inappropriate glucagon secretion by the α cells due to glucose toxicity, and ultimately exacerbate both fasting and post-prandial hyperglycaemia in the context of overt type 2 diabetes.

Finally, excessive flux of fatty acids to the liver will promote NAFLD through increased hepatic esterification, which occurs in a mostly insulin-independent manner and therefore is not dependent on postulating *selective hepatic insulin resistance* [177]. Hepatic mitochondria may transiently adapt to the increased substrate availability by upregulating their oxidative capacity at the expense of decreased coupling efficiency until NAFLD develops [150]. Ongoing substrate overloading will blunt the liver's antioxidant capacity and increase hepatic oxidative stress, with subsequent leakage of mitochondria and decreased mitochondrial biogenesis, resulting in NASH and aggravated insulin resistance.

Several studies provided experimental support for the concept of the stepwise development of insulin resistance in humans (Figure 17.5). Monitoring energy distribution employing $^{13}\text{C}/^{1}\text{H}$ NMR spectroscopy and hepatic *de novo* lipogenesis after ingestion of

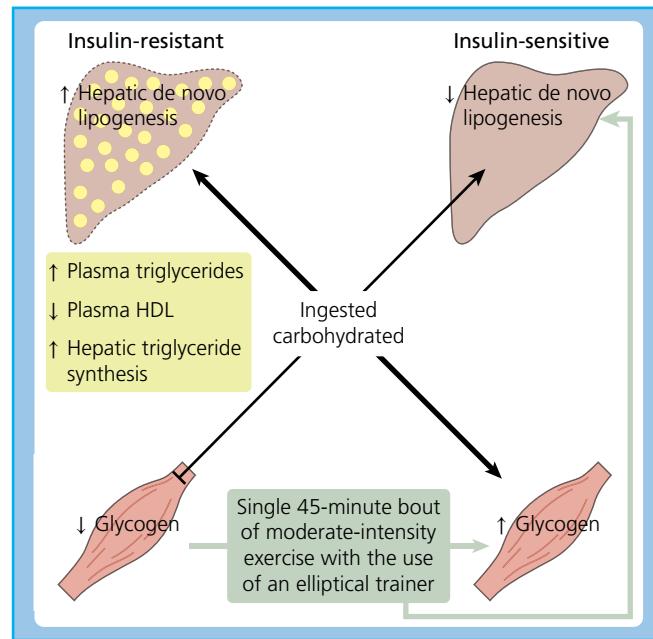

Figure 17.5 Concept of the stepwise development of insulin resistance from skeletal muscle to atherogenic dyslipidaemia and non-alcoholic fatty liver disease. In healthy, young, lean people, selective insulin resistance in skeletal muscle results in the diversion of ingested carbohydrates from muscle glycogen synthesis to the liver. Combined with compensatory hyperinsulinaemia, this stimulates hepatic *de novo* lipogenesis, synthesis of triglycerides, and secretion of very low-density lipoproteins (VLDL), resulting in hypertriglyceridaemia and reduced plasma high-density lipoprotein (HDL) levels. It is of note that even one bout of exercising is able to restore the abnormal pattern of energy storage after carbohydrate ingestion by stimulating glucose uptake and glycogen synthesis in muscle through insulin-independent adenosine 5'-monophosphate-activated protein kinase (AMPK) activation of glucose transporter 5 (GLUT4) recruitment, and further improves hepatic carbohydrate and lipid metabolism. a high-carbohydrate meal revealed that post-prandial muscle glycogen synthesis was reduced by ~60% in insulin-resistant compared with insulin-sensitive young, lean individuals [177]. On the other hand, liver TAG content and hepatic *de novo* lipogenesis were doubled in the insulin-resistant group. This was accompanied by 60% higher plasma TAG and uric acid contents and 20% lower fasting HDL-C, but with no changes in circulating adipocytokines. These data confirmed that muscle insulin resistance *per se* shifts the distribution of post-prandial energy storage away from muscle glycogen and leads to upregulation of hepatic lipid synthesis and hepatic lipid storage and export of VLDL, thereby contributing to the development of atherogenic dyslipidaemia; these are features of the metabolic syndrome independently of visceral obesity or subclinical inflammation. Meal-dependent increases in liver glycogen synthesis were comparable in insulin-resistant and insulin-sensitive individuals, which is in accordance with the low amount of liver lipids and normal hepatic insulin sensitivity in these individuals with muscle insulin resistance [92, 178]. It is noteworthy that a single bout of moderate-intensity exercise abrogated the abnormal pattern of energy storage, which promoted muscle glycogen synthesis after carbohydrate ingestion through increased glucose transport activity [172, 179] (Figure 17.5). Moreover, non-obese insulin-resistant women with a history of gestational diabetes also feature doubled fasting liver TAGs without NAFLD, which correlates with insulin resistance and fat mass [120]. Hepatic, but not visceral, fat mass relates to hepatic insulin resistance and increased TAG release [180]. Finally, loss of adaptation of hepatic mitochondria to excessive substrate delivery may accelerate steatosis and promote the progression of NAFLD, which is a major and independent predictor of cardiovascular morbidity and mortality in the context of type 2 diabetes [181].

Conclusion

Insulin resistance is the initial event preceding type 2 diabetes by decades before the onset of any relevant insulinopaenia, which is required for the transition from normoglycaemia to fasting and post-prandial hyperglycaemia. Insulin resistance in insulin liver, muscle, and white adipose tissue can be attributed to increases in plasma membrane-bound *sn*-1,2-DAG, which accumulates in these tissues as ectopic lipid due to an imbalance between fatty acid delivery or synthesis versus intracellular metabolism by oxidation and/or storage as neutral lipid (triglyceride). Increases in plasma

membrane-bound *sn*-1,2-DAG in turn lead to activation or translocation of PKC ϵ in these tissues, which results in phosphorylation of the insulin receptor on threonine¹¹⁶⁰ and inhibition of IRK activity. Activated PKC ϵ also phosphorylates many additional proteins, including p70S6K, which in turn will also contribute to insulin resistance downstream of the insulin receptor. In skeletal muscle, increases in plasma membrane-bound *sn*-1,2-DAG also result in activation/translocation of PKC θ , which phosphorylates IRS-1 and inhibits insulin signalling at the level of IRS-associated PI3K. Excess delivery of substrates (fatty acids) to muscle, which exceed rates of mitochondrial fatty acid oxidization and/or storage as triglycerides in the lipid droplet, is currently the most common reason for obesity and lipodystrophy-associated muscle insulin resistance. Under conditions of a positive energy balance, impaired muscle insulin action, due to this plasma membrane-bound *sn*-1,2-DAG/nPKC mechanism, distributes ingested carbohydrate away from muscle glycogen storage towards hepatic *de novo* lipogenesis, resulting in NAFLD, the metabolic syndrome, and type 2 diabetes. During the later stages of obesity, macrophage infiltration of the white adipose tissue causes local increases in cytokines (e.g. TNF- α , IL-6), which favour lipolysis, leading to increased flux of fatty acids and glycerol to the liver [173]. Greater fatty acid availability raises hepatic acetyl-CoA and the activity of pyruvate carboxylase, resulting in increased hepatic gluconeogenesis. Greater glycerol availability – via substrate push – stimulates glycerol conversion to glucose, thereby further increasing hepatic gluconeogenesis [173]. Increases in hepatic gluconeogenesis, on top of peripheral insulin resistance, lead to β -cell exhaustion, likely due to glucose toxicity and possibly other factors, which results in the transition from whole-body insulin resistance to impaired glucose tolerance and type 2 diabetes.

18 Obesity and Diabetes

Nick Finer

National Centre for Cardiovascular Prevention and Outcomes, UCL Institute of Cardiovascular Science, London, UK

Key points

- Obesity is a chronic disease characterized by an abnormal or excessive accumulation of adipose tissue and biomechanical and metabolic complications.
- The huge rise in the prevalence of obesity over the past 50 years has driven the commensurate increase seen in type 2 diabetes.
- It is estimated that 89% of individuals with type 2 diabetes have obesity or overweight.
- The triad of obesity, type 2 diabetes, and non-alcoholic fatty liver disease (NAFLD) is well recognized.
- Body mass index (BMI), defined as weight in kg/(height in m)², is the most convenient population-level measure of overweight and obesity, but this has limitations when defining the clinical severity of excess weight.
- Waist circumference is commonly used as a surrogate of visceral fat accumulation, but imaging techniques with computer-assisted tomography or magnetic resonance imaging are the gold standard.
- The overlapping epidemics of obesity and type 2 diabetes have been considered as *syndemic*.
- Heritability for both obesity and type 2 diabetes is estimated to be moderate to high at between 30% and 70%.
- Insulin resistance correlates with visceral fat mass, total fat mass, BMI, and waist circumference, but to a much lesser extent with subcutaneous fat, emphasizing the importance of adipose distribution.
- The twin cycle model links obesity to the development of type 2 diabetes and explains how weight loss can reverse the process; positive energy balance promotes liver fat deposition. The process is promoted by insulin and results in decreased hepatic insulin sensitivity and increased hepatic glucose output, forming the first vicious cycle. The second vicious cycle results from a spillover of liver-derived triglyceride-rich, very low-density lipoprotein, which drives ectopic fat deposition in other tissues, including the pancreatic β cells. This impairs β -cell function and contributes to chronic hyperglycaemia.
- Therapeutic weight loss is a powerful intervention that can ameliorate or reverse many of the metabolic abnormalities present in people with diabetes.
- Very low-energy diets can lead to diabetes remission and are associated with improvements in blood pressure, lipid abnormalities, carbohydrate metabolism, and cardiorespiratory function.
- The development of glucagon-like peptide (GLP-1) receptor agonists, already well established as treatments for type 2 diabetes, as well as dual agonists that combine GLP-1 and glucose-dependent insulinotropic peptide (GIP) agonism, has transformed, and is transforming, the potential for anti-obesity medications. They lead to $\geq 10\%$ weight loss and prevent and reverse type 2 diabetes.
- Bariatric surgery with gastric bypass or sleeve gastrectomy improves glycaemia through a variety of mechanisms other than weight loss alone.

Obesity is now considered a chronic disease characterized by biomechanical and metabolic complications. While the link between obesity and ill health was first recognized 400 years BCE by Hippocrates and Hindu physicians [1], the specific link with diabetes is more recent [2], culminating in the now widely coined term *diabesity* that describes the association [3,4]. The huge rise in obesity prevalence in the past 50 years is now recognized to have driven the commensurate increase seen in type 2 diabetes incidence and prevalence. Obesity, a disease in its own right [5–7], was estimated by the World Health Organization (WHO) in 2016 to affect 650 million adults over the age of 18 years; 1.9 billion had overweight [8]. This represents 13% of all adults. Obesity in children and adolescents has increased even faster, such that 124 million children and adolescents (6% of all girls and 8% of all boys) are classified as having obesity. Compared to 1975, there has been a three-fold increase in prevalence in adults and a six- to eightfold increase in children, but this masks large regional variations. The highest prevalence rates are in the USA (37% of all adults), Middle East

(up to 35%), and Pacific islands (over 50%) [8]. It is estimated that 89% of individuals with type 2 diabetes have obesity or overweight [9]. The global prevalence of diabetes is estimated to reach 8.0% (454 million) by 2030, with type 2 diabetes accounting for ~90% of the total [10] driven by obesity [11] and an ageing population [10]. This chapter explores the pathophysiology of the disease of obesity, its links to diabetes, and its clinical management.

Obesity: definitions and phenotypes

Obesity is defined as an abnormal or excessive accumulation of adipose tissue that may impair health [5]. Adipose tissue is present throughout the body. As weight is gained, fats (lipids) are stored:

- In different adipose depots – subcutaneous, visceral, or intra-abdominal (e.g. omental and peri-renal).
- Ectopically – in tissues such as liver, muscle, heart, and pancreas and even in the vasculature and bone marrow.

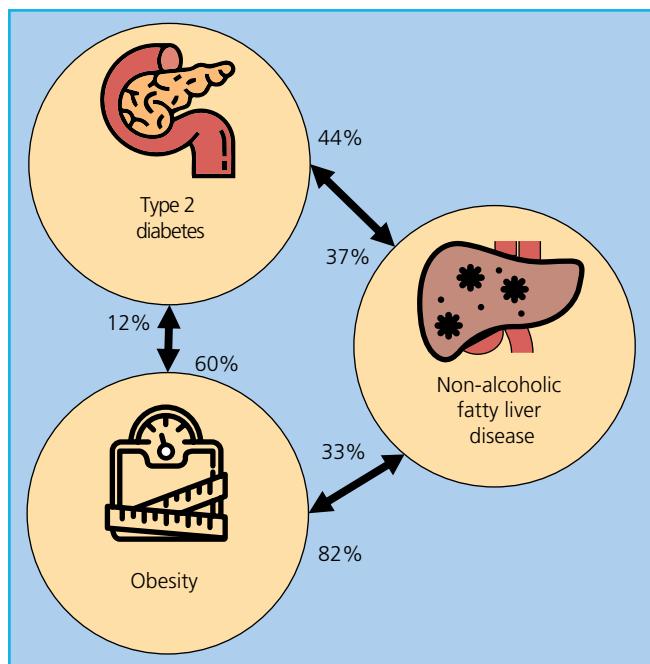

Figure 18.1 The prevalences of type 2 diabetes, obesity, and non-alcoholic fatty liver disease. Generally accepted epidemiological evidence suggests that, among people with non-alcoholic fatty liver disease (global prevalence: 5%–6%), 82% live with obesity, and 44% with type 2 diabetes; among those with type 2 diabetes (global prevalence in 2019: 9%, 463 million), 37% are estimated to have non-alcoholic fatty liver disease, and approximately 60% have obesity; for obesity (global prevalence: 35%, 650 million), 33% may have non-alcoholic fatty liver disease and 12% diabetes.

The triad of obesity, type 2 diabetes, and non-alcoholic fatty liver disease (NAFLD) is well recognized (Figure 18.1) [12]. NAFLD, defined by the presence of steatosis in $\geq 5\%$ of hepatocytes after excluding other causes of fatty liver, includes a spectrum of conditions, ranging from hepatic steatosis to non-alcoholic steatohepatitis and liver fibrosis, which may progress to cirrhosis and hepatocellular carcinoma. The term metabolic (dysfunction)-associated fatty liver disease (MAFLD) is increasingly used, as it

emphasizes the role of the metabolic dysfunction common (but not necessarily due) to obesity and diabetes [13].

Adipose tissue is not just an energy storage organ, but an active endocrine tissue secreting hormones such as leptin and adiponectin, as well as many adipocytokines that increase systemic and paracrine inflammation [14]. Operationally, body mass index (BMI), defined as weight in kg/(height in m)², is the most convenient population-level measure that estimates overweight and obesity. A BMI $\geq 30 \text{ kg/m}^2$ is considered to define obesity in people of white North European ancestry, while a BMI $\geq 25 \text{ kg/m}^2$ defines overweight (now termed pre-obesity). Different thresholds have been proposed for Asian ($\geq 23 \text{ kg/m}^2$ pre-obesity, $\geq 25 \text{ kg/m}^2$ obesity) [15] and Japanese populations ($\geq 25 \text{ kg/m}^2$) [16]. BMI has limitations when defining the clinical severity of excess weight, since at any given BMI there may be a threefold variation in % body fat [17]. Additionally, many factors, such as age, sex, ethnicity, muscle mass, illness, and weight loss, can alter the relationship between BMI and body fat. BMI does not give information about fat distribution [18]. Adipose tissue physiology differs considerably depending on its location, with visceral (intra-abdominal, peri-renal, and ectopic fat) most closely related to obesity complications. Epidemiologically many obesity complications, especially cardiometabolic and diabetes, correlate better with visceral fat accumulation than BMI [19–21]. While waist circumference or other anthropometric ratios (waist-to-hip and waist-to-height) [22,23] are commonly used as surrogates of visceral fat accumulation, imaging techniques with computer-assisted tomography or magnetic resonance imaging (MRI) are the gold standard [24].

Severity of obesity has been, rather arbitrarily, classified into BMI bands (Table 18.1). The recognition that fat distribution is of fundamental importance in determining the pathogenicity of obesity has led to the inclusion of waist circumference to improve the definition of risk within each BMI band (Table 18.1). More recent classifications (both of which include the presence of type 2 diabetes) are clinically rather than anthropometrically based. The Edmonton Obesity Staging System [27] is based on the presence of obesity-related risk factors or complications (Table 18.2) that correlate better than BMI with mortality [28,29], while the King's Obesity Staging Criteria (Table 18.3), albeit based on arbitrary criteria, can guide clinical management and assess responses to treatment [30].

Table 18.1 Classification of obesity and risk based on anthropometric measures.

Classification	BMI kg/m ²	International classification [25]		Asian population ^a [15]	Japanese guidelines ^a [16]
		Waist circumference Men $\leq 102 \text{ cm}$ Women $\leq 88 \text{ cm}$	Waist circumference Men $> 102 \text{ cm}$ Women $> 88 \text{ cm}$		
Underweight	< 18.5				< 18.5
Normal range	≥ 18.5 to < 25			≥ 18 to < 23	≥ 18.5 to < 25
Pre-obesity ^a	≥ 25 to < 30	Increased	High	≥ 23 to < 25	
Obesity	≥ 30		High	> 25	
Obesity class I	≥ 30 to < 35	High	Very high		≥ 25 to < 30
Obesity class II	≥ 35 to < 40	Very high	Very high		≥ 30 to < 35
Obesity class III	≥ 40	Extremely high	Extremely high		≥ 35 to < 40
Obesity class IV					≥ 40

^a Waist circumference for different populations: Asian: men $\leq 102 \text{ cm}$, women $\leq 88 \text{ cm}$; Japanese: men $> 90 \text{ cm}$, women $> 80 \text{ cm}$ [26].

Table 18.2 Edmonton staging system for obesity.

Stage	Definition
0	No apparent obesity-related risk factors, physical symptoms, psychopathology, functional limitations, and/or impairment of well-being
1	Obesity-related subclinical risk factor(s), e.g. borderline hypertension, impaired fasting glucose, elevated liver enzymes, etc., mild physical symptoms (e.g. dyspnoea on moderate exertion, psychopathology, functional limitations, and/or impairment of well-being)
2	Established obesity-related chronic disease(s), e.g. hypertension, type 2 diabetes, sleep apnoea, osteoarthritis, reflux disease, polycystic ovary syndrome, anxiety disorder, moderate limitations in activities of daily living and/or well-being
3	Established end-organ damage, e.g. myocardial infarction, heart failure, diabetes complications, incapacitating osteoarthritis, significant psychopathology, functional limitation(s), and/or impairment of well-being
4	Severe (potentially end-stage) disability/ies from obesity-related chronic disease disabling psychopathology, functional limitation(s), and/or impairment of well-being

The obesity and diabetes syndemic

The overlapping epidemics of obesity and type 2 diabetes have been considered as syndemic. As originally conceived, the term syndemic was introduced to bring ‘new perspectives on the interaction between co-existing disorders in specific communities and with biological, behavioural and social factors that influence the occurrence and consequences of the diseases’ [31]. Obesity and type 2 diabetes represent two types of adverse interaction clustering: a biological–biological interface and a biological–social interface (Figure 18.2) [32, 33]. The former relates to common genetic and physiological factors that underlie both obesity and type 2 diabetes, while shared environmental factors include changes in nutrition, physical activity, and psychological health [34].

Heritability for both obesity and type 2 diabetes is estimated to be moderate to high at between 30% and 70% (Chapters 12 and 13) [35].

Genome-wide association studies have identified ~700 variants for obesity [36] and >400 for type 2 diabetes [37]. There is little shared genetic aetiology, which only accounts for ~15–20% of known heritability [38]. A report in 2015 listed 49 loci (33 new) associated with waist-to-hip ratio adjusted for BMI, and an additional 19 loci newly associated with related waist and hip circumference measures [39]. Many observational studies have shown correlations of obesity (and fat distribution) with type 2 diabetes [40, 41], but do not in themselves allow inferences. The causal relationship between obesity and type 2 diabetes has been investigated, and established, using Mendelian randomization techniques. A polygenic risk score, based on 93 single-nucleotide polymorphisms (SNP) related to obesity in 119 859 individuals in the UK Biobank, found a near twofold increased risk for type 2 diabetes for each increase in BMI of 4.83 kg/m², findings replicated in a study of up to 213 556 individuals from 14 prospective studies and randomized trials and 4 consortia [42]. Genetic susceptibility to type 2 diabetes is mediated both through effects on insulin-release and insulin sensitivity [43]. Epigenetic effects, impairing β-cell function, are also well described and can be acquired *in utero*, or by exposure to lifestyle factors including inactivity and obesity [44].

Syndromic obesities are increasingly recognized and for many the genetic basis has been identified. Many of the 79 identified syndromes in which obesity is a feature (e.g. Prader-Willi, Bardet-Biedl, Alström syndromes) also include a high prevalence of type 2 diabetes [45]. Monogenic obesities are increasingly recognized, especially in children presenting with severe early-onset obesity, often with other features such as learning disability (Table 18.4) [46]. The development of specific treatments for a small minority of such obesities, some of which may progress to adulthood undiagnosed, emphasizes the increasing need for genetic diagnosis.

Pathophysiology of obesity and diabetes

The pathophysiology of type 2 diabetes is complex [47] and characterized by insulin resistance [48] and pancreatic insulin hypersecretion to overcome the insulin resistance early in the evolution of the disease. Both β-cell dysfunction and decreased insulin sensitivity are pivotal in the pathogenesis and progression of type 2 diabetes [49]. Insulin resistance drives accumulation of free fatty acids in target

Table 18.3 King’s obesity staging criteria.

	Stage 0 Normal health	Stage 1 At disease risk	Stage 2 Established disease	Stage 3 Advanced disease
Airways	Normal	Snoring	Requires CPAP	Cor pulmonale
Body mass index (BMI) (kg/m ²)	<35	35–40	40–60	>60
Cardiovascular	<10% risk	10–20% risk	Heart disease	Heart failure
Diabetes	Normal	Impaired fasting glucose	Type 2 diabetes	Uncontrolled diabetes
Economic	Normal	Increased expenses	Workplace discrimination	Unemployed due to obesity
Functional	Can manage 3 flights of stairs	Can manage 1–2 flights of stairs	Requires walking aids or wheelchair	Housebound
Gonadal	Normal	Polycystic ovary syndrome	Infertility	Sexual dysfunction
Health – perceived	Normal	Low mood or quality of life	Depression	Severe depression
Image	Normal	Dislikes body	Body image dysphoria	Eating disorder with purging

CPAP, continuous positive airway pressure.

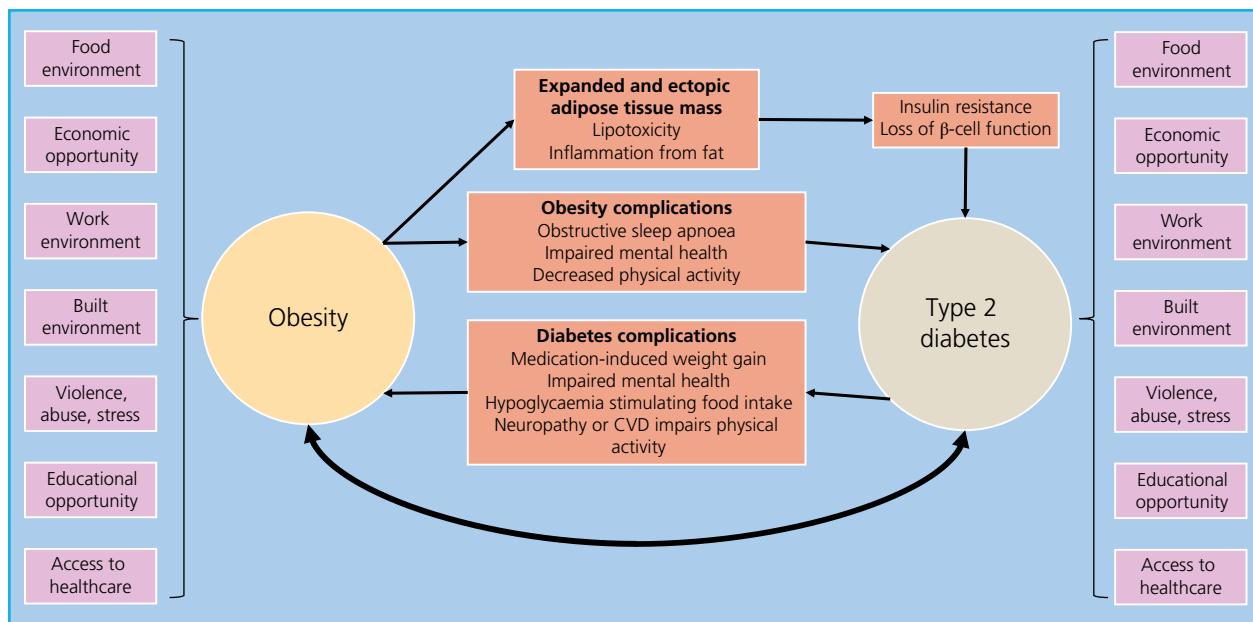

Figure 18.2 Pathways linking the syndemic of obesity and type 2 diabetes. CVD, cardiovascular disease.

Table 18.4 Genetic obesity syndromes.

Obesity syndrome	Gene name	Main distinguishing features
Monogenic		
Leptin deficiency	LEP	Severe hyperphagia, hypogonadism, impaired immunity, undetectable serum leptin
Leptin receptor mutation	LEPR	Severe hyperphagia, hypogonadism, very high serum leptin
MC4R deficiency	MC4R	Accelerated growth, increased final height
POMC deficiency	POMC	Hypopigmentation, isolated ACTH deficiency
Prohormone convertase	PCSK1	Glucocorticoid deficiency, postprandial hypoglycaemia, hypogonadism, elevated plasma proinsulin and split proinsulin
BDNF deficiency	BDNF	Developmental delay, hyperactivity, impaired memory, impaired pain sensation
TrkB deficiency	NTRK2	Developmental delay, hyperactivity, impaired memory, impaired pain sensation
Polygenic		
Bardet-Biedl syndrome	BBS1–16	Polydactyly, retinal dystrophy, hypogonadism, renal abnormalities
Alström syndrome	ALMS1	Progressive loss of vision and hearing, dilated cardiomyopathy, type 2 diabetes, short stature
Prader-Willi syndrome	15q11–13	Hypotonia, learning disability, short stature, hypogonadism, severe hyperphagia
Down's syndrome	Trisomy 21	Learning disability, short stature, heart disease, moderate obesity from infancy

cells (liver, skeletal muscle, and adipose tissue) [50]. Measures of insulin resistance such as the homeostatic model assessment of insulin resistance (HOMA-IR) correlate with visceral fat mass, total fat mass, BMI, and waist circumference, but to a much lesser extent with subcutaneous fat, highlighting the importance of adipose distribution [51]. This interplay between obesity and diabetes is further emphasized by the impact of accumulated adipose tissue on insulin resistance that drives cardiometabolic disease progression towards type 2 diabetes, NAFLD, and cardiovascular disease [52]. The bidirectional contribution of NAFLD to both type 2 diabetes and obesity is also well established [50]. However, there exists a wide variation in

insulin resistance and β-cell dysfunction and inflammation within the current diabetes classification. This heterogeneity relates to the effects of epigenetic, genetic, environmental, and lifestyle factors on the disease and its progression and complications. Attempts to increase the precision of diagnosis suggest six subtypes of diabetes, of which two are associated with a high BMI [53, 54]. Severe insulin-resistant diabetes is characterized by late onset, high BMI, most insulin resistant, highest liver fat content, fatty liver index, NAFLD fibrosis score, and prevalence of NAFLD. Severe insulin-resistant diabetes has the highest risk for macroalbuminuria, chronic renal disease, and ischaemic heart disease and stroke. By contrast, a

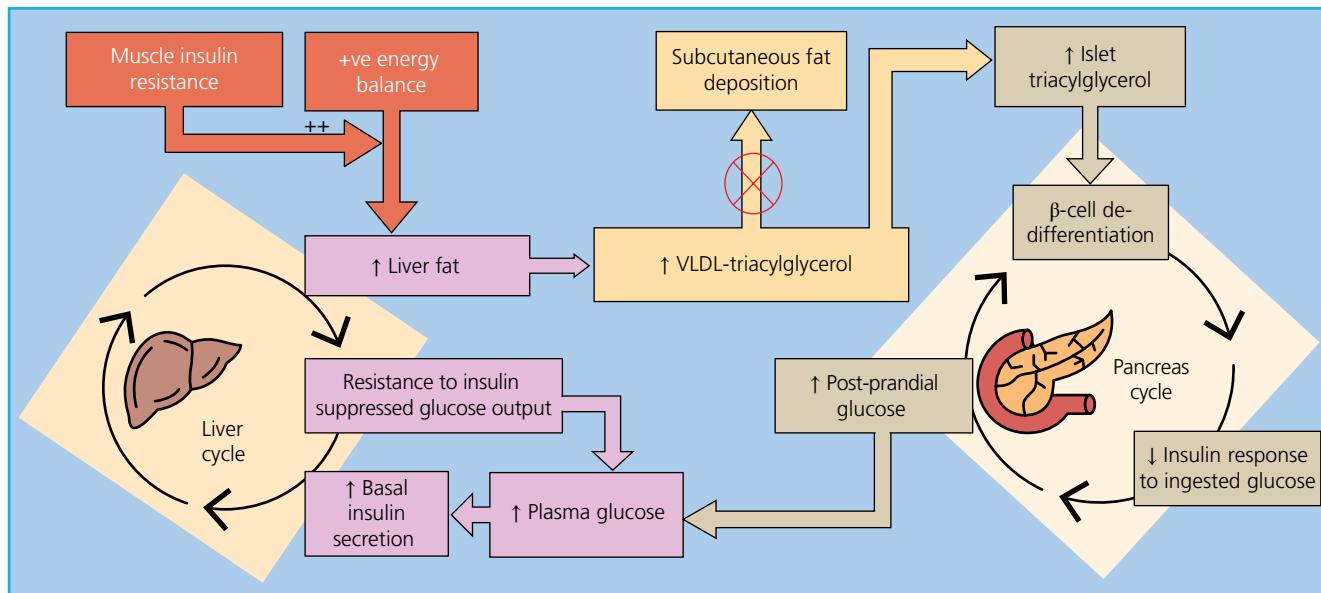

Figure 18.3 Pathways in the twin cycle hypothesis. VLDL, very low-density lipoprotein.

subgroup characterized by a more benign course of their disease is termed mild obesity-related diabetes, with high BMI, early-onset diabetes with intermediate insulin resistance and an intermediate prevalence and risk of diabetes-related complications.

A model (the twin-cycle model) links obesity to the development of type 2 diabetes and explains how weight loss can reverse the process (Figure 18.3) [55]. The model describes how a positive energy balance promotes the deposition of fat in the liver by a process promoted by insulin. The presence of elevated insulin levels drives liver fat accumulation, resulting in decreased hepatic insulin sensitivity, which impairs insulin suppression of hepatic glucose output. This leads to both an increase in blood glucose levels and basal insulin secretion, forming the first vicious cycle. The second vicious cycle results from a spillover of liver-derived triglyceride-rich, very low-density lipoprotein (VLDL). Once subcutaneous fat stores are replete, this drives ectopic fat deposition in other tissues and exposes pancreatic β cells to triacylglycerol accumulation. Since pancreatic β cells are particularly susceptible to fatty acids, this impairs the function and response to post-meal glucose, which combine to elevate blood glucose levels and further impair glucose homeostasis. The resulting chronic hyperglycaemia increases insulin secretion, which results in increased fat deposition in the liver and increased hepatic lipogenesis, so driving both cycles faster. Once these effects on β cells reach a certain threshold, β -cell decompensation occurs, with the onset of clinically overt type 2 diabetes.

It has long been known that these effects are readily reversible, particularly in early type 2 diabetes [56]. Both negative energy balance from energy restriction [57–59] and weight loss [60] can improve insulin resistance and hyperglycaemia, and this has led to a reawakening of interest in the role of therapeutic weight loss in the management of type 2 diabetes.

Treatment

Since obesity is the primary driver for the development of type 2 diabetes, it is unsurprising that therapeutic weight loss is a powerful intervention that can ameliorate or reverse many of the metabolic

abnormalities present in those with diabetes. However, this therapeutic approach was largely discredited by the UK Prospective Diabetes Study (UKPDS), which reported in the 1990s that its findings ‘confirm(ed) the value of dieting, but in view of the large weight loss and equivalent large reduction in energy intake required in most patients, it is not surprising that few patients achieve near-normal fasting plasma glucose concentrations by diet alone’ [61,62].

The metabolic impact of weight loss was shown in an elegant study in which experimental individuals (without diabetes) underwent stepwise periods of weight reduction and weight stabilization. A 5% weight loss did not affect oral glucose tolerance or other measures of glycaemia, but improved organ-specific insulin sensitivity in adipose tissue, liver, and skeletal muscle when assessed by clamp studies [63]. Insulin-mediated suppression of hepatic glucose production and adipose tissue lipolytic activity were maximal after 5% weight loss, whereas insulin-stimulated muscle glucose uptake increased further with greater amounts of weight loss of 11–16%. Greater loss beyond 5% further improved β -cell function, intrahepatic triglyceride content, and adipose tissue expression of genes involved in cholesterol flux, lipid synthesis, extracellular matrix remodelling, and oxidative stress. The impact of the Cuban economic collapse from 1991 to 1995 provided real-world evidence for the impact of energy restriction on weight loss and diabetes: the combination of food shortages and unavoidable increases in physical activity put the entire population in a negative energy balance of at least 20%, with a population-wide average weight loss of 5.5 kg that was associated with rapid declines in diabetes – a 53% fall in incidence at the lowest point [64].

However, despite this knowledge, over the past decades the development of a multiplicity of glucose-lowering drugs, together with potent drugs to manage blood pressure and lipids, has tended to marginalize weight loss as a therapy for diabetes. A recent UK survey found that between 2002 and 2016 there had been a steady increase in the number of people with type 2 diabetes treated with medications (from 39.6% to 56.3%), but that in 2016 fewer than 1 in 4 people with type 2 diabetes received weight management support or referral. The proportion receiving weight management was similar for those with either overweight or obesity [65]. More recently

there has been a revival of interest in developing intensive weight loss regimens with the aim of reversing or remitting type 2 diabetes.

Diabetes reversal and remission

The concept that diabetes could be cured, remitted, or reversed with weight loss was given impetus by a provocatively titled paper: 'Who would have thought it? An operation proves to be the most effective therapy for adult-onset obesity' [66]. Increasing publications on the effects of bariatric surgeries on type 2 diabetes were hampered by a lack of consensus as to what was meant by *cure* or *remission*. The American Diabetes Association (ADA) noted that 'distinction between successful treatment and cure is blurred in the case of diabetes. Presumably improved or normalised glycemia must be part of the definition of remission or cure and that it may be more accurate to use the term remission than cure' [67]. The ADA established a consensus group who defined three outcomes:

- Partial remission.
- Complete remission.
- Prolonged remission based on the duration and degree of normalization of blood glucose off anti-diabetes treatment.

A reconvened consensus group in 2022, representing the European Association for the Study of Diabetes (EASD), Diabetes UK, and the ADA, expanded on the definition and interpretation of remission according to timing and intervention (Table 18.5) [68]. However, these criteria are not without problems. They reflect a highly glucocentric view of type 2 diabetes. First, the criteria for a *normal* glycated haemoglobin (HbA_{1c}) are not universally agreed, and normalizing HbA_{1c} does not necessarily imply normoglycaemia; for example, after bariatric surgery, wide excursions from hyper- to hypoglycaemia are common [69]. Continuous glucose monitoring has shown that after bariatric surgery, hypoglycaemia affects more than 50% of individuals, increases at increasing time from surgery, and is comparable after gastric bypass and sleeve gastrectomy [70]. The risk of inpatient care for hypoglycaemia following gastric bypass is increased nearly threefold [71]. Another

conceptual issue is that individuals who have had bariatric surgery retain the operative altering of nutrient passage through the gastrointestinal system, with the related changes in gut hormone, microbiota, and bile acids, and so effectively have not ceased treatment. Even treatment with diet and lifestyle changes may persist after the acute intervention, such that *remission* is retained while they maintain these changes. Last, there are few data on the impact of remission on the reversal of already established or longer-term development of micro- and macrovascular disease.

Very low-energy diets and reversal or remission of diabetes

From the earliest days it was recognized that fasting and weight loss could improve carbohydrate metabolism [72]. In the 1970s protein-sparing modified fasts, which were essentially equivalent to contemporary very low-energy (VLED) or very low-calorie diets (VLCD), were investigated for people with insulin-treated type 2 diabetes [73]. Within 19 days of the diet, insulin could be withdrawn with improvements in blood pressure, lipid abnormalities, carbohydrate metabolism, and cardiorespiratory function, and preservation of lean body mass. While a 2004 Cochrane review found insufficient quality of data to recommend VLCDs over other diets in type 2 diabetes [74], evidence for their benefits continues to emerge [75]. β -cell function in people with type 2 diabetes undergoing VLED treatment improves [76], with falls in fasting plasma insulin and C-peptide levels [77] and improvements in dynamic insulin secretion and overall insulin production, modulation of pulsatility, and improved synchrony [78].

Initial interest in VLEDs, usually in the form of liquid meal replacements, was in their potential as an exploratory interventional tool rather than a clinically appropriate therapeutic diet. However, the acceptability of VLEDs, alone or in combination with anti-obesity medications, has increased over the past 20 years and they can be safely and effectively delivered in primary care [75, 79, 80]. The potential for energy restriction and weight loss to reverse type 2 diabetes has recently been evaluated in Counterpoint [81] and Counterbalance [82], a series of studies on type 2 diabetes remission. The Counterpoint study provided proof of concept that normalization of glycaemia was possible through weight loss using a VLED, which showed improvement in hepatic insulin resistance and normalization of β -cell function. The Counterbalance study aimed to assess the effect of a VLED on individuals with longer duration of type 2 diabetes. They found that at eight weeks 87% of individuals with short type 2 diabetes duration (<4 years) experienced remission, versus only 50% of those with longer disease duration (>8 years).

The Diabetes Remission Clinical Trial (DiRECT) assessed whether effective weight management, delivered in the primary care setting, could produce sustained remission of type 2 diabetes [83]. Individuals aged 20–65 years with non-insulin-treated type 2 diabetes, diagnosed within the past six years, and a BMI of 27–45 kg/m², were cluster randomized across 49 primary care practices to either an intervention in which anti-diabetes and anti-hypertensive drugs were withdrawn, and a total diet replacement (825–853 kcal/d formula diet for 3–5 months), stepped food reintroduction (2–8 weeks), and structured support for long-term weight loss maintenance were provided, versus a control group receiving best-practice standard care. At one year 24% of participants in the intervention group and none in the control group achieved weight loss ≥ 15 kg; diabetes remission (defined as HbA_{1c} less than 6.5% [<48 mmol/mol] after at least two months off all anti-

Table 18.5 Consensus on requirements that define diabetes remission.

Intervention (remission requires an HbA_{1c} measure immediately prior to intervention)	Interval before testing of HbA_{1c} can reliably evaluate the response	Subsequent measurement of HbA_{1c}
Lifestyle	>6 mo after beginning of intervention and >3 mo after stopping pharmacotherapy	
Pharmacotherapy Surgery	>3 mo treatment cessation >3 mo after procedure and >3 mo after stopping pharmacotherapy	>3 mo and <1 yr

Glycated haemoglobin (HbA_{1c}) below the level currently used for initial diagnosis of diabetes, 6.5% (48 mmol/mol), and remaining at that level for at least 3 mo without continuation of the usual anti-diabetes agents as the main defining measurement. In some circumstances, an estimated A_{1c} ($e\text{A}_{1c}$) or glucose management indicator (GMI) <6.5% can be considered an equivalent criterion.

diabetes medications) was achieved in 46% of participants in the intervention group and 4% in the control group. Remission varied with weight loss in the whole study population. At 24 months, in the intention-to-treat population of 149 participants per group, 17 (11%) receiving the intensive intervention and 3 (2%) in the control group had lost ≥ 15 kg; 53 (36%) and 5 (3%), respectively, had diabetes remission [84].

More recently, the Diabetes Intervention Accentuating Diet and Enhancing Metabolism (DIADEM-I) compared an intensive lifestyle intervention that included a VLED with usual medical care on weight loss and glycaemic outcomes in individuals from the Middle East and North Africa region with type 2 diabetes, aged 18–50 years, a short diabetes duration of less than three years, and a BMI of ≥ 27.0 kg/m². After one year the intensive intervention group achieved a mean 11.98 kg weight loss, with 61% obtaining diabetes remission, compared to a 3.98 kg loss and 12% remission in the control group [85]. The Doctor Referral of Overweight People to Low Energy total diet replacement Treatment Trial (DROPLET) included participants with a BMI ≥ 30 kg/m² (15% of whom had type 2 diabetes) and compared weekly behavioural support for 12 weeks and monthly support for three months with a commercial VLED providing 810 kcal/d (3389 kJ/d) as the sole food during the first eight weeks, followed by reintroduction of food with usual care from a practice nurse and a diet programme with modest energy restriction [86]. Mean weight change at 12 months was –10.7 kg in the VLED group and –3.1 kg in the usual care group, with greater reductions in HbA_{1c} (adjusted difference –2.2 mmol/mol, 95% confidence interval [CI] –4.4 to 0.0 mmol/mol; p = 0.05). Based on these results, the NHS Low Calorie Diet Programme is piloting a low-calorie, total diet-replacement programme for people who are overweight and living with type 2 diabetes [87].

Anti-obesity medications

The development of anti-obesity medications has been hampered until recently by drugs that were of modest weight loss efficacy, and many of which proved to have serious unwanted effects [88–91]. Currently, compared to treatment options for hypertension or type 2 diabetes, few anti-obesity medications are available, but as the physiology of energy balance is increasingly elucidated, many new druggable targets for weight loss have reawakened the search for effective and safe therapies [92].

The development of glucagon-like (GLP-1) receptor agonists, already well established as treatments for type 2 diabetes, as well as dual agonists that combine GLP-1 and glucose-dependent insulinotropic peptide (GIP) agonism, has, and is, transforming the potential for anti-obesity medications not only to produce double-digit weight loss (i.e. $\geq 10\%$) but to prevent and reverse type 2 diabetes (Table 18.6). Central GLP-1 is a physiological regulator of food intake acting on both appetite and reward-related brain areas [103], while GIP appears to activate neurons distinct from GLP-1, to inhibit food intake in a manner that is additive to GLP-1 [104]. The main unwanted effects of this class of drugs, which have been seen across all clinical trials, are gastrointestinal with mild to moderate nausea and vomiting when treatment is initiated. These side effects can be limited by slow dosage escalation. An increase in gallstones appears not to be fully accounted by weight loss and can rarely lead to pancreatitis.

Liraglutide underwent evaluation as an anti-obesity medication in the Satiety and Clinical Adiposity Liraglutide Evidence in Nondiabetic and Diabetic Individuals (SCALE) programme [105]. Four pivotal trials (the design of which informed the clinical eval-

uation of both semaglutide and tirzepatide) included a 56-week trial of 3731 individuals without type 2 diabetes and a BMI ≥ 30 kg/m² or ≥ 27 kg/m² with an obesity complication. Weight loss was significantly greater with liraglutide compared to placebo (estimated treatment difference –5.6 kg; 95% CI –6.0 to –5.1; p < 0.001) and more individuals achieved $\geq 5\%$ of their body weight. There were also significantly greater reductions in blood pressure, total cholesterol, low-density lipoprotein (LDL) cholesterol, triglycerides, fasting glucose, fasting insulin, and HbA_{1c} with liraglutide compared to placebo. The other trials evaluated efficacy in individuals with obesity and sleep apnoea, type 2 diabetes, and for weight maintenance after an initial intensive diet. A *post hoc* analysis confirms cardiovascular safety and suggests possible benefit [106] in keeping with evidence of liraglutide (and semaglutide) at a lower dose indicated for type 2 diabetes [107].

Semaglutide is a human GLP-1 analogue with 94% structural homology with native human GLP-1. An amino acid substitution at position 8 makes semaglutide less susceptible to degradation by dipeptidyl peptidase-4, and acylation of the peptide backbone with a spacer and C-18 fatty di-acid chain allows specific binding to albumin giving a half-life of approximately one week, to allow once-weekly administration [108]. Extensively evaluated as a treatment for type 2 diabetes, the Semaglutide Treatment Effect in People with Obesity (STEP) clinical trial programme has investigated higher doses (2.4 mg weekly by subcutaneous injection) in combination with diet and lifestyle advice, in overweight and obesity [109]. In the pivotal STEP 1 trial [110], weight loss after 68 weeks was 14.9% in those on semaglutide compared to 2.4% on placebo. For the trial product estimand (the effect if the drug or placebo was taken as intended), the corresponding changes were –16.9% and –2.4% (estimated treatment difference –14.4%; 95% CI –15.3 to –13.5). One third of individuals lost $\geq 20\%$ of their initial weight on semaglutide compared to 1.7% receiving placebo. Semaglutide produced highly clinically significantly greater reductions in waist circumference and cardiometabolic risk factors. The STEP trials included individuals with pre-diabetes, but not type 2 diabetes who were studied in STEP 2 [102]. The glycaemic effects are shown in Table 18.6. The results of the Semaglutide Effects on Heart Disease and Stroke in Patients with Overweight or Obesity (SELECT) cardiovascular outcome trial in people with overweight and obesity (but not type 2 diabetes) are awaited [111].

Tirzepatide is a dual GIP and GLP-1 receptor agonist developed for the treatment of type 2 diabetes, obesity, and non-alcoholic steatohepatitis. Evaluated and approved for the treatment of type 2 diabetes, the SURMOUNT-1 trial has reported efficacy and safety of tirzepatide 5, 10 and 15 mg weekly by subcutaneous injection, in adults with obesity or overweight who did not have diabetes [112]. After 72 weeks, the mean weight loss was 15.0% with 5 mg weekly doses of tirzepatide, 19.5% with 10 mg, and 20.9% with 15 mg doses compared to 3.1% with placebo. A loss of $\geq 20\%$ was achieved by 57% of those on the highest dose, and over one-third lost $\geq 25\%$; waist circumference reduced by 20 cm. Nearly all with pre-diabetes at baseline reverted to normoglycaemia. All pre-specified cardiometabolic measures improved including blood pressure, fasting insulin, and lipids.

Setmelanotide, a melanocortin-4 receptor agonist, has been developed for use in individuals with severe obesity due to either proopiomelanocortin, proprotein convertase subtilisin/kexin type 1 (PCSK1), or leptin receptor deficiency [113]. While many of these syndromic obesities are associated with the development of type 2

Table 18.6 Headline results of trials exploring the effect of anti-obesity medications in people with pre-diabetes and diabetes.

Medication name	Mode of action	Weight loss-independent effects on diabetes	Impact on individuals with pre-diabetes	Impact on individuals with diabetes

diabetes, the trials did not show statistical glycaemic improvement, but were small and underpowered [114, 115].

Many promising new anti-obesity medications (both novel compounds and combinations such as amylin analogues and GIP + glucagon + GLP-1 tri-agonists) are in clinical development and promise greater weight loss efficacy and/or precision medicine [92].

Bariatric surgery

Bariatric surgery with gastric bypass or sleeve gastrectomy improves glycaemia through a variety of mechanisms other than weight loss alone (Chapter 38). Caloric restriction drives early improved glycaemic homeostasis, but the anatomical alterations of the gut and intestines lead to more rapid delivery of undigested food to the small intestine with subsequent increased release of the gut-derived GLP-1. Exclusion of duodenal nutrient exposure is postulated to produce weight loss-independent effects on glucose homeostasis. Additionally, changes in the gut microbiota may contribute [116]. The Swedish Obese Subjects (SOS) study first showed that 10 years after a variety (some now obsolete) of procedures, mean weight loss of 16.1% was associated with both recovery from (36% vs 13% in controls) and reduction in the incidence of (7% vs 24% in controls) type 2 diabetes [117]. Bariatric surgery is an effective way of obtaining weight loss and improving intermediate glycaemic outcomes in people with type 2 diabetes and obesity class 1 [118, 119]. Recent studies comparing surgery to conventional diabetes treatment suggest that better glycaemic levels can be achieved with surgery, with a substantial proportion of individuals developing prolonged remission from diabetes. A systematic review of the remission rate of type 2 diabetes after gastric bypass and sleeve gastrectomy found that at one year it was higher among those undergoing gastric bypass, at 57%, and 47% of those with sleeve gastrectomy achieved remission. After 2–5 years' follow-up, the remission rate was 50% and 46%, respectively [120]. Many models have been developed and proposed to predict diabetes remission after surgery [121], two of which are well validated with acceptable to excellent discrimination [122]. Whether surgery can or will ever be scaled up sufficiently to meet clinical need, or could be (partially) displaced by new anti-obesity medications that produce nearly equivalent weight losses, remains to be seen.

Management of obesity in type 1 diabetes

A growing problem is the increasing prevalence of obesity in individuals with type 1 diabetes in whom absolute insulin deficiency coexists with insulin resistance due to adiposity, so-called *double diabetes*. The consequences of overweight or obesity in people with type 1 diabetes are worrisome, as diabetes-related and obesity-related complications, including cardiovascular disease, stroke, and various types of cancer, are increased [123]. In one clinic, 64% had a BMI of >25 kg/m² and 25% had a BMI of ≥30 kg/m² [124], while a type 1 diabetes registry in the USA found that 29% of adults had

overweight and 20% obesity [125]. It is postulated that over and above the factors driving weight gain in the general population, in those with type 1 diabetes insulin-intensive therapies, hypoglycaemia avoidance strategies, and possibly changes in growth hormone could exacerbate the difficulties of weight control [123]. While all approaches to treating obesity in people with type 2 diabetes could be applied to those with type 1 diabetes, there is much less evidence on which to assess efficacy and, importantly, safety.

Convergence of obesity and diabetes treatments

Interventions initially designed to treat obesity are increasingly being considered as primary treatment of type 2 diabetes (e.g. bariatric surgery) and, conversely, anti-obesity medications initially developed for type 2 diabetes are (often at higher doses) highly effective medications. Many people living with type 2 diabetes are not on guideline-directed weight loss therapy and a survey found that among 2910 adults with type 2 diabetes who qualified for anti-obesity treatment, only 40 participants (2.2%) were on an anti-obesity medications within 30 days of survey interview [126]. Furthermore, weight loss goals may be compromised by the fact that up to 66% of individuals are receiving weight-inducing anti-diabetes therapy. The now substantial evidence of the impact of weight loss on type 2 diabetes (and many other obesity complications), readily achievable by intensive dietary and lifestyle interventions, anti-obesity medications, or bariatric surgery, should make weight loss a principal, if not primary, goal for the management of type 2 diabetes [127]. Substantial barriers remain. Few healthcare providers reimburse obesity treatment. Even when treatment costs are covered, implicit rationing is commonplace, either of access to bariatric surgery or continued treatment with anti-obesity medications [128]. In the UK, the National Institute for Health and Care Excellence (NICE) recommends an expedited assessment for people with a BMI ≥35 kg/m² with onset of type 2 diabetes in the past 10 years, assessment for people with a BMI of 30.0–34.9 kg/m² with the onset of type 2 diabetes within 10 years, and people of Asian origin with the onset of type 2 diabetes at a lower BMI than other populations [129], yet rates of surgery meet less than 1% of need [130]. Although both obesity and diabetes management guidelines are evolving to recognize the importance of weight management as pivotal to good diabetes care, prejudice and ignorance about treating obesity remain common. In one study of primary care providers randomly assigned to evaluate the records of individuals with either obesity or normal weight, providers who evaluated those with obesity were more likely to rate the encounter as a waste of time and indicated that they would spend 28% less time with the individual with diabetes compared with those who evaluated normal-weight individuals [131, 132]. Endocrinologists are not immune from these views and attitudes [133].

Key points

- The intestinal microbiome is a diverse collection of over 1000 bacterial species that are increasingly recognized as playing critical roles in host function and subsequently health and disease.
- A range of lifestyle and environmental factors, including diet, medication, and hygiene, have been shown to influence the composition of the intestinal microbiome and associations between the microbial composition and both body mass and type 2 diabetes have been reported.
- The intestinal microbiome can influence intestinal permeability and thereby play a regulatory role in the development of metabolic endotoxaemia.
- Metabolic endotoxaemia has the potential to activate immune pathways that interface with insulin signalling pathways and can affect glycaemic levels.

- Microbial metabolites can act locally at the intestinal mucosa to regulate enteroendocrine cell function, incretin signalling, and subsequently glycaemic levels.
- The intestinal microbiome can modulate composition of the bile acid pool and downstream signalling pathways, including farnesoid X receptor (FXR) and G-protein–coupled bile acid receptor (TGR5), to influence glycaemic levels.
- The intestinal microbiota may also contribute to the risk for type 1 diabetes; inappropriate immune education by the microbiota may potentiate autoimmune destruction of pancreatic β cells in genetically susceptible individuals.

The microbiome

The human body is inhabited by a diverse and populous array of microorganisms, termed the microbiome, including bacteria, viruses, fungi, and archaea. The genetic material from this collection of microbes, termed the metagenome, is now estimated to be 150 times larger than that of the human genome [1]. The gastrointestinal tract contains the majority of commensal microbes; however, the urogenital tract, skin, and oral cavity provide niche environments for additional species [2]. Microbes colonize the sterile gastrointestinal tract during birth and are implicated in early-life programming of the immune and metabolic systems, protection from infection, and the synthesis of vitamins, minerals, and fatty acids, which continues throughout the lifespan of an individual [3]. Given its size, diversity of physiological functions, and interactions with other organ systems, the microbiome can be considered as an organ in its own right.

Revised estimates suggest close to 2000 different bacterial species may persist in the gut [1], with the number of bacterial cells exceeding 10^{13} and being as numerous as the total number of host cells in the body [4]. Given the dominance of anaerobic species, early attempts to characterize the diversity of the intestinal microbiome were limited by available sample collection methods and culture techniques [5]. Advances in molecular biology techniques, including use of deep- and next-generation sequencing, have facilitated several large-scale projects, including the European MetaHIT

Project [6] and the National Institutes of Health Human Microbiome Project [7], which have provided additional insights into the diversity of the commensal species. Initially these projects classified 90% of gut bacteria as belonging to either one of two phyla, namely Bacteroides or Firmicutes. Within these two divisions three enterotypes were defined based on variation in either *Bacteroidetes* (enterotype 1), *Prevotella* (enterotype 2), or *Ruminococcus* (enterotype 3) that appeared stable across continents [8, 9]. Classification of stable enterotypes is now considered oversimplified, with the abundance of resident species along the gastrointestinal tract alone displaying up to 90% diversity between individuals in similar geographical locations and thought to be shaped by age, hygiene, medication use, and diet [10].

The microbial species resident in the gastrointestinal tract are increasingly recognized as playing critical roles in host function and subsequently health and disease [11–13]. The synergistic relationship between the intestinal microbiota and host provide several benefits to the host, including (i) resistance to infection by pathogenic microorganisms through direct competition for nutrients and attachment sites and production of antimicrobial substances; (ii) promotion of epithelial cell proliferation and differentiation to maintain an intact mucosal surface; (iii) promotion of the development of the gut-associated lymphoid tissue via initiation of dendritic cell maturation and B- and T-lymphocyte differentiation; and (iv) energy harvest from non-digestible dietary starches [14–18] (Figure 19.1).

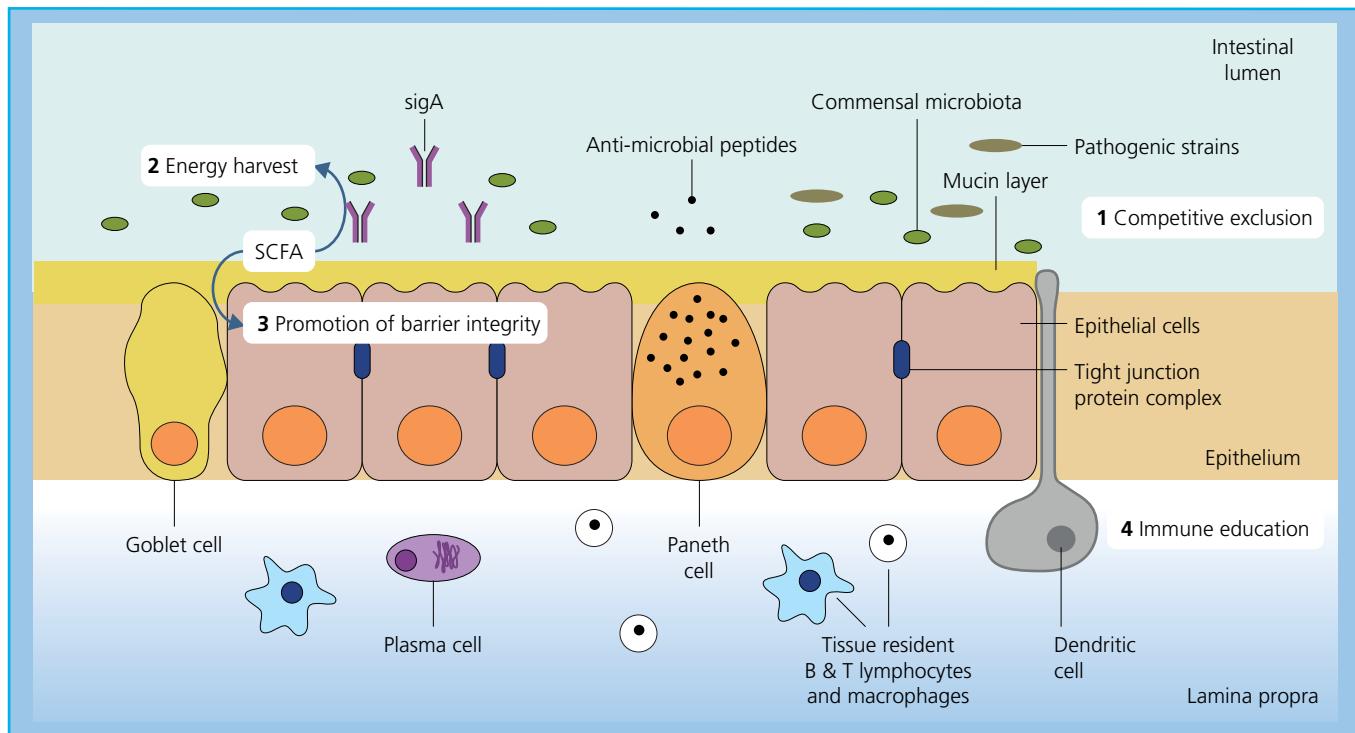

Figure 19.1 A synergistic relationship between the intestinal microbiome and post provides a number of benefits, including (1) competitive exclusion of pathogenic strains; (2) energy harvest; (3) promotion of barrier integrity; and (4) immune education. SCFA, short-chain fatty acids. Source: Modified from Cox et al. 2014 [11].

Bacterial fermentation of non-digestible dietary starch occurs predominantly in the colon [19] and produces short-chain fatty acids (SCFAs; primarily acetate, propionate, and butyrate), which have received particular attention as mediating the beneficial effects provided by the intestinal microbiome. Butyrate in particular is recognized as the main energy source for colonic epithelial cells, and is thought to stimulate blood flow and the secretion of gut hormones, enhance fluid and electrolyte uptake, and increase mucin release, all of which contribute to a local tropic effect, epithelial cell proliferation and differentiation, and maintaining integrity of the intestinal mucosa [20–22]. The application of ‘-omics’ technologies has further broadened knowledge of the roles of the commensal microbial species in host function, with bacterial communities identified with specific roles in regulating biochemical and metabolic pathways [23, 24].

Greater understanding of the role of the microbiota in regulating metabolic function and immune homeostasis has also led to a growing focus on the contribution of the microbiota to risk for diabetes. The composition of the microbiota is altered in obesity and may promote increased extraction of energy from food, altered intestinal permeability, and upregulation of inflammatory signalling. Links between the microbiota and the biochemical processes underpinning the onset and progression of diabetes offer promise that microbial manipulation may be a strategy to reduce the growing burden of associated disease. This chapter will explore the ways in which the intestinal microbiota contribute to diabetes by promoting the accumulation of adipose tissue and altering metabolic and immune homeostasis.

The intestinal microbiome is associated with body mass

Given the documented relationship between excess body mass and risk for type 2 diabetes, links between the intestinal microbiome and excess body mass are of interest when considering the role of

the microbiome in diabetes pathogenesis. In animal models, lower body mass and body fat in germ-free mice compared to wild-type counterparts [25], even following exposure to a high-fat and sugar-rich Western-style diet [26], suggest that the absence of microbial colonization in the gastrointestinal tract impairs energy harvest. Studies involving transplantation of the intestinal microbiota further implicate the microbiome as a contributor to excess body mass; transplantation of wild-type microbiota to germ-free mice normalizes body weight between groups [25], while transplantation of microbiota from obese mice results in an increase in fat mass in germ-free animals [27]. Research examining the transplantation of microbiota from obese or lean human donors into germ-free mice is mixed. One investigation has reported greater weight gain over 50 days in recipient animals receiving obesity-associated microbiota [28]. However, a comparison of three diets including a control diet, Western diet, or 45% high-fat diet in mice with gut microbiota from lean or obese human donors found that after 22 weeks, final body weight or body composition of animals did not significantly differ based on source of human-donor material (lean or obese) [29]. Collectively, these data suggest that particular microbiome profiles may favour accumulation of excess body weight, itself a risk factor for type 2 diabetes.

In humans, direct comparison of the composition of the intestinal microbiota between individuals with overweight and lean individuals has produced mixed findings, likely to be the result of modest sample sizes examined in early studies and inherent variability between individuals in response to other environmental factors [30], in addition to host genetics [31]. A significant decrease in the relative abundance of Bacteroidetes, but an increase in Firmicutes in individuals with obesity, has been reported [32]. Similarly, reductions in overall bacterial diversity [33, 34] and reductions in relative abundance of Bacteroidetes, increased relative abundance of Actinobacteria, but no significant change in Firmicutes between individuals

with obesity and lean individuals have also been observed [34]. However, others report no difference in the dominant phyla [35, 36], and an increased relative abundance of Bacteroidetes in individuals with obesity compared to lean individuals [37]. While these inconsistencies are increasingly acknowledged [38], these studies have revealed that the intestinal microbiota is not static and that the composition of the microbiome can vary both within and between populations.

Dietary intervention studies further support the dynamic nature of the intestinal microbiome. Increased caloric content (2400 or 3400 kcal/d at similar macronutrient profiles; 24% protein, 16% fat, and 60% carbohydrates) in otherwise healthy humans for as little as three days has been reported to increase the abundance of Firmicutes and decrease the abundance of Bacteroidetes [35]. Even more acute changes have been suggested, with a subsequent study in otherwise healthy adults noting changes in the composition of the intestinal microbiota within 24 hours of initiation of a high-fat diet [39]. Changes in the intestinal microbiota in response to weight-reducing diets have also been reported, including reduction in the abundance of some specific Firmicutes species following a four-week low-carbohydrate weight-reducing diet in men with obesity [36] and a decreased relative abundance of Bacteroidetes in men with obesity following a four-week high-protein low-carbohydrate diet [40]. It remains to be determined if alterations in the intestinal microbiota that promote energy harvest are a cause or a consequence of Western diets and excess body mass. However, given the functions of the intestinal microbiota beyond energy harvest, additional mechanisms may also contribute to the risk for obesity and associated disease.

Composition of the intestinal microbiome is altered in type 2 diabetes

Potential contributions of the gut microbiota to the pathogenesis of metabolic syndrome and type 2 diabetes are increasingly recognized [41–44]. Comparison of intestinal microbial composition between individuals with and without type 2 diabetes has traditionally relied on 16s rRNA characterization. Conflicting outcomes in terms of overall microbial diversity are noted; some groups report no difference in overall microbial diversity between individuals with type 2 diabetes and controls [45, 46], while others suggest a decrease in microbial diversity in people with type 2 diabetes [47–49]. Despite the discrepancies relating to microbial diversity, the majority of studies report differences in the relative abundance of specific microbial taxa between people with and without type 2 diabetes [45, 50–52], including decreased relative abundance of specific Bacteroidetes species, such as Bifidobacteria [46, 53] and Bacteroides [47, 54]. The modest sample sizes (groups from 8 to 64 individuals) employed in some of the earlier studies and the degree of species identification possible using 16s rRNA methodologies are recognized limitations in the field and have limited the wider application of such observations.

However, the adoption of full metagenome sequencing methodologies in response to reduced costs has provided greater insights into altered microbial composition in type 2 diabetes. Notable studies include those performed in an ethnic Chinese type 2 diabetes case-control cohort ($n = 345$) in a two-stage design [55]; in a cohort of almost 3000 European women classified into those with type 2 diabetes, impaired glucose tolerance, or normal glucose metabolism [56]; in a cohort of people with treatment-naïve type 2 diabetes, pre-diabetes, and normal glucose tolerance ($n = 254$) [57]; and a multi-ethnic cohort ($n = 784$) with stratification of individuals with type 2 diabetes based on metformin treatment [58]. All studies report

differences in the abundance of specific bacterial taxa in individuals with type 2 diabetes compared to those without diabetes. Consistent observations include enrichment of opportunistic pathogens, including *Eggerthella* species and *Escherichia coli* [55, 57], as well as *Lactobacillus* species [56, 58] and depletion of known butyrate producers including *Faecalibacterium prasnitzii*, *Roseburia* species, and *Eubacterium* species [55–58] in individuals with type 2 diabetes relative to controls. Beyond microbial composition, metagenome analysis allows for inferences of potential collective microbial function. For the studies mentioned, and consistent with the compositional observations, decreased potential for butyrate biosynthesis has been noted in individuals with type 2 diabetes [55], along with increased potential for membrane transport of sugars [55, 56] and upregulation of a range of genes involved in oxidative stress pathways [55, 56]. In addition, these studies have been able to use combinations of metagenome markers to successfully predict type 2 diabetes status [55–57], providing further support for the relationships between the gut microbiome and risk of type 2 diabetes.

The intestinal microbiome can influence intestinal permeability

A permeable intestinal mucosa is necessary to facilitate critical absorptive functions, but maintenance of barrier exclusion is essential in isolating the intestinal microbiota within the intestinal lumen. The interaction between various integral membrane proteins and cytoskeletal components provides a structural framework to maintain integrity of the intestinal mucosa via intercellular tight junctions. The intestinal microbiota has been suggested to contribute to the ongoing remodelling of the mucosal epithelium [59, 60] and the direct roles of particular microbial metabolites, including tryptophan metabolites, in regulating mucosal barrier function are also recognized [61, 62]. *In vitro* experiments utilizing cultured intestinal epithelial cells have demonstrated that treatment with commensal and probiotic microbial species [63, 64] or a *Faecalibacterium prasnitzii*-derived protein preparation [65] elicit upregulation and increased phosphorylation of key tight junction proteins and reductions in paracellular permeability. Likewise, colonization of germ-free mice with probiotic species has been shown to result in the upregulation of key tight junction proteins [66] and normalization of intestinal barrier function in animal models of disease [66, 67]. Further, human clinical studies involving manipulation of the intestinal microbiota via probiotic supplementation report outcomes that include increased tight junction protein expression in collected duodenal biopsy samples [68], decreased faecal excretion of the key tight junction protein zonulin [69], and reductions in intestinal permeability assessed using a dual-glucose absorption test [70, 71], all suggesting preserved integrity of the intestinal mucosa mediated by the intestinal microbiota. Conceivably, altered composition of the intestinal microbiota reported in obesity could impact adversely on intestinal permeability and contribute to translocation of the intestinal microbiota to the circulation and subsequent systemic responses that may contribute to an increased risk for type 2 diabetes.

Metabolic endotoxaemia

Regardless of the initiating sequence of events, alterations in intestinal permeability have the potential to trigger metabolic endotoxaemia. Metabolic endotoxaemia describes modest concentrations

of bacterial lipopolysaccharide (LPS) in the systemic circulation in the absence of infectious stimuli [72]. LPS is a cell wall component of Gram-negative bacterial species and the intestinal microbiota represents a significant reservoir for LPS entry into the circulation. The appearance of LPS in the circulation has been proposed to result from passive diffusion across an intestinal mucosa where tight junction integrity has been compromised and intestinal permeability increased [73]. Active transport pathways have also been implicated in metabolic endotoxaemia. LPS has been found to be incorporated in chylomicron fractions [74, 75], suggesting that active absorption across the intestinal mucosa as part of normal digestion and absorption may also account for the appearance of LPS in the circulation.

Indeed, diet has been one factor shown to influence LPS translocation across the intestinal mucosa. A dose-dependent relationship between dietary fat content (40–70% total caloric content over four weeks) and plasma endotoxin levels has been reported in several murine feeding studies [72, 76]. The same murine model has also shown that antibiotic treatment, resulting in a decreased intestinal microbial load, attenuates the increase in plasma LPS concentrations following the four-week high-fat feeding [77] and provides further confirmation that the intestinal microbiota is a critical component of metabolic endotoxemia. Likewise, attenuation of the increase in plasma LPS concentrations following a 14-week high-fat (70%) diet has also been reported in a mouse model where the diet was supplemented with a fermentable dietary fibre [78], thought to preserve the integrity of the intestinal mucosa, further implicating intestinal permeability as a determinant of metabolic endotoxaemia.

An association between dietary composition and metabolic endotoxaemia has also been reported in human studies. Acute increases in plasma LPS have been reported within one [79, 80] to three hours [81] following consumption of a high-fat meal by otherwise healthy volunteers, with elevations persisting for up to five hours post-prandially [82], and greater post-prandial excursions in LPS also reported in individuals who subsequently develop overt type 2 diabetes [83]. Further, dietary fat content was significantly correlated with plasma LPS concentrations in an epidemiological study of 201 healthy middle-aged men [76] and a small feeding study demonstrated that, even among healthy volunteers ($n = 8$), a month long Western-style (40% fat) diet was associated with significant (~70%) increases in plasma LPS [84]. These data support the potential for dietary habits associated with risk for obesity and obesity-associated disease to also trigger translocation of the intestinal microbial contents to the circulation.

Metabolic endotoxaemia in type 2 diabetes

While the relationships between obesity, diet, and metabolic endotoxaemia have received particular attention, epidemiological data also implicate circulating endotoxin in risk for type 2 diabetes. Higher plasma LPS concentrations have been reported in both adults with impaired fasting glucose relative to healthy controls [85] and those with overt type 2 diabetes [86–88]. In addition, a larger analysis involving the FINRISK97 cohort of ~6600 Finnish adults found that circulating endotoxin concentrations at baseline were significantly higher in the individuals with type 2 diabetes and were predictive of those who developed overt type 2 diabetes over the 10-year follow-up period [89]. Likewise, another prospective study, which quantified total 16s rDNA concentration present in the circulation, as a surrogate of intestinal permeability, at baseline and following nine years of follow-up, found that higher baseline con-

centrations were predictive of type 2 diabetes development over follow-up [90]. Given these relationships, understanding the physiological responses to increased transit of microbial moieties across the gut mucosa may provide further insight into the pathogenesis of type 2 diabetes.

While the impact of sepsis on glucose metabolism has been established [91, 92], ethical and logistical challenges mean that few studies have directly manipulated plasma LPS and/or the intestinal microbiota as a way to establish causality for type 2 diabetes. However, LPS infusion in a mouse model has been shown to induce changes in insulin sensitivity and glucose levels, supporting a causal role for metabolic endotoxaemia in type 2 diabetes development [72]. Chronic low-dose subcutaneous LPS infusion (300 µg/kg/d) over four weeks elicited increases in fasting glucose and insulin, impaired glucose clearance in response to an oral glucose load, and increased hepatic gluconeogenesis, all suggesting the loss of glycaemic control [72]. In healthy humans, the acute effects of intravenous LPS infusion (20 U/kg ~2 ng/kg total dose) have been assessed during a 10-hour euglycaemic hyperinsulinaemic clamp protocol and significant reductions in glucose utilization were noted [93]. Subsequent studies have also reported decreases in insulin sensitivity and increased insulin resistance in response to low-dose LPS infusion protocols [94, 95], further implicating LPS as a causal factor in the development of insulin resistance.

Modulation of the intestinal microbiome can alter in insulin sensitivity

Beyond these seminal studies implicating bacterial LPS as an initiating factor in impaired glucose metabolism, direct modulation of the intestinal microbiota also affects indices of glucose homeostasis. Use of antibiotic treatment over periods ranging from two to eight weeks in genetically modified phenotypically obese mice (*ob/ob*) [77, 96] and in diet-induced obesity models [97, 98] modulates the gut microbial composition, reduces the level of endotoxaemia, and elicits improvements in indices of glucose metabolism. Further, a growing number of studies also support the potential for probiotic supplements to have positive effects on glucose metabolism. Single-strain probiotic supplements administered over 14 weeks of high-fructose feeding and over eight weeks in a diabetic rat model were associated with lower fasting glucose and insulin and improved glucose clearance following a glucose tolerance test [99], and lower fasting insulin and homeostatic model assessment for insulin resistance (HOMA-IR) [100], respectively. Similarly, in high-fat fed mice, improved glucose clearance after glucose tolerance tests has been reported following *Lactobacillus* single-strain probiotic supplementation over 5 [101] and 10 weeks [102], and also in response to dual- [103] and multistrain supplements [104]. Collectively, these data support the potential for modulation of the intestinal microbiota to mediate improvements in insulin sensitivity.

Findings from antibiotic studies have yet to be widely replicated in humans in the context of glucose metabolism. A recent meta-analysis assessing the impacts of antibiotics on metabolic status in adults with obesity includes just two placebo-controlled trials, with effects that are largely unclear [105]. The effects of probiotic supplementation have also been assessed in a series of human clinical studies. While not all probiotic supplementation trials have been able to demonstrate definitive benefits on glycaemia [106, 107], early positive findings included improved insulin sensitivity following four weeks of probiotic supplementation in a cohort of adults with overweight ($n = 45$) and a range of glucose tolerance [108].

In addition, two trials from the same laboratory report reductions in fasting glucose, fasting insulin, and HOMA-IR in a cohort of overweight adults [109] and in otherwise healthy young adults [110] following six weeks of probiotic supplementation. A series of recent meta-analyses also support modest, but beneficial, effects of probiotics on measures of glycaemic metabolism in individuals with type 2 diabetes [111–114]; however, selection of specific strains likely to have the greatest efficacy is unresolved.

The application of faecal microbial transplantation as a further strategy for modulation of the gut microbiota in obesity and metabolic disease is of growing interest [115–117]. However, there remain few human clinical studies assessing indices of metabolic health as primary outcomes. An early study involving men with metabolic syndrome administered either an autologous gut microbiota duodenal infusion ($n = 9$) or an allogenic gut microbiota duodenal infusion from healthy lean donors ($n = 9$) and reported improvements in peripheral insulin sensitivity and a trend towards reduced endogenous glucose production six weeks following allogenic infusion only [118]. A subsequent investigation from the same team, also involving men with obesity and metabolic syndrome ($n = 38$) and utilizing a similar design reported that improvements in peripheral insulin sensitivity observed at 6 weeks were not maintained at 18 weeks, and noted that low baseline microbial diversity was predictive of positive metabolic responses among recipients of faecal microbial transplantation [119].

Microbial metabolites may be key mediators linking the gut microbiota and insulin signalling pathways. Serum metabolite signatures, specifically increased abundance of branched-chain amino acids (BCAAs), which are unable to be synthesized by humans and therefore must be obtained from the diet or derived from microbial metabolism, have been associated with insulin resistance in two independent studies [120, 121]. In a series of follow-up experiments utilizing a high-fat fed murine model, the authors of one study demonstrated that challenging mice with *Prevotella copri*, a species identified as synthesizing BCAAs, over three weeks resulted in increased circulating BCAA concentrations and exacerbated insulin resistance [121]. Another metabolite, imidazole propionate, which is a byproduct of the microbial metabolism of dietary histidine, was also found at higher circulating concentrations in individuals with type 2 diabetes and was associated with severity of insulin resistance [122]. Interestingly, in a murine model, administration of imidazole propionate impaired glucose tolerance independent of changes in insulin concentrations; subsequent *in vitro* experiments revealed alterations in phosphorylation of the insulin receptor substrate (IRS) and activation of the mechanistic target of rapamycin complex (mTORC1) in response to imidazole propionate [123]. These insights provide early evidence of a causal link between the gut microbiota and alterations in insulin signalling pathways.

The microbiome contributes to type 2 diabetes risk via innate immune pathways

As a key component of Gram-negative pathogenic strains, LPS is recognized by pattern recognition receptors that play a critical role in the activation of immune and inflammatory pathways. Immune responses to circulating LPS are well characterized in models of infection and sepsis, but activation of similar signalling pathways would also be anticipated in metabolic endotoxaemia and understanding these pathways provides insights into how the intestinal microbiota contribute to risk for type 2 diabetes. Regardless of the trigger for LPS translocation, once in the circulation LPS binds to

LPS-binding protein (LPB), a constitutively expressed plasma protein, which facilitates the interaction between LPS and various receptors and binding sites. Among these receptors are the toll-like receptor 4 (TLR4) cell surface molecule and its associated co-receptor, cluster of differentiation 14 (CD14). TLR4 activation initiates an extensive intracellular signalling cascade that initially involves recruitment of the MyD88 adaptor protein and activation of IL-1R1-associated protein kinases (IRAKs) [124], which can trigger (i) subsequent phosphorylation of IKB kinase (IKK-B), the degradation of IKB and NF-KB translocation to the nucleus to facilitate transcriptional regulation of inflammatory mediators, including interleukin (IL)-1, tumour necrosis factor (TNF)- α , and IL-6 [125]; and (ii) c-Jun NH2-terminal kinase (JNK) activation [126]. Interestingly, saturated fatty acids also act as ligands for TLR4 [124] and provide an additional stimulus for initiating these same signalling pathways in obesity.

The crosstalk between TLR4 and insulin signalling pathways provide a mechanism linking the intestinal microbiota to insulin resistance (Figure 19.2). Classic insulin signalling pathways involve a complex series of phosphorylation events initiated by the interaction between insulin and its cell surface receptor. Receptor-ligand binding triggers the autophosphorylation of the intracellular domain of the insulin receptor and subsequent phosphorylation (predominantly at tyrosine residues) of the intracellular IRS family members with additional kinase activity, including Akt involvement, culminating in the exocytosis of glucose transporters to the cell surface to facilitate glucose uptake [127]. Insulin signalling can be regulated by a negative feedback loop where phosphorylation of IRS members (predominantly at serine/threonine residues) inhibits further signal transduction, essentially impeding further cellular glucose uptake [128, 129]. Insulin signalling pathways also contribute to the regulation of glycogen synthesis (via glycogen synthase activation [127]) and regulation of metabolic pathways (via transcription factor regulation [128]) and in this way contribute to glucose homeostasis more globally beyond cellular glucose uptake.

Signalling cascades initiated by LPS-TLR4 binding have the potential to regulate the insulin signalling pathways at multiple points. Notably, JNK activation downstream of TLR4 activation can trigger phosphorylation of IRS members at serine/threonine residues, inhibiting further insulin signalling [130, 131]. Additional triggers have been identified for JNK activation and subsequent disruption of insulin signalling, notably endoplasmic reticulum (ER) stress [132, 133]; while these pathways are also relevant in understanding the pathogenesis of type 2 diabetes, particularly in the context of obesity and nutrient excess, there is little evidence suggesting direct modulation by the intestinal microbiota. However, inflammatory cytokines secreted in response to TLR4 signalling and as part of the unfolded protein response can signal back to cells in an autocrine or paracrine fashion and, via their own cell surface receptors, trigger further activation of the JNK pathway, contributing to a cycle of persistent amelioration of insulin signalling [134, 135].

Indeed, studies involving animal knockout models, loss-of-function mutations, and receptor antagonists provide support for the involvement of the TLR4 and JNK pathways in linking the microbiome and insulin resistance. Animal models involving TLR4 mutants or knock-outs [136, 137] and a human clinical trial involving infusion of an anti-CD14 antibody [138, 139] all demonstrate attenuated inflammatory responses to LPS exposure, confirming the role of TLR4/CD14 signalling in mediating the inflammatory response to LPS exposure. Similarly, the murine model mentioned earlier whereby LPS infusion was sufficient to trigger changes in insulin sensitivity and glucose

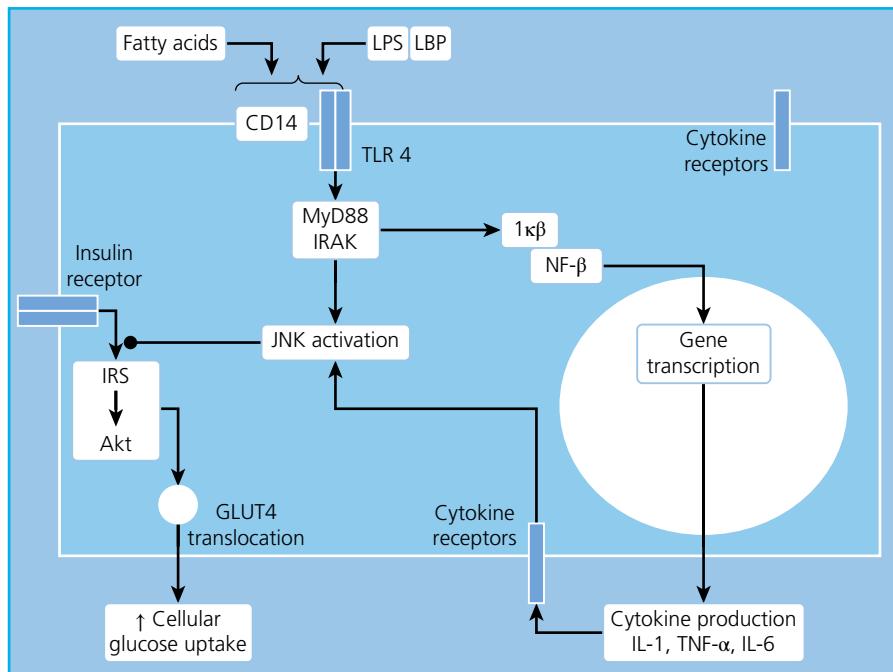

Figure 19.2 Components of the intestinal microbiota (namely lipopolysaccharide, LPS) have the potential to activate innate immune pathways. Crosstalk between toll-like receptor 4 (TLR4) and insulin signalling pathways provides a mechanism linking the intestinal microbiota to insulin resistance. CD14, cluster of differentiation 14; GLUT4, glucose transporter 4; IL, interleukin; IRAK, IL-1R1-associated protein kinases; IRS, insulin receptor substrate; JNK, c-Jun NH₂-terminal kinase; LBP, lipopolysaccharide-binding protein; LPS, lipopolysaccharide; TNF, tumour necrosis factor.

levels also demonstrated that this series of responses was attenuated in CD14-deficient mice [72]. These findings are consistent with those from a murine model with a TLR4 loss-of-function mutation and utilizing a high-fat feeding protocol; the downregulated TLR4/CD14 signalling pathway was protective for metabolic dysregulation and was associated with attenuated IKKB and JNK signalling [140]. Similarly, JNK knockout mice are protected from insulin resistance triggered by high-fat feeding [141] and in an obese diabetic mouse model administered a JNK inhibitory peptide, lower fasting glucose and insulin concentrations and improved insulin sensitivity in response to glucose and insulin tolerance tests have been reported [142]. While these findings are from animal studies only, collectively these data highlight key signalling pathways that link the intestinal microbiome and risk for type 2 diabetes.

The microbiome contributes to type 2 diabetes risk via modulation of enteroendocrine cell function

Beyond the purported roles of bacterial fermentation products in promoting colonocyte health [143], identification of the signalling pathways via which SCFAs may contribute to metabolic regulation further implicate the intestinal microbiome in the pathogenesis of type 2 diabetes. SCFAs have been identified as ligands for a series of G-protein-coupled receptors (GPCRs) expressed on the intestinal epithelium as well as by adipose tissue and immune cells [144]. SCFAs differentially activate various GPCRs: propionate shows the highest affinity for GPR41 (also known as free fatty acid receptor 3) and GPR43 (also known as free fatty acid receptor 2), acetate for GPR43, and butyrate for GPR41 and GPR109A [145]. Activated downstream signalling pathways include those implicated in enteroendocrine cell function [146, 147], as discussed shortly (Figure 19.3), as well as the regulation of immunity and inflammation [148], which has the potential to influence insulin signalling pathways.

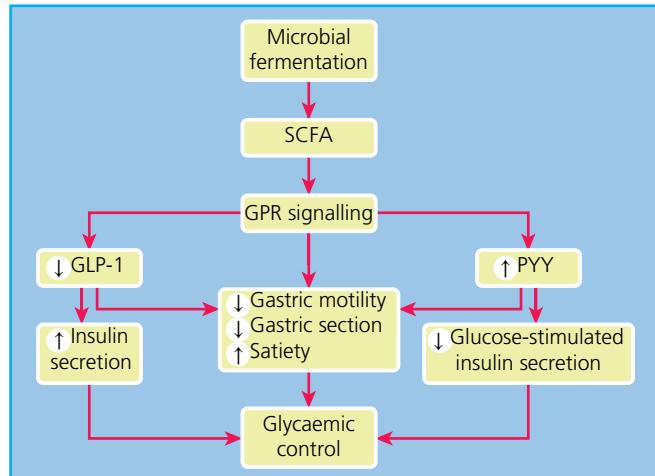

Figure 19.3 Short-chain fatty acids (SCFA) are produced during microbial fermentation of non-digestible dietary starches. SCFA signalling via G-protein-coupled receptors (GPR) can regulate incretin signalling, namely glucagon-like peptide 1 (GLP-1) and polypeptide YY (PYY), with downstream effects on glycaemic levels.

Potential regulation of enteroendocrine function, particularly glucagon-like peptide-1 (GLP-1) and polypeptide YY (PYY) secretion, may be especially relevant when considering the role of the intestinal microbiome in type 2 diabetes pathogenesis. GLP-1 and PYY are co-secreted from enteroendocrine cells resident in the colonic mucosa in response to nutrient sensing [149, 150]. Some effects of GLP-1 and PYY are similar, including attenuation of gastrointestinal motility and gastric acid secretion [149, 151] and induction of satiety, likely via centrally mediated mechanisms [152, 153]. However, GLP-1 and PYY have opposing effects on insulin secretion. GLP-1 acts to increase glucose-stimulated insulin secretion [151, 152], whereas PYY has been shown to inhibit glucose-stimulated insulin release from the pancreas [154]. Both GLP-1 and PYY undergo enzymatic cleavage by dipeptidyl peptidase (DPP)-4; for

GLP-1 this plays a role in clearance of the active form [155], but for PYY this generates the biologically active form [154]. Given the documented effects of GLP-1 and PYY in the context of glucose metabolism, it is not surprising that both GLP agonists and DPP-4 inhibitors have been developed for the treatment of type 2 diabetes [156].

The potential for the intestinal microbiome, via SCFA, to modulate GLP-1 and PYY secretion [157] represents a further pathway via which the intestinal microbiome may contribute to risk insulin resistance and type 2 diabetes. *In vitro* and animal models and human supplementation studies support this possibility. In primary colonic cultures from wild-type mice, treatment with SCFA induced GLP-1 secretion, an effect that was attenuated in tissue from GPR41 and GPR43 knockout mice [147]. Similarly, more pronounced impairments in plasma GLP-1 in response to oral glucose load were noted in the knockout animals [147], further supporting SCFA-induced signalling via GPR41/43 as a key trigger for incretin secretion. Additional studies in rodent models assessing both GLP-1 and PYY responses to SCFA reported similar outcomes for both primary colonic cultures [158] and isolated perfused colon preparations [159]. Interestingly, use of prebiotic fermentable fibre supplements, to increase colonic production of SCFAs, have not resulted in increased GLP-1 or PYY secretion in acute single-meal interventions [160, 161]. However, several small-scale studies in otherwise healthy adults have reported higher glucose-induced plasma concentrations of PYY [162] and GLP-1 [163, 164] following 2–12 weeks of prebiotic supplementation. Similarly, a 6-week prebiotic supplementation study in adults with overweight or obese also found increased post-prandial GLP-1 and PYY secretion at the end of the intervention period [165], while a longer 12-month supplementation study involving hyperinsulinaemic adults ($n = 40$) and supplementation with dietary high-fibre cereal (a form of non-digestible starch and a substrate for the intestinal microbiota) reported significant increases in plasma SCFAs and increases in both basal and post-prandial GLP-1 concentrations [166]. These data generally support an association between SCFA and GLP-1 and PYY, and highlight the need for further consideration of the value of modulation of the intestinal microbiota to mitigate disrupted incretin signalling in metabolic disease.

The microbiome contributes to type 2 diabetes risk via modulation of bile acids

The role of bile acids in lipid digestion and absorption is well established, with bile acid turnover providing a pathway for cholesterol excretion [167]. Beyond these actions, regulatory roles of bile acids in glucose metabolism have also been acknowledged. Bile acid composition has been associated with features of insulin resistance in European adults [168] and altered bile acid composition has also been noted in adults with diabetes [169, 170]. Further, over recent years, clinical trials have demonstrated the effects of bile acid sequestrants on glucose metabolism. A pair of meta-analyses have both reported positive effects of bile acid sequestrants on measures of glucose metabolism, including fasting blood glucose and HbA_{1c} [171, 172], which broadly supports an association between regulation of the bile acid pool and glucose control.

While the exact mechanisms linking the bile acid pool and glucose metabolism are yet to be fully defined, two pathways have received particular attention (Figure 19.4). Bile acids are known ligands for the nuclear receptor farnesoid X receptor (FXR), which activates the transcription factor short heterodimer protein (SHP) [173] and regulates the expression of a number of genes involved in bile acid synthesis and metabolism, thereby establishing a feedback loop facilitating bile acid self-regulation [167, 174, 175]. FXR-mediated signalling has been associated with glucose homeostasis [167]. FXR receptor knockout mice have impaired plasma glucose clearance in response to both glucose and insulin tolerance tests [176, 177]. Conversely, administration of FXR agonists in a diabetic mouse model decreases fasting glucose and insulin [178], suggesting preserved insulin sensitivity. In both settings, intracellular signalling pathways were also examined and either decreased (in the FXR knockouts) or increased (in response to FXR agonist) Akt phosphorylation was reported [176, 178], suggesting that FXR signalling may contribute directly to regulation of insulin signalling pathways. Other studies have implicated FXR in the downregulation of genes involved in hepatic gluconeogenesis [177, 179], as well in glucose-induced insulin secretion from pancreatic β cells

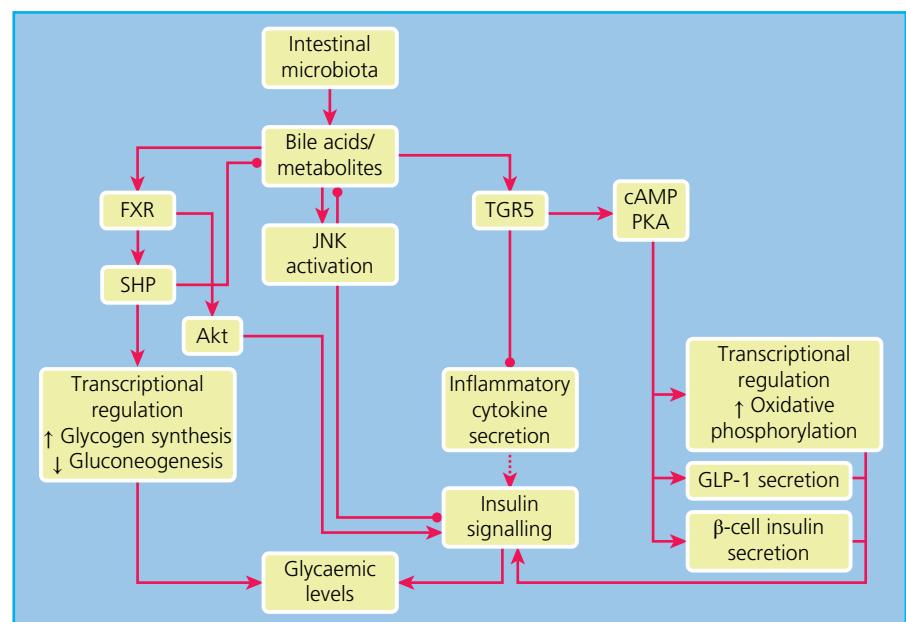

Figure 19.4 The intestinal microbiome influences composition of the bile acid pool and metabolites. Bile acid signalling through the farnesoid X receptor (FXR) and the G-protein-coupled receptor (TGR5) pathways can affect transcriptional regulation of various metabolic pathways. Regulation of other signalling pathways can also contribute to alterations in glycaemic control. cAMP, cyclic adenosine monophosphate; GLP-1, glucagon-like peptide 1; JNK, c-Jun NH₂-terminal kinase; PKA, protein kinase; SHP, short heterodimer protein.

[180, 181], providing further mechanisms via which bile acids may contribute to insulin resistance.

In addition to signalling via FXR, bile acids have also been identified as a ligand for the G-protein-coupled bile acid receptor (TGR5) [182, 183]. Activated intracellular signalling pathways are thought to involve protein kinase A and the cyclic AMP response element binding protein, which can regulate gene expression and allows for a range of downstream effects [174]. In the context of insulin resistance, *in vitro* models have shown that bile acid signalling can induce GLP-1 secretion from enteroendocrine and primary intestinal cell cultures, with small interfering RNAs and TGR5 agonists confirming that these responses are mediated via TGR5 activation [184, 185]. Animal models also support a role for TGR5 signalling in mediating glucose homeostasis [186]. Use of selective TGR5 agonists in high-fat fed mice decreases plasma glucose and insulin and improves glucose clearance rates in glucose tolerance tests [187, 188]. Further, TGR5 overexpression in a transgenic mouse model resulted in improved glucose clearance rates in a glucose tolerance test and augmented post-prandial GLP-1 and insulin secretion, whereas glucose tolerance and GLP-1 secretion were impaired in TGR5 knockout animals [188]. In some human clinical studies involving bile acid sequestrants, GLP-1 responses have been shown to parallel changes in insulin sensitivity [189], further supporting GLP-1 as a link between bile acid signalling and risk for diabetes. Finally, evidence suggesting that TGR5 activation by bile acids may have inhibitory effects on inflammatory cytokine production [183, 190] provides a further mechanism via which bile acid signalling may indirectly contribute to the regulation of insulin signalling pathways.

Given the potential for bile acids to contribute to glucose regulation, modulation of the bile acid pool by the intestinal microbiota provides another interface between the microbiota and risk for diabetes. While enterohepatic circulation recovers a large proportion of secreted bile acids from the distal ileum, a proportion reach the large bowel where the microbiota catalyse a series of reactions, including deconjugation, dehydrogenation, and dehydroxylation reactions, resulting in the formation of secondary bile acids [191, 192]. Secondary bile acids may themselves contribute to the feedback inhibition of bile acid synthesis and secretion, and other downstream effects via the FXR and TGR5 signalling pathways [193, 194]. Animal models support the involvement of the intestinal microbiota in modulation of the bile acid pool, with the composition of the bile acid pool shown to differ between germ-free and conventionalized animals in both rodent [195] and murine models [196]. Further, in several rodent and murine models, antibiotic treatment modulates the composition of the bile acid pool in favour of primary bile acids [197, 198] and upregulates FXR signalling pathways [199, 200]. Modulation of the intestinal microbiota in humans also influences composition of the bile acid pool. Of particular interest is a seven-day antibiotic intervention in 20 men with obesity, whereby a reduction in faecal secondary bile acids was noted and alterations in bile acid composition were correlated with alterations in peripheral insulin sensitivity pre- to post-intervention [201]. These findings have been broadly replicated in a larger cohort ($n = 57$) of men with overweight or obese [202]. Gut microbial manipulation via probiotic and prebiotic intervention also alters bile acid metabolism. In one study involving 134 adults with overweight or obese in a parallel (four) group design, a reduction in plasma concentrations of specific primary and secondary conjugated bile acids were reported following six months of supplementation with a synbiotic supplement [203]. Similarly, a placebo-controlled crossover trial of three probiotic supplements over six-week intervention periods in adults with

obesity ($n = 103$) resulted in increases in total plasma deconjugated bile acids in response to *Bacillus subtilis* and *Bifidobacterium animalis* subspecies *lactis* supplements [204]. Although the bile acid signalling pathways are complex, effects on glucose levels are plausible and, given the established roles of the intestinal microbiota in regulating the composition of the bile acid pool, contributions of the intestinal microbiota to risk for type 2 diabetes via these pathways cannot be discounted.

Type 1 diabetes

It would be remiss to ignore a potential role of the intestinal microbiota in the pathogenesis of type 1 diabetes. While the precise mechanisms and molecular signalling pathways remain under investigation, support for the interplay between the intestinal microbiota, intestinal permeability, and immune aberrations in initiating the autoimmune destruction of pancreatic β cells continues to grow [205, 206]. Reduced microbial diversity and differences in the composition of the intestinal microbiota between individuals with and without type 1 diabetes are documented [207], suggesting, at minimum, an association between the intestinal microbiota and type 1 diabetes risk. Studies involving germ-free animal models that report increased type 1 diabetes incidence [208] support the importance of a robust intestinal microbiome in mitigating type 1 diabetes risk. Similarly, animal models demonstrating that modulation of the intestinal microbiota, using either antibiotics [209] or probiotic supplementation [210], results in delayed onset and reduced incidence of diabetes provide further evidence in support of a potential link between gut microbiome and type 1 diabetes risk. Alterations in intestinal permeability have also been noted in both animal models of type 1 diabetes [211, 212] and human clinical studies [213, 214], and provide insight into the mechanisms that may link the intestinal microbiome and type 1 diabetes. Given the identified roles of butyrate-producing bacterial strains in promoting the integrity of the intestinal mucosa [66, 67], alterations in microbial composition may underpin diminished mucosal integrity in type 1 diabetes. Increased intestinal permeability and associated translocation of LPS and other antigens across the mucosal surface may trigger aberrations in immune regulation and the development of autoimmune responses in genetically susceptible individuals.

The role of the microbiota in shaping host immune development can also not be overlooked in the context of type 1 diabetes risk. The increased prevalence of type 1 diabetes in developed nations has been interpreted by some to support the hygiene hypothesis, whereby inappropriate immune development in response to limited microbial exposure is considered a risk factor for the development of autoimmunity [215]. Immunological aberrations reported previously in type 1 diabetes include reduction in FoxP3+ regulatory T cells (Tregs) in the intestinal mucosa [216], reduction in peripheral Tregs [217] and natural killer (NK) T cells [217], and dysregulated cytokine signalling, suggestive of impaired T-cell function [218] in individuals with type 1 diabetes. T helper 17 (Th17) responses have also received particular attention for their roles in inflammatory control and autoimmune disease [219, 220], and an upregulation of peripheral Th17 cells has been reported in individuals with type 1 diabetes [221]. Of further interest is the growing recognition of the role of the intestinal microbiota in regulating Th17 and Treg phenotypes [222, 223]; although the precise mechanisms underpinning these effects are yet to be elucidated,

these associations do further implicate the intestinal microbiome, via modulation of the immune system, in risk for type 1 diabetes.

Conclusion and perspectives

Given the considerable size of the metagenome and associated metabolic machinery, it is not surprising that the interface between intestinal microbiome and human host has the potential to have impacts on health, including risk for disease. The potential for crosstalk between the microbiome and immunological and metabolic pathways is relevant in type 2 diabetes; activation of innate immune pathways, modulation of enteroendocrine cell function,

and regulation of metabolic signalling pathways by the microbiome all have the potential to disrupt insulin signalling pathways and contribute to impaired glucose metabolism. In the context of type 1 diabetes, inappropriate immune education by the microbiome may potentiate autoimmune destruction of pancreatic β cells in otherwise susceptible individuals, thereby increasing risk. Given the increasing prevalence of both type 1 diabetes and type 2 diabetes, particularly in the developed world, understanding the molecular mechanisms by which the microbiome contributes to risk for diabetes may prove beneficial in the development of additional risk-stratification tools. Further, the potential to manipulate the composition of the microbiome may enhance existing treatment and management strategies.

4 Other Types of Diabetes

20

Monogenic Causes of Diabetes

Brittany L. Resnick¹, Maggie H. Shepherd^{1,2}, and Andrew T. Hattersley²

¹Exeter NIHR Clinical Research Facility, Royal Devon University Healthcare NHS Foundation Trust, Exeter, UK

²Institute of Biomedical and Clinical Science, University of Exeter Medical School, Exeter, UK

Key points

- Monogenic diabetes should be suspected where:
 - presentation is atypical for type 1 diabetes or type 2 diabetes;
 - there is an autosomal dominant family history or maternally inherited diabetes in mitochondrial disorders;
 - there are characteristic associated features such as deafness in mitochondrial diabetes or fat loss in lipodystrophy; or
 - diabetes has been diagnosed within the first six months of life.
- Variants in the glucokinase gene, which is important in sensing blood glucose levels in the pancreas, result in resetting of fasting glucose to a higher level (5.5–8.0 mmol/l; 90–145 mg/dl). People with glucokinase variants have dominantly inherited mild fasting hyperglycaemia with only modest changes in glycated haemoglobin. Complications are rare and no treatment is needed.
- Variants in the transcription factor genes *HNF1A* and *HNF4A* result in dominantly inherited progressive hyperglycaemia with symptomatic diabetes in adolescence or young adulthood. People with *HNF1A* or *HNF4A*

diabetes are very sensitive to sulfonylurea treatment and may not require insulin until middle or old age.

- Mitochondrial variants can result in maternally inherited diabetes, often with bilateral sensorineural hearing loss and a range of other disorders.
- Diabetes diagnosed before 6 months of age is very unlikely to be type 1 diabetes and a genetic cause should be sought even where the person is now an adult. High-dose sulfonylurea treatment is often more effective than insulin where variants affecting Kir6.2 and SUR1 subunits of the β-cell potassium channel are identified.
- Acanthosis nigricans is the key feature of insulin resistance and a genetic cause should be considered where there is no concomitant obesity. Partial lipodystrophy results in thin muscular limbs with hypertriglyceridemia and insulin resistance and suggests a variant in *LMNA* or *PPARG*. In the absence of lipodystrophy, an insulin receptor variant is the commonest cause.

Monogenic diabetes results from inheritance of one or more variants in a single gene and accounts for 1–3% of diabetes cases diagnosed under the age of 30 years. Variants may be inherited in a dominant or recessive fashion. The majority (90%) of monogenic diabetes cases are initially misdiagnosed as type 1 diabetes or type 2 diabetes. Correct genetic diagnosis is important to predict clinical course, explain other associated clinical features, enable genetic counselling, diagnose family members, and most importantly guide appropriate treatment.

Monogenic diabetes where the primary disorder affects the β cell has four main clinical presentations:

- Familial mild fasting hyperglycaemia (glucokinase maturity-onset diabetes of the young, MODY).
- Familial young-onset diabetes (transcription factor MODY).
- Neonatal diabetes.
- Diabetes with extra-pancreatic features.

Clinical and biochemical features that help differentiate the common forms of monogenic diabetes that result in β-cell dysfunction from type 1 diabetes and type 2 diabetes are summarized in Table 20.1. Classification and key features of monogenic diabetes are further summarized in Figure 20.1 and their role in β-cell physiology is depicted in Figure 20.2. Single-gene variants may also cause diabetes through insulin resistance, as occurs in the inherited

lipodystrophies and insulin receptor variants. A number of monogenic multisystem diseases (e.g. haemochromatosis and cystic fibrosis) may cause diabetes; these are beyond the scope of this chapter and are discussed elsewhere (Chapter 23).

Maturity-onset diabetes of the young

MODY is autosomally dominantly inherited diabetes that, despite a young age of onset, is not insulin dependent [2, 3]. It results from β-cell dysfunction rather than insulin resistance [2]. The underlying genetic aetiology has now been defined, allowing MODY to be sub-classified according to the gene involved [4, 5]. Variants in at least 11 genes have been linked to MODY [1, 6, 7]. These include variants in the gene encoding the glucose-sensing enzyme glucokinase (*GCK*) and variants in several transcription factors that affect β-cell development and function, the frequencies of which are summarized in Figure 20.3. Clinical presentation varies greatly depending on the underlying genetic variant. Table 20.2 summarizes the clinical features of glucokinase and transcription factor diabetes. The strikingly different subtypes of MODY mean it is important to define the underlying genetic aetiology. We recommend the use of clinical categories based on underlying genetic cause, for example familial mild fasting

Part 4 Other Types of Diabetes

Table 20.1 Differentiating β -cell monogenic diabetes from type 1 diabetes and 2 diabetes.

Features	Type 1 diabetes	Young type 2 diabetes	GCK MODY	HNF1A MODY	MIDD	K _{ATP} PNDM
Optimal treatment	Insulin	OAD	None	Low-dose SU	Insulin	High-dose SU
Parent affected	2–4%	Usually (may have both parents affected)	Yes	Yes	Mother	15%
Typical age of onset	6 mo to adult	Adolescent and young adult	Birth (may be diagnosed at any age)	Adolescent to young adult	Young adult	Under 6 mo
Obesity	Pop freq	Yes	Pop freq	Pop freq	Rare	Pop freq
Acanthosis nigricans	No	Yes	No	No	No	No
Glycaemia	High	Variable	Mild	High	Variable	High
β -cell autoantibodies	Yes (90% of cases)	No	No	No	No	No

GCK, glucokinase; HNF1A, hepatocyte nuclear factor 1A (HNF4A is similar); MIDD, maternally inherited diabetes and deafness; MODY, maturity-onset diabetes of the young; OAD, oral anti-diabetes drugs; PNDM, permanent neonatal diabetes; Pop freq, population frequency (frequency of obesity seen in the general population); SU, sulfonylureas.

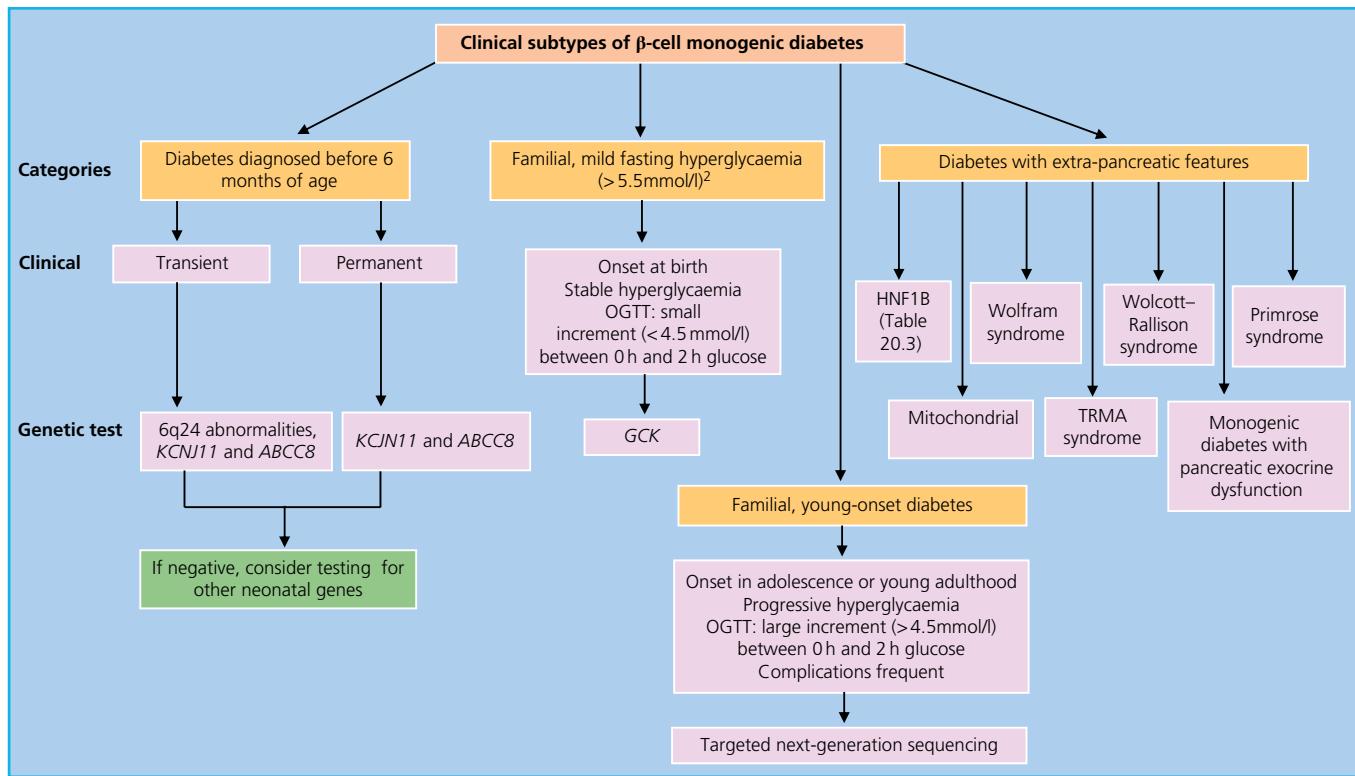

Figure 20.1 Clinical subtypes of monogenic β -cell diabetes. To convert plasma glucose measurements to mg/dl, multiply by 18. ABCC8, ATP binding cassette subfamily C; GCK, glucokinase gene; HNF, hepatocyte nuclear factor; KCNJ11, potassium inwardly rectifying channel, subfamily J, member 11 gene; OGTT, oral glucose tolerance test; TRMA, thiamine responsive megaloblastic anaemia.

hyperglycaemia resulting from glucokinase gene variants (GCK MODY), familial young-onset progressive diabetes resulting from HNF1A and HNF4A variants (transcription factor MODY), and renal cysts and diabetes syndrome (RCAD) resulting from HNF1B variants.

Variants in the genes associated with MODY should be considered in people with diabetes diagnosed under 25 years of age who do not fully fit the phenotypes of type 1 diabetes or type 2 diabetes and who have a strong family history of diabetes (Table 20.1). Differentiating from apparent type 1 diabetes is particularly important, as these individuals can often be most effectively treated without the use of injected insulin. The differentiation of MODY from other types of diabetes is challenging and attention has turned to

strategies that will enable better stratification of those requiring genetic testing, which include the use of a probability calculator (available at www.diabetesgenes.org to view and to download as a phone application), measurement of C-peptide and autoantibodies, as well as advances in genetic testing that allow panels of genes to be tested simultaneously using targeted next-generation sequencing.

Prevalence of MODY variants

MODY was previously indicated to have a minimum population prevalence of 108 cases per million, but this was recognized as an underestimate [8]. Prevalence estimates from large systematic surveys are between 1% and 3% of young-onset diabetes; in the UK Using

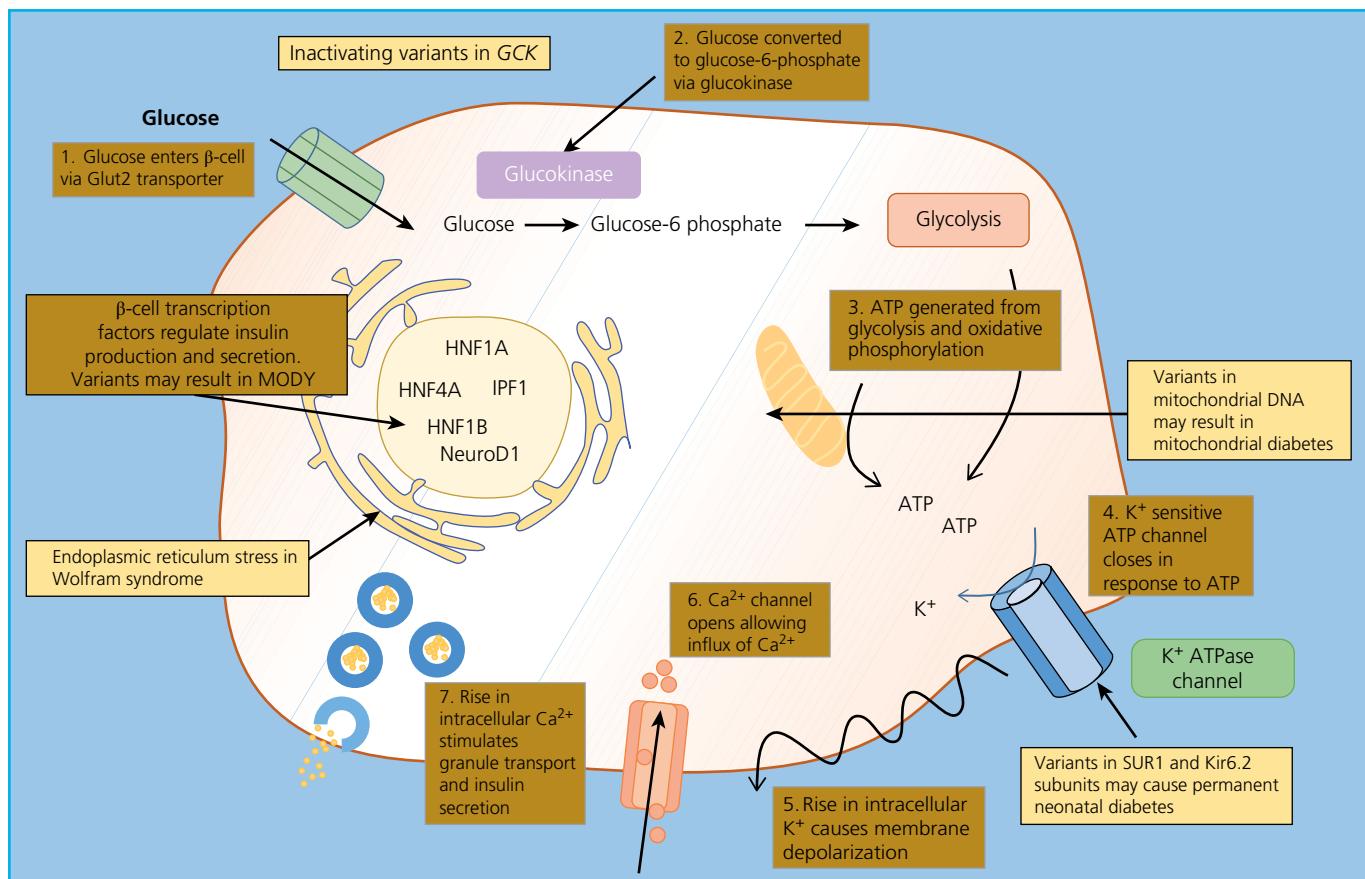

Figure 20.2 Schematic of β-cell depicting key steps in glucose sensing and insulin secretion (brown boxes) and transcription factors, enzymes, organelles, and protein channels that may, if mutated, be a cause of monogenic diabetes (pale yellow boxes). ATP, adenosine triphosphate; GCK, glucokinase gene; MODY, maturity-onset diabetes of the young. Source: Adapted from Fajans et al. [1].

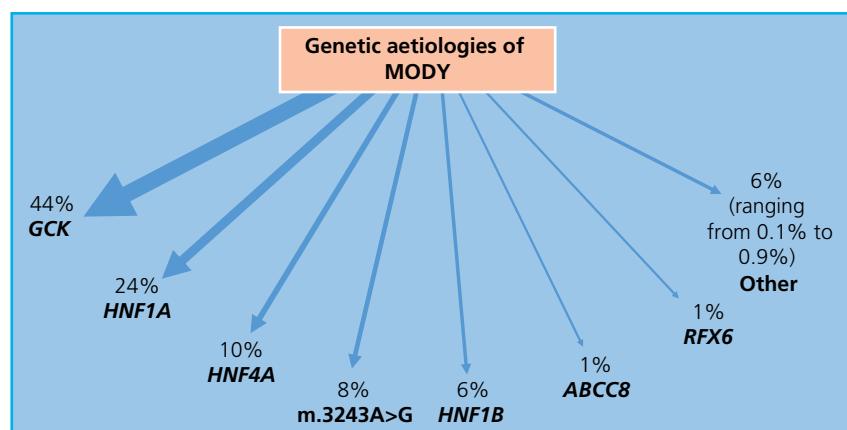

Figure 20.3 The different genetic aetiologies in a UK maturity-onset diabetes of the young (MODY) series from the Exeter Molecular Genomics Laboratory at the Royal Devon and Exeter NHS Foundation Trust, UK, from 2015 to 2020. Other includes *WFS1*, *INSR*, *PPARG*, *INS*, *LMNA*, *PDX1*, *KCNJ11*, *NEUROD1*, *GATA6*, *SLC19A2*, and *TRMT10A* subtypes. Source: Personal communication from Kevin Coldough.

pharmacogeNetics to Improve Treatment in Early-onset Diabetes (UNITED) study, 3.6% of all diabetes diagnosed <30 years of age [9] and 2.5% of all diabetes diagnosed <20 years of age were MODY [10], while the SEARCH for Diabetes in Youth study undertaken in the USA found that 1.2% of all cases diagnosed under 20 years of age were MODY [11]. A population study based on screening pregnant women estimated the glucokinase prevalence to be 1.1 in 1000 population prevalence (or 1100 cases/million population) [12], suggesting that most people with glucokinase variants are not coming to medical

attention or are not being diagnosed. Based on previous estimates of MODY prevalence, 80–90% of cases were likely to be misdiagnosed or unrecognized, highlighting the need for improved case finding.

Strategies to improve case finding

The key approach to diagnosing MODY is to consider whether there are clinical features that are unusual for type 1 diabetes and type 2 diabetes and to undertake genetic testing in these individuals to confirm monogenic diabetes (Figure 20.4). Though the cost of

Part 4 Other Types of Diabetes

Table 20.2 Comparison of the clinical characteristics of glucokinase and transcription factor maturity-onset diabetes of the young (MODY).

	Glucokinase MODY	Transcription factor MODY
Onset of hyperglycaemia	Birth	Adolescence/early adulthood
Presentation	Usually asymptomatic, detected by screening or on routine testing	Usually symptomatic
Nature of hyperglycaemia	Minimal increase in glycaemia with age Mild (FPG usually 5.4–8.3 mmol/l) HbA_{1c} 40–60 mmol/mol (5.8–7.6%)	Progressive deterioration of glycaemia with age May be severe (FPG frequently >14 mmol/l off treatment) HbA_{1c} variable depending on age and treatment, may be high
Pattern in an oral glucose tolerance test	FPG >5.5 mmol/l (2 h FPG) 2 h increment usually <3.5 mmol/l	FPG often <5.5 mmol/l (2 h FPG) 2 h increment usually >3.5 mmol/l
Microvascular complications	Rare	Frequent
Pathophysiology	β -cell defect (glucose sensing defect)	β -cell defect (initially insulin secretion maintained at normal glucose values but not increased in hyperglycaemia)
Extra-pancreatic manifestations	Altered birth weight	See Table 20.3
Treatment	Pharmacological treatment rarely needed	Sensitive to sulfonylurea treatment May progress to require insulin

FPG, fasting plasma glucose – to convert plasma glucose measurements to mg/dl multiply by 18; HbA_{1c} , glycated haemoglobin.

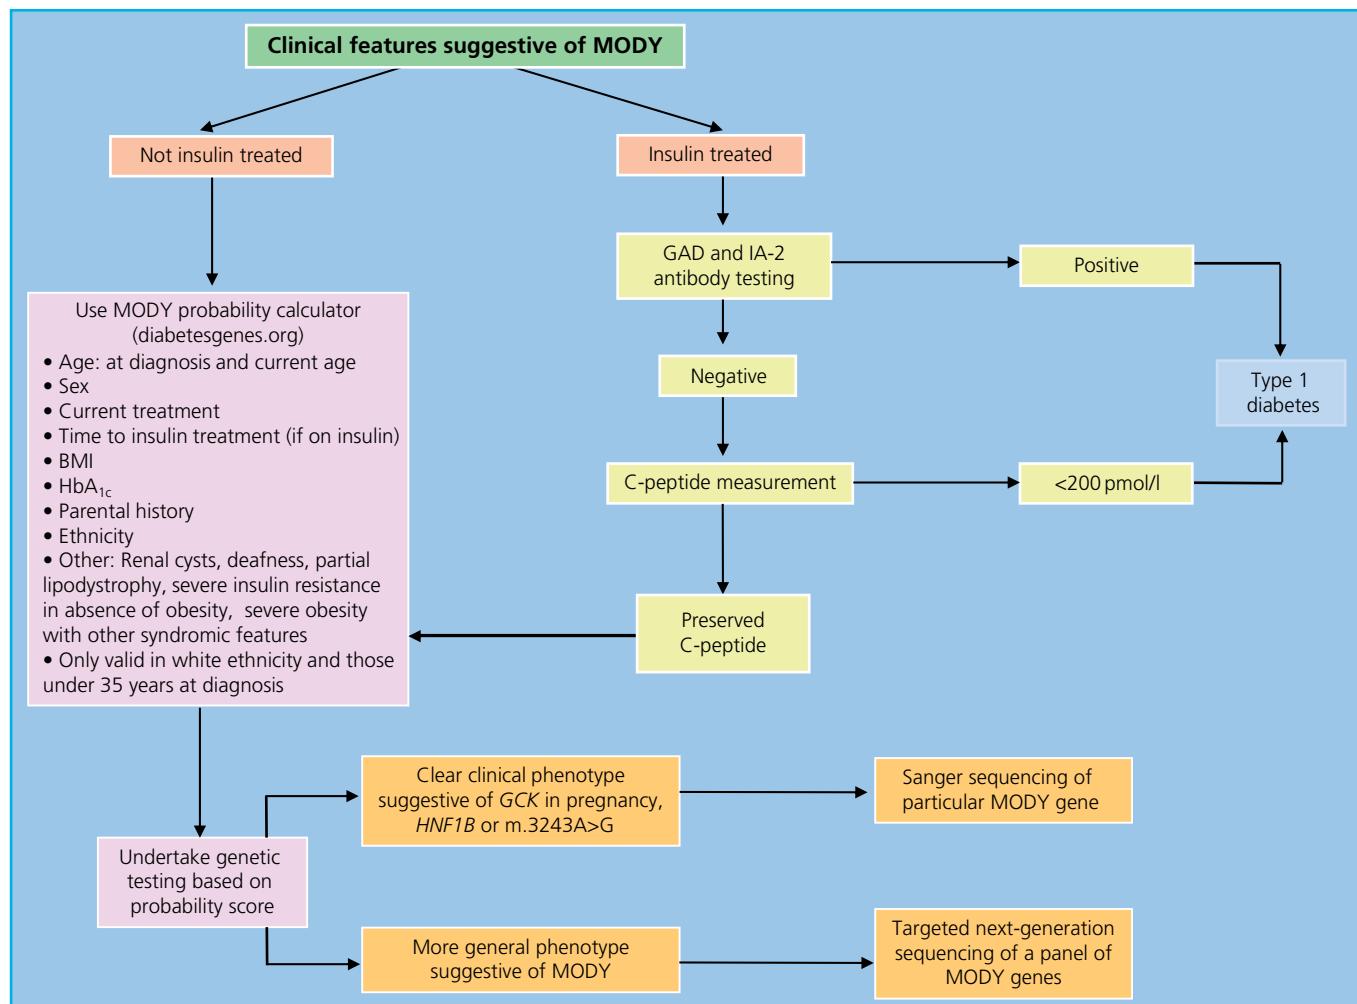

Figure 20.4 An approach to genetic testing in people with suspected MODY mutations. BMI, body mass index; GAD, glutamic acid decarboxylase; HbA_{1c} , glycated haemoglobin; IA-2, islet antigen 2. Source: Shields et al. [13] and De Franco et al. [14].

molecular testing continues to fall, it is still relatively expensive and it is therefore recommended that testing is restricted to those individuals with a moderate to high possibility of a positive result. Traditional clinical features, such as age at onset, a parental history of diabetes, and non-insulin treatment, overlap considerably between MODY and other types of diabetes [8] and therefore independently have poor discriminatory value.

A MODY probability calculator (available at www.diabetesgenes.org) offers an excellent way to establish if a diagnosis of MODY is likely: it combines clinical information to predict the probability of testing positive for MODY [13]. The calculator markedly improved the sensitivity and specificity of identifying MODY compared with standard criteria of diagnosis age <25 years with an affected parent.

Biomarkers such as C-peptide measurement, pancreatic autoantibodies, lipid profiles, and high-sensitive C-reactive protein (CRP) all have some discriminatory value in differentiating cases of MODY from other subtypes; however, they are not without limitations [15–20]. Pancreatic autoantibodies are positive close to diagnosis in approximately 90% of people with type 1 diabetes if glutamic acid decarboxylase (GAD), islet antigen 2 (IA2), and zinc transporter 8 (ZnT8) antibodies are measured, compared to only 1% of those with MODY [17]. A negative test does not exclude type 1 diabetes, especially as with increasing duration of diabetes antibody positivity is lost. Testing pancreatic autoantibodies in people treated with insulin is therefore of value, if positive, in excluding MODY. The presence of preserved C-peptide secretion in a person with type 1 diabetes of long duration may also help stratify those in whom MODY testing should be considered; however, 8% of people with long-term type 1 diabetes have stimulated C-peptide levels of >200 pmol/l [21]. Utilization of non-invasive urinary C-peptide to creatinine ratios assists in differentiating MODY from type 1 diabetes and avoids the need for blood samples [16]. In the paediatric population, the Swedish Better Diabetes Diagnosis (BDD) study found that absence of all pancreatic autoantibodies and modest hyperglycaemia (glycated haemoglobin [$\text{HbA}_{1\text{c}}$] 58 mmol/mol; <7.5%) at diagnosis of diabetes were discriminatory clinical features of MODY from type 1 diabetes and should lead to genetic testing [22]. This again emphasizes that antibody testing is helpful since a positive result excludes MODY.

New discriminatory tools have been developed to aid differentiation of MODY from type 1 diabetes, including the type 1 diabetes genetic risk score [23]. The type 1 diabetes genetic risk score is generated by genotyping common genetic variants associated with an increased risk of type 1 diabetes and summing their effective weight into a numerical score [23, 24].

Use of diagnostic and pre-symptomatic molecular testing in monogenic diabetes

Diagnostic testing for the major causes of monogenic diabetes is now widely available. Molecular genetic testing is traditionally guided by the clinical phenotype and also the relative prevalence of variants within that population. A good example of this approach is in people with a very specific clinical phenotype, where Sanger sequencing of the selected gene alone may be pragmatic, for example GCK testing in someone with fasting hyperglycaemia or *HNF1B* testing in a person with renal cysts and diabetes. However, for other types of monogenic diabetes, for example transcription factor MODY or neonatal diabetes, it may be difficult to predict the

affected gene using clinical features alone. In the past this would have resulted in sequential testing of multiple genes, with associated delays in obtaining a diagnosis. Advances in DNA sequencing technologies now mean that panels of genes can be tested simultaneously using next-generation sequencing platforms without the considerable costs and time associated with earlier sequencing approaches [14, 25] and these are consequently replacing traditional single gene-targeted testing [26]. However, Sanger sequencing of a selected gene may still have value for specific individuals, for example GCK testing in a pregnant woman with mild fasting hyperglycaemia, in whom a rapid GCK test result would guide management of pregnancy.

Some caution is needed, as monogenic diabetes can occur in families that also have type 1 diabetes or type 2 diabetes. For similar reasons, the results of molecular genetic testing should be interpreted in the context of the clinical findings, for example a person with glucokinase diabetes could also develop type 1 or type 2 diabetes.

Where a family member has a confirmed genetic diagnosis, phenotypically unaffected relatives can be tested to assess whether they will be at risk of developing diabetes in the future. However, recommendations vary depending on the gene affected. In families with GCK MODY, screening of family members is not indicated as no follow-up or treatment is required. In *HNF1A* MODY families, annual urine testing for glycosuria in unaffected family members may be considered. In other types of monogenic diabetes, annual $\text{HbA}_{1\text{c}}$ may be preferred to pre-symptomatic genetic testing, as even when a positive genetic test result is identified in a family member without diabetes it is not possible to accurately predict when the diabetes will develop. Where families request testing of members without diabetes, they should receive comprehensive genetic counselling on the potential benefits and disadvantages and be allowed to make their own decisions on the most appropriate option for them.

Glucokinase MODY

Glucokinase catalyses the phosphorylation of glucose to glucose-6-phosphate, the first and rate-limiting step in intracellular glucose metabolism in both β cells and hepatocytes (Figure 20.2). Owing to the unique catalytic properties of the enzyme, the rate of glucose phosphorylation is proportional to the glucose concentration, thus allowing β cells and hepatocytes to respond to changes in glycaemia. In the β cell, glucokinase acts as a glucose sensor, ensuring insulin release is appropriate to the glucose concentration [27]. Heterozygous loss-of-function variants in GCK result in a shift of the dose-response curve to the right [28]. Glycaemia is therefore regulated at a higher set-point, but remains tightly controlled. People with glucokinase variants are still able to stimulate their β cells maximally [28]. Glucokinase is also present in the liver and as a result these individuals have reduced hepatic glycogen synthesis [29]. Over 900 pathogenic variants have been identified that cause GCK MODY [30]. Homozygous loss-of-function glucokinase variants are a rare cause of insulin requiring diabetes presenting in the neonatal period [31]. Gain-of-function variants cause congenital hyperinsulinism [32].

Clinical features

People with GCK MODY, due to heterozygous loss-of-function variants, have mild fasting hyperglycaemia from birth, usually 5.4–8.3 mmol/l (97–149 mg/dl), and $\text{HbA}_{1\text{c}}$ results range between 40

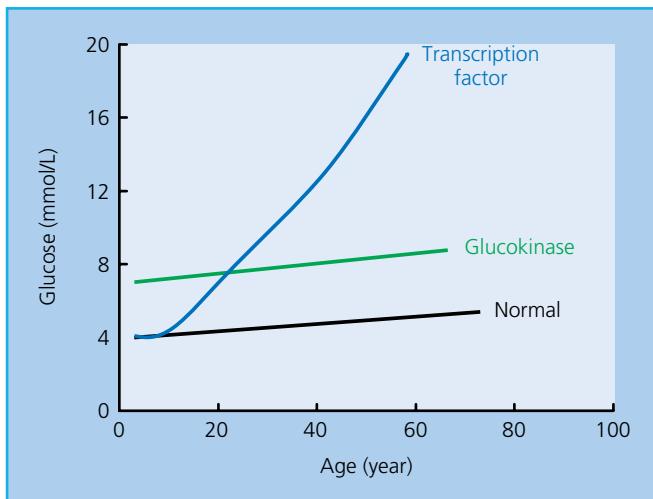

Figure 20.5 Variation of blood glucose concentration with age in people with glucokinase and transcription factor maturity-onset diabetes of the young.
Source: Steele et al. [33] and Hattersley [35].

and 60 mmol/mol (5.8–7.6%) [33,34]. There is only a minor increase in HbA_{1c} with age, but this is also seen in older healthy people (Figure 20.5) [33, 34]. People with GCK MODY do not typically have symptoms of hyperglycaemia. Post-meal glucose values are only mildly raised and there is frequently only a small increase (<3 mmol/l in 70% [36] and <4.6 mmol/l in 90% [37] of those with GCK MODY) seen at two hours on an oral glucose tolerance test, which may explain the near-normal HbA_{1c} and rarity of complications [38, 39]. Glycated haemoglobin values above 60 mmol/mol (7.6%) would be suggestive of an alternative diagnosis and marked worsening of the glycaemia suggests the development of type 1 diabetes or type 2 diabetes in addition to GCK MODY. Microvascular and macrovascular complications are not seen, even when mild hyperglycaemia is present for 50 years [39]. Almost all individuals with GCK will have an affected parent; however, as glucokinase MODY is asymptomatic there may be no known family history of diabetes, despite its autosomal dominant inheritance. Testing of apparently unaffected parents can reveal that one parent has mildly raised fasting plasma glucose.

Differentiating from type 1 diabetes and 2 diabetes

Diagnosis of glucokinase MODY is most important in young individuals who may otherwise be thought to have type 1 diabetes and treated with insulin [40]. Unlike type 1 diabetes, hyperglycaemia remains mild and β -cell antibodies are expected to be negative; these individuals are only likely to be positive for antibodies in the same proportion as the normal population. Fasting C-peptide will remain detectable and the post-meal rise in glucose concentration will be far less than in type 1 diabetes. Differentiating glucokinase MODY from type 2 diabetes can be challenging, as both conditions can cause mild hyperglycaemia with a family history. Lack of obesity and absence of insulin resistance, a raised fasting glucose with a mild post-prandial rise, HbA_{1c} 40–60 mmol/mol (5.8–7.6%), and non-progression over time all suggest glucokinase MODY.

Management

Outside pregnancy, anti-diabetes medication is not recommended as hyperglycaemia is mild, significant microvascular complications are not seen, and medication does not lower glucose because the

homeostatic regulation of glycaemia is preserved [41, 42]. Once diagnosis is confirmed, all diabetes treatment should be discontinued and no follow-up is required [34, 43]; however, this should be done with caution as it is possible for type 1 diabetes or type 2 diabetes to coexist with a GCK variant.

Glucokinase MODY and pregnancy

Clinical features

Women with GCK variants are frequently found to have hyperglycaemia during screening in pregnancy and represent 2% of white European women with gestational diabetes [12, 34, 44]. Their identification is important because they have a different clinical course than others with gestational diabetes. The birth weight of the newborn infant will depend on the variant status of both the mother and the fetus (Figure 20.6). Where only the mother carries the variant, maternal hyperglycaemia may result in increased fetal insulin secretion and growth, causing the fetus to be large for gestational age [45]. Infants that do not inherit the maternal GCK gene variation are at increased risk of macrosomia and its associated obstetric complications [46]. If the fetus inherits the variant from the father, however, birth weight is reduced by approximately 500 g as a result of reduced fetal insulin secretion and insulin-mediated fetal growth [45]. If both mother and fetus have the GCK variant, the two opposing effects are cancelled out and the newborn infant is of normal weight, provided that maternal blood glucose has been left untreated.

Genetic testing for GCK variants in pregnancy

We recommend testing for GCK variants when a pregnant woman is found to have persistently raised fasting plasma glucose, 5.4–8.3 mmol/l (97–149 mg/dl), both during or outside pregnancy. An absence of family history should not exclude the diagnosis, as asymptomatic hyperglycaemia in a parent may not have been detected. Genetic testing of women with a body mass index (BMI) <25 kg/m² and a fasting blood glucose >5.5 mmol/l (>100 mg/dl) has a sensitivity of 68% and on average 2.7 women will need to be tested to identify one case of GCK MODY [12].

Management

Women with hyperglycaemia resulting from glucokinase variants are often treated with insulin during pregnancy in an attempt to

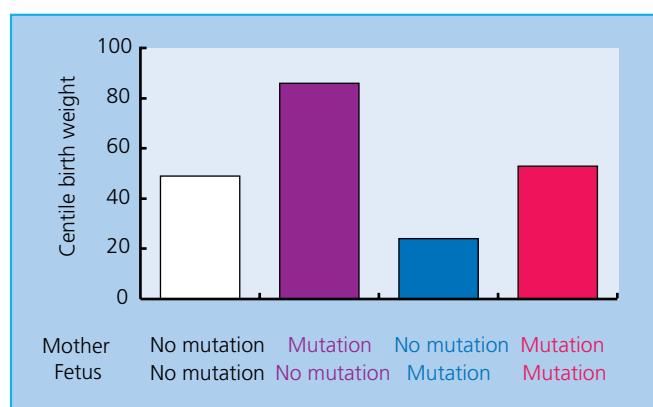

Figure 20.6 The centile birth weight of children in families with glucokinase variants. The weight is increased by the presence of a maternal variant and decreased by the presence of a fetal variant. Source: Data from Hattersley et al. [45].

correct the fasting hyperglycaemia. Fetal genotype, however, is a far greater determinant of fetal birth weight than maternal treatment and insulin appears to have little effect on fetal growth [46]. This probably reflects the difficulty in lowering the blood glucose in women with GCK MODY because of increased counter-regulation [47]. Women stop producing their own insulin and produce counter-regulatory hormones if blood glucose is reduced to normal levels, making successful control of blood glucose with insulin difficult. This results in frequent hypoglycaemic symptoms at non-hypoglycaemic blood glucose concentration and means that large doses of insulin may be required to reduce fasting hyperglycaemia to normal levels [47, 48]. In some cases where the fetus has inherited the variant, intensive insulin treatment has resulted in a low-birth weight child [48]. This is to be expected, as a small baby is seen when the fetus inherits a variant from the father and is born to a normoglycaemic mother [45, 49].

At present treatment decisions in glucokinase gestational diabetes are related to fetal growth as shown by ultrasound scans, rather than being made solely on maternal glycaemia [48]. If the abdominal circumference is greater than the 75th centile, insulin may be used, but early delivery is the most successful strategy [34]. Testing fetal genotype *in utero* is not without risk and is not recommended unless amniocentesis or chorionic villus sampling is being undertaken for an alternative reason [50]. However, assays to detect cell-free fetal DNA (cffDNA) in maternal serum have recently been developed to allow non-invasive fetal genotyping, which can be used to determine appropriate treatment for maternal hyperglycaemia and identify pregnancies at risk of macrosomia [51]. The test is highly sensitive and specific (86.8% and 100%, respectively [51]), with no reported false positives or false negatives. Further guidelines for the management of pregnancy in individuals with GCK variants are available at www.diabetesgenes.org.

HNF1A and HNF4A (Transcription factor MODY)

Transcription factors are proteins that bind to DNA and form part of a complex regulatory network controlling gene expression. The majority of people with MODY have a heterozygous variant in a transcription factor gene, by far the commonest being variants in the hepatic nuclear factors 1A and 4A (*HNF1A* and *HNF4A*). Diabetes resulting from variants in other transcription factor-encoding genes including *HNF1B* and insulin promoter factor 1 (IPF-1) are discussed elsewhere in this chapter.

Transcription factor variants alter insulin secretion in the mature β cell as well as altering β-cell development, proliferation, and cell death. Variants in the hepatic nuclear factors alter levels of proteins critical in metabolism, including the glucose transporter GLUT2 and key enzymes in the mitochondrial metabolism of glucose [52–54]. Reduced β-cell proliferation and preserved or increased apoptosis could explain the progressive deterioration in β-cell function seen in these individuals [54–57]. Variants in *HNF1A* account for up to 70 % of cases of MODY, with over 500 different variants reported [30]. In the UK, variants in *HNF4A* account for approximately 10 % of MODY cases [8].

Clinical features

Heterozygous transcription factor variants cause autosomal dominant diabetes presenting in adolescence or early adulthood resulting from progressive failure of insulin secretion. While diabetes is

similar in *HNF1A* and *HNF4A* variant carriers, as a result of a common pattern of β-cell dysfunction, several differences in extra-pancreatic features occur (Table 20.3).

Diabetes

People with transcription factor MODY are usually born with normal glucose tolerance and then show progressive β-cell dysfunction until they develop diabetes, usually aged 10–30 years (Figure 20.5). Of *HNF1A* carriers, 63% are diagnosed with diabetes by the age of 25 years and 79% by the age of 35 years. The age of diagnosis is partly related to the location of the underlying variant within the gene [58–60]. The age of diagnosis is earlier in people with *HNF1A* than *HNF4A* [7]. Those who show deteriorating glycaemia with age require pharmacological treatment. In the oral glucose tolerance test in those with *HNF1A* MODY, in contrast to people with glucokinase variants, the fasting glucose is often normal initially, but there is marked elevation of glycaemia at two hours and consequently a large two-hour increment (>5.0 mmol/l; 90 mg/dl) [36]. This occurs because insulin secretion rates in early *HNF1A* MODY remain appropriate, with blood glucose values <8.0 mmol/l (145 mg/dl); however, when blood glucose levels rise above 8.0 mmol/l, the insulin secretion rates are reduced significantly in comparison to non-variant carriers without diabetes and result in a rise in blood glucose levels [61]. Microvascular complications are frequent particularly when hyperglycaemia is inadequately treated [62]. People with transcription factor MODY tend to be lean and insulin sensitive; obesity occurs at similar levels to the normal population.

Extra-pancreatic clinical features

These are summarized in Table 20.3 and discussed in more detail in the following.

HNF1A

People with *HNF1A* variants have elevated levels of high-density lipoprotein (HDL) cholesterol, which contrasts with the reduced HDL levels seen in type 2 diabetes [63]. Despite this, they have a greater risk of coronary heart disease than people with type 1 diabetes. Frequency of microvascular complications is similar to that seen in type 1 and type 2 diabetes and relates to glycaemic levels [62]. *HNF1A* variants are associated with a reduced renal threshold

Table 20.3 Extra-pancreatic features assisting in the differential diagnosis of transcription factor maturity-onset diabetes of the young (MODY).

Transcription factor	Extra-pancreatic clinical features
<i>HNF1A</i>	Low renal glucose threshold (glycosuria) Raised HDL cholesterol Raised cardiovascular risk (in excess of type 2 diabetes) Liver adenomas
<i>HNF4A</i>	Increased birth weight or macrosomia Neonatal hypoglycaemia Low HDL cholesterol, low lipoprotein A1 and A2, raised LDL cholesterol
<i>HNF1B</i>	Renal cysts and renal development disorders and multiple others. See Table 20.5
<i>NeuroD1</i>	None described

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

for glucose. Variant carriers without diabetes may develop glycosuria after a glucose challenge even if glycaemia remains within normal limits [64]. Individuals with *HNF1A* variants have a greater risk of liver adenomatosis and its complications, including acute intra-abdominal haemorrhage [65]. Screening for liver adenomas, in people with *HNF1A* variants with no clinical features suggesting adenomas, needs to be considered carefully, as there is no treatment that can be offered at present.

HNF4A

HNF4A variants are associated with an 800 g increase in birth weight compared with non-variant-carrying siblings [66]. This means that the offspring of *HNF4A* variant-carrying fathers, as well as the offspring of *HNF4A* mothers, are at risk of macrosomia. There is also an increased risk of hypoglycaemia in affected neonates. These features relate to increased insulin secretion *in utero* and in early infancy, which evolves into reduced insulin secretion and diabetes in later life [66]. Recently, cffDNA testing has become available to determine fetal genotype and aid the management of *HNF4A* pregnancies [51]. *HNF4A* variant carriers have reduced levels of HDL (and lipoprotein A1 and A2) and frequently have raised LDL cholesterol, while triglyceride levels are similar to population norms [67].

Differentiating from type 1 diabetes

Individuals with *HNF1A* or *HNF4A* MODY are frequently misdiagnosed as having type 1 diabetes as they have symptomatic diabetes presenting in adolescence or young adulthood. We recommend genetic testing by targeted next-generation sequencing to detect variants in *HNF1A/HNF4A* in any young adult with apparent type 1 diabetes, who is antibody negative to at least GAD and IA2 at diagnosis and also has a parent with diabetes. *HNF4A* should be suspected where there is increased birth weight and/or neonatal hypoglycaemia. Evidence of non-insulin dependence increases the likelihood of a positive result, shown by a non-fasting random C-peptide >200 pmol/l 3–5 years after diagnosis (i.e. outside the honeymoon period) [37].

Differentiating from type 2 diabetes

HNF1A/HNF4A should be suspected and targeted next-generation sequencing performed in people otherwise suspected to have type 2 diabetes where the following features are present ([37] and www.diabetesgenes.org):

- Young-onset diabetes: typically diagnosed before 25 years of age in at least one family member.
- Family history of diabetes: in at least two generations and ideally two individuals diagnosed in their 20s or 30s, particularly where affected individuals do not have obesity.
- Absence of obesity, acanthosis nigricans, or other evidence of insulin resistance.

In addition, marked sensitivity to sulfonylureas (hypoglycaemia on low doses) and a lipid profile showing normal or raised HDL cholesterol and normal or low triglycerides (atypical for type 2 diabetes) would all be supportive of a diagnosis of *HNF1A* rather than type 2 diabetes [63]. Individuals with *HNF4A* variants have a normal renal threshold for glucose, but frequently have a personal and/or family history of high birth weight and/or neonatal hypoglycaemia.

Management

People with both *HNF1A* and *HNF4A* variants are sensitive to sulfonylurea therapy, which is recommended as first-line treatment [67, 68]. Better glycaemic levels are often seen with sulfonylureas than

with insulin and the fasting glucose-lowering effect is four times greater than that seen in type 2 diabetes [68, 69]. Transfer to sulfonylurea treatment is successful in the majority of people, although insulin therapy may be required as the duration of diabetes progresses [70]. Even very low doses of sulfonylurea may cause hypoglycaemia in individuals with *HNF1A/HNF4A* MODY. The starting dose of sulfonylurea should therefore be low, typically an initial dose of 20–40 mg/day gliclazide or 2.5 mg/day glibenclamide in adults. If there is hypoglycaemia with low doses of standard agents, a short-acting agent such as nateglinide may be appropriate [71]. Recent data from the UK UNITED study indicate that individuals with *HNF1A/HNF4A* MODY who were more likely to be successfully managed on sulfonylurea therapy alone had a shorter diabetes duration, lower HbA_{1c}, and lower BMI at the time of genetic testing [43]. However, individuals with *HNF1A/HNF4A* MODY with a longer duration of diabetes (>11 years), especially in those with overweight or obesity and who had a high HbA_{1c} at the time of genetic diagnosis, were more likely to require insulin treatment in addition to a sulfonylurea [43]. Glucagon-like peptide 1 (GLP-1) receptor agonists are also effective at reducing glycaemia [72]. When sulfonylureas are not controlling hyperglycaemia, sodium-glucose cotransporter-2 (SGLT-2) inhibitors can improve glycaemic levels, but may result in marked hypovolaemia due to excessive urinary glucose loss. More research is required to assess the safety and efficacy of SGLT-2 inhibitors in individuals with *HNF1A* MODY, who have a low renal threshold for glucose due to reduced SGLT2 activity. Recently, the DPP-4 inhibitor linagliptin was shown to be an effective add-on treatment to the sulfonylurea glimepiride in individuals with *HNF1A* variants by improving glycaemic variability and HbA_{1c}, without increasing the risk of hypoglycaemia [73]. Due to the increased risk of cardiovascular disease in *HNF1A*, statin therapy should be recommended for those aged over 40 years.

Management in pregnancy

Evidence to support management strategies for *HNF1A* and *HNF4A* in pregnancy is limited, but there is a 50% chance that the fetus of an affected parent will inherit the variant. The sulfonylurea glibenclamide has been widely used for treatment of gestational diabetes; however, glibenclamide crosses the placenta [74, 75] and stimulates fetal insulin secretion, resulting in an increased risk of macrosomia and neonatal hypoglycaemia [76, 77]. Due to the risk of stimulating fetal insulin secretion, women with *HNF1A/HNF4A* variants treated with sulfonylurea prior to conception with good glycaemic levels should either transfer to insulin before conception, at the risk of a brief increase in glycaemic levels, or continue with glibenclamide treatment in the first trimester and transfer to insulin in the second trimester [78]. In women with *HNF1A/HNF4A* MODY, glibenclamide should be avoided during the third trimester to avoid increased fetal weight gain [78].

Special considerations in *HNF4A* pregnancies

If a fetus carries the affected *HNF4A* gene, the risk of macrosomia and neonatal hypoglycaemia is extremely high whether the variant is inherited from the mother or father [66], as it will add >800 g to the birth weight, which may result in considerable obstetric complications. Early delivery should be considered when the fetus inherits a *HNF4A* variant from either parent [78]. In women with *HNF4A*, there is an additional contribution to fetal birth weight from maternal glycaemia and it is very important to avoid adding to this further by refraining from sulfonylurea (glibenclamide) treatment from the second trimester onwards.

Recent developments in non-invasive prenatal testing to detect cfDNA in maternal blood will enable personalized management of pregnancies based on the fetal genotype and identify pregnancies at increased risk of macrosomia [51] due to *HNF4A* variants. Further guidelines for the management of pregnancy in individuals with *HNF4A* variants are available at www.diabetesgenes.org.

Rare subtypes of MODY

Two rare subtypes of MODY are *ABCC8* [79] and *KCNJ11* [80] and are important to recognize, as affected individuals can be successfully treated with sulfonylureas. The variants in *ABCC8* and *KCNJ11* that cause MODY can, but do not always, present as transient neonatal diabetes mellitus and are discussed shortly.

Transcription factor variants very rarely causing autosomal dominant β -cell diabetes have been identified in the genes *IPF1* [81], *NEUROD1* [82–84] and *RFX6* [7]. These genes often only cause a MODY-like phenotype when there are severe protein-truncating variants with reduced penetrance [7, 82]. The rarity of these cases and reduced penetrance mean that no information has been published on how these individuals should be optimally managed. Variants in *KLF11*, *PAX4*, and *BLK* were previously suggested as causal genes, but are now known not to cause MODY and therefore should not be tested.

Neonatal diabetes and diabetes diagnosed within six months of life

Individuals diagnosed with diabetes within the first six months of life (referred to as neonatal diabetes) are likely to have monogenic diabetes and not type 1 diabetes [85–88]. These individuals usually present with ketoacidosis and absent or very low C-peptide. Neonatal diabetes is rare, affecting 1 in 100 000 live births [89, 90]. Approximately half of cases remit spontaneously and are therefore termed transient neonatal diabetes mellitus (TNDM), as opposed to permanent neonatal diabetes mellitus (PNDM) where diabetes persists [91]. TNDM often recurs in later life after the initial remission [93]. Neonatal diabetes results from variants of key genes involved in β -cell development or function [14]. Table 20.4 summarizes the known genetic causes of neonatal diabetes.

Permanent neonatal diabetes

Approximately half of PNDM is caused by variants in the genes *KCNJ11* and *ABCC8*, which encode the Kir6.2 and SUR1 subunits, respectively, of the β -cell adenosine triphosphate (ATP)-sensitive potassium channel (K_{ATP} channel) [79, 80, 97–99]. This channel is constitutively open and regulates insulin secretion by closing in response to the raised intracellular ATP levels that occur as a consequence of hyperglycaemia. Channel closure triggers depolarization of the β -cell membrane, which leads to insulin secretion. Activating variants in *KCNJ11* and *ABCC8* prevent closure of the potassium channel in response to increased ATP, so the β cell remains hyperpolarized and unable to secrete insulin [100]. Sulfonylureas close the β -cell K_{ATP} channel by an ATP-independent route and have been used successfully in the management of individuals with neonatal diabetes resulting from *KCNJ11* and *ABCC8* variants [101]. In offspring of unrelated parents the majority of PNDM resulting from K_{ATP} channel variants arise spontaneously

from *de novo* heterozygous variants. The remaining cases are inherited mainly in an autosomal dominant pattern [99].

The K_{ATP} channel is also present in the brain, nerves, and muscles. Reflecting this distribution of channels, 20% of children with *KCNJ11* variants (and occasionally those with *ABCC8* variants) have severe neurological features [80, 88, 97, 100]. Recent data suggest that after thorough assessment the rate of psychological and neurological features is much higher in both *KCNJ11* and *ABCC8* PNDM than previously suggested [102, 103]. In-depth testing of 27 individuals with K_{ATP} channel gene variants (*KCNJ11* and *ABCC8*) found that all the participants had neuropsychological dysfunction [102]. In long-term follow-up studies, neurological features were found to persist into adulthood in all *KCNJ11* participants [104, 105]. In individuals with *ABCC8*-related PNDM, 62% had persistent, long-term psychiatric or neurological features [103].

Heterozygous variants in the insulin gene (*INS*) have been identified in ~12% of cases of isolated PNDM and insulin treatment is required [106, 107]. Other genetic causes appear to be relatively rare [14, 108], as outlined in Table 20.4. Parental consanguinity is more likely to result in autosomal recessive inheritance [14]. In children born to consanguineous parents, the commonest cause of PNDM is a homozygous variant in the *EIF2AK3* gene, causing Wolcott–Rallison syndrome [14].

Clinical features

Diabetes caused by *KCNJ11* variants typically present in the first 26 weeks of life (median 4–6 weeks) with marked hyperglycaemia often accompanied by ketosis. C-peptide is usually undetectable and pancreatic auto-antibodies negative [80]. As with all neonatal diabetes subtypes, infants are often small for gestational age as a result of reduced fetal insulin secretion with consequent decreased insulin-mediated growth.

Neonatal diabetes caused by an *ABCC8* variant has a similar phenotype but leads to TNDM more commonly than PNDM [97–99]. Children with neonatal diabetes due to *INS* variants present at a median age of 9 weeks and are also often small for gestational age, but do not have extra-pancreatic features [106].

The most common neurological features identified in individuals with PNDM resulting from *KCNJ11* and *ABCC8* variants are developmental delay and learning difficulties [103, 104]. Neurological features persist into adulthood, despite sulfonylurea therapy [103, 104], as a result of the limited function of the K_{ATP} channel in the brain and not as a consequence of long-standing diabetes [104]. The most severe form where neonatal diabetes is accompanied by developmental delay and epilepsy has been named developmental delay, epilepsy, and neonatal diabetes (DEND). *Intermediate DEND* (iDEND) refers to neonatal diabetes with less severe developmental delay and no epilepsy. The severity of the clinical condition relates closely to the underlying variant and its effect on K_{ATP} channel ATP sensitivity [100, 109].

Management

Although insulin therapy is commonly used in the initial period after diagnosis, the majority of those with *KCNJ11* and *ABCC8* variants can successfully transfer from insulin to sulfonylurea therapy, usually with significant improvements in glycaemic levels [98, 101]. Of those with *KCNJ11* variants 90% can discontinue insulin, while HbA_{1c} appears to improve in all, with a mean drop from 6.5 to 4.6 mmol/mol (8.1% to 6.4%) after 12 weeks [101]. Glibenclamide was initially chosen as it is non-selective and widely available; it has been used in the

Part 4 Other Types of Diabetes

Table 20.4 Causes of neonatal diabetes.

Pancreatic pathophysiology	Protein, chromosome, or gene affected	Inheritance	Phenotype
Reduced β-cell function	KCNJ11	Autosomal dominant (often <i>de novo</i>)	Permanent or transient neonatal diabetes and DEND syndrome
	ABCC8	Autosomal dominant or recessive	Permanent or transient neonatal diabetes and DEND syndrome
	Glucokinase (homozygous for variant)	Autosomal recessive	Isolated permanent neonatal diabetes. Both parents have heterozygous glucokinase associated hyperglycaemia
	SLC2A2	Autosomal recessive	Fanconi–Bickel syndrome: permanent neonatal diabetes, hypergalactosaemia, and liver dysfunction
	SLC19A2	Autosomal recessive	Roger syndrome: permanent neonatal diabetes, thiamine-responsive megaloblastic anaemia, and sensorineural deafness
Abnormal pancreatic development	Chromosome 6q24	Variable	Transient neonatal diabetes, macroglossia, and umbilical hernia
	GATA6	Autosomal dominant	Permanent neonatal diabetes, pancreatic agenesis, congenital heart defects, and biliary abnormalities
	PTF1A	Autosomal recessive	Permanent neonatal diabetes, pancreatic and cerebellar agenesis
	ZFP57	Autosomal recessive	Syndromic transient neonatal diabetes
	GLIS3	Autosomal recessive	Permanent neonatal diabetes, congenital hypothyroidism, glaucoma, liver fibrosis, developmental delay, and cystic kidney disease
	PDX1	Autosomal recessive	Permanent neonatal diabetes and pancreatic agenesis
	GATA4	Autosomal dominant	Permanent neonatal diabetes, pancreatic agenesis, and congenital heart defects

majority of cases and may be more effective than other sulfonylurea agents [110]. The doses needed are often higher than those needed for the treatment of type 2 diabetes: a median dose of 0.45 mg/kg/day is required, with doses up to 1.5 mg/kg/day [101, 111]. Doses up to 2 mg/kg/day have been reported [112], but doses of 1 mg/kg/day or less are usually sufficient. Reports of side effects are mild and comprise transient gastrointestinal disturbances, the most common being diarrhoea, and tooth discolouration [105]. In individuals with PNDM caused by *KCNJ11* and *ABCC8* variants, sulfonylurea therapy is a safe and effective long-term treatment, maintaining excellent glycaemic levels for over 10 years without severe hypoglycaemia or serious side effects, even in high doses [103, 105]. Initiation of sulfonylurea therapy immediately after *KCNJ11* or *ABCC8* variants are confirmed appears to improve neurological outcomes [113] and sulfonylurea therapy may result in some improvement in neurological features, particularly in higher doses [103, 105, 110, 114, 115]. Earlier age at initiation of sulfonylurea therapy, ideally in the first six months of life, appears to correlate with better dose response [116]. Further information on transferring these individuals from insulin to sulfonylureas can be found at www.diabetesgenes.org. Neonatal diabetes resulting from *INS* variants requires insulin treatment [106].

Affected individuals with a heterozygous *KCNJ11* or *ABCC8* variant contemplating parenthood should be counselled that they have a 50% chance of passing on the variant to their offspring. Where unaffected parents, with a child affected by a heterozygous variant, are planning further pregnancies, the risk of further affected children is low because the possibility of a germline variant is approximately 5–10% [117]. Where parents have a child with neonatal diabetes caused by a recessive *ABCC8* variant, there is a 25% chance of each further offspring being affected, but the risk is low for subsequent generations. In pregnancy, if the fetus inherits a K_{ATP} neonatal diabetes variant (*KCNJ11* or *ABCC8*) from their mother, fetal insulin secretion will be greatly reduced *in utero*, resulting in reduced fetal growth by ~900 g [78, 80, 88, 118]. If the fetus and the mother both have K_{ATP} neonatal diabetes, maternal glibenclamide treatment is recommended as it will cross the placenta and provide *in utero* treatment to the affected fetus and normalize fetal growth. If the fetus is unaffected, maternal glibenclamide treatment is not recommended in the third trimester as it will exacerbate neonatal hypoglycaemia and excessive fetal growth [78, 119]. Awareness of fetal genotype through the use of cffDNA testing is an important addition to guide management of K_{ATP} neonatal diabetes pregnancies [51].

Transient neonatal diabetes

The genetic aetiology of more than 90% of TNDM has been established. The majority (70%) of cases result from abnormalities in the q24 region of chromosome 6 (6q24) affecting imprinted genes [92, 120]. Genetic imprinting occurs when only the maternally or paternally inherited allele of a gene is expressed and this is usually controlled by methylation. In TNDM paternal uniparental disomy, paternal duplication of 6q24 or abnormal methylation of the maternal copy of the chromosome causes overexpression of the paternal copies of the genes *PLAGL1* (also known as *ZAC*) and *HYMA1* [120, 121]. Paternal duplication of 6q24 can be inherited, therefore this abnormality causes the majority of inherited TNDM cases. Uniparental disomy causes sporadic TNDM; cases resulting from abnormal methylation of the maternal copy of chromosome 6 may be sporadic or inherited [120, 121]. The majority (90%) of TNDM not associated with 6q24 abnormalities are caused by variants in *KCNJ11* and *ABCC8* [14, 88, 92, 98, 122, 123].

Clinical features

6q24 diabetes usually presents in the first week of life, often with severe hyperglycaemia and dehydration but usually without ketosis. Pancreatic auto-antibodies are usually negative and C-peptide is low or negligible. Low birth weight is common (mean birth weight approximately 2.0 kg), and there may be associated macroglossia and/or umbilical hernia [124]. Insulin treatment is required for a median of 12 weeks before the child goes into remission [120]. Diabetes recurs later in life, with an average age of recurrence of 14 years in approximately 50% as a result of β -cell dysfunction [120]. In some cases, hyperglycaemia may be intermittent and seen only at times of stress [120, 125]. Where TNDM is caused by *KCNJ11* and *ABCC8* variants, diabetes tends to present later (median 4 weeks), takes longer to remit, and is associated with less intrauterine growth restriction (median birth weight 2.6 kg) [92]. Importantly, in *KCNJ11*- and *ABCC8*-related TNDM individuals may not present in the neonatal period and may only present in the relapse phase in adolescence or young adulthood [92], usually with a dominant family history, and they are sulfonylurea sensitive.

Management

Insulin is required in the neonatal period for all cases initially, whereas treatment following relapse varies from diet to oral anti-diabetes agents or insulin [125]. In TNDM cases resulting from *KCNJ11* and *ABCC8* variants, diabetes may be successfully managed with sulfonylureas [92, 98]. The best treatment options for 6q24-related TNDM following relapse remain unclear; however, recent data indicate that non-insulin-based therapies, including sulfonylureas, may be effective [126, 127].

Genetic counselling depends on the underlying genetic aetiology. Cases caused by uniparental disomy are sporadic and therefore have low risk of occurrence in either siblings or offspring of the affected child. Methylation defects often result from homozygous variants in the transcription factor gene *ZFP57* and therefore may be inherited in an autosomal recessive manner [121]. Offspring of men with 6q24 duplication have a 50% chance of developing TNDM, whereas if the abnormality is inherited from the mother they will not be affected because both maternal copies would be inactive due to methylation; however, the TNDM may occur in the following generation [125, 128].

Genetic testing in neonatal diabetes

At the time of diagnosis of neonatal diabetes it is unknown whether the diabetes will be transient or permanent. We recommend urgent Sanger testing for the most common causes of neonatal diabetes (*KCNJ11*, *ABCC8*, and *INS* variants) at diagnosis in all cases where diabetes is diagnosed before 6 months of age and if possible those between 6 and 9 months. Identifying variants in these genes is important as it will influence treatment. If a variant is not identified, we recommend testing for all known neonatal diabetes genes by targeted next-generation sequencing. An early diagnosis and very low birth weight make 6q24 most likely. A genetic cause (*KCNJ11* or *INS*) can be established in ~7% of diabetes diagnosed between 6 months and 1 year of age and so consideration should be given to testing this age group, especially where autoantibody tests are negative [87]. Novel screening methods to identify neonatal diabetes early have recently been developed, including utilizing dried blood spot cards to measure glucose, which can detect hyperglycaemia and

Part 4 Other Types of Diabetes

neonatal diabetes on day 5 of life [129]. Genetic testing for neonatal diabetes is provided for any individual diagnosed before 9 months of age anywhere in the world through the Genomics Laboratory at the Royal Devon and Exeter Foundation Trust. Details are available at www.diabetesgenes.org.

Diabetes with extra-pancreatic features

Several monogenic causes of diabetes are associated with distinct features occurring outside the pancreas. In many cases extra-pancreatic disease may be the presenting feature, for example in cystic fibrosis and haemochromatosis (Chapter 23).

Maternally inherited diabetes and deafness

Maternally inherited diabetes and deafness (MIDD) results from a variant in mitochondrial DNA and causes maternally inherited diabetes with bilateral sensorineural deafness that may be accompanied by a wide range of other features. It affects up to 1% of those with diabetes, but is frequently misdiagnosed [130].

Pathogenesis and inheritance

The vast majority of mitochondrial diabetes results from the m.3243A>G point variant in mitochondrial DNA and other mitochondrial DNA variants are rare [131]. The m.3243A>G variant affects the mitochondrial respiratory chain and therefore results in cellular energy deficiency. Organs with high metabolic activity including the endocrine pancreas and cochlea are most affected. Mitochondrial dysfunction in pancreatic islets results in abnormal β -cell function, loss of β -cell mass, and insulin deficiency [130]. As mitochondria are inherited from the mother, only the maternal line in a family is affected, and children of an affected father are not at risk. All children of an affected woman will inherit the variant; however, phenotype varies widely within a family due to heteroplasmy. Offspring inherit a mix of variant and wild-type mitochondrial DNA and the proportion of mitochondria carrying the variant will vary, as will segregation of variant and wild-type mitochondria to different tissues [132].

Clinical features

The characteristic clinical features of MIDD are summarized in Figure 20.7. The majority of variant carriers develop diabetes

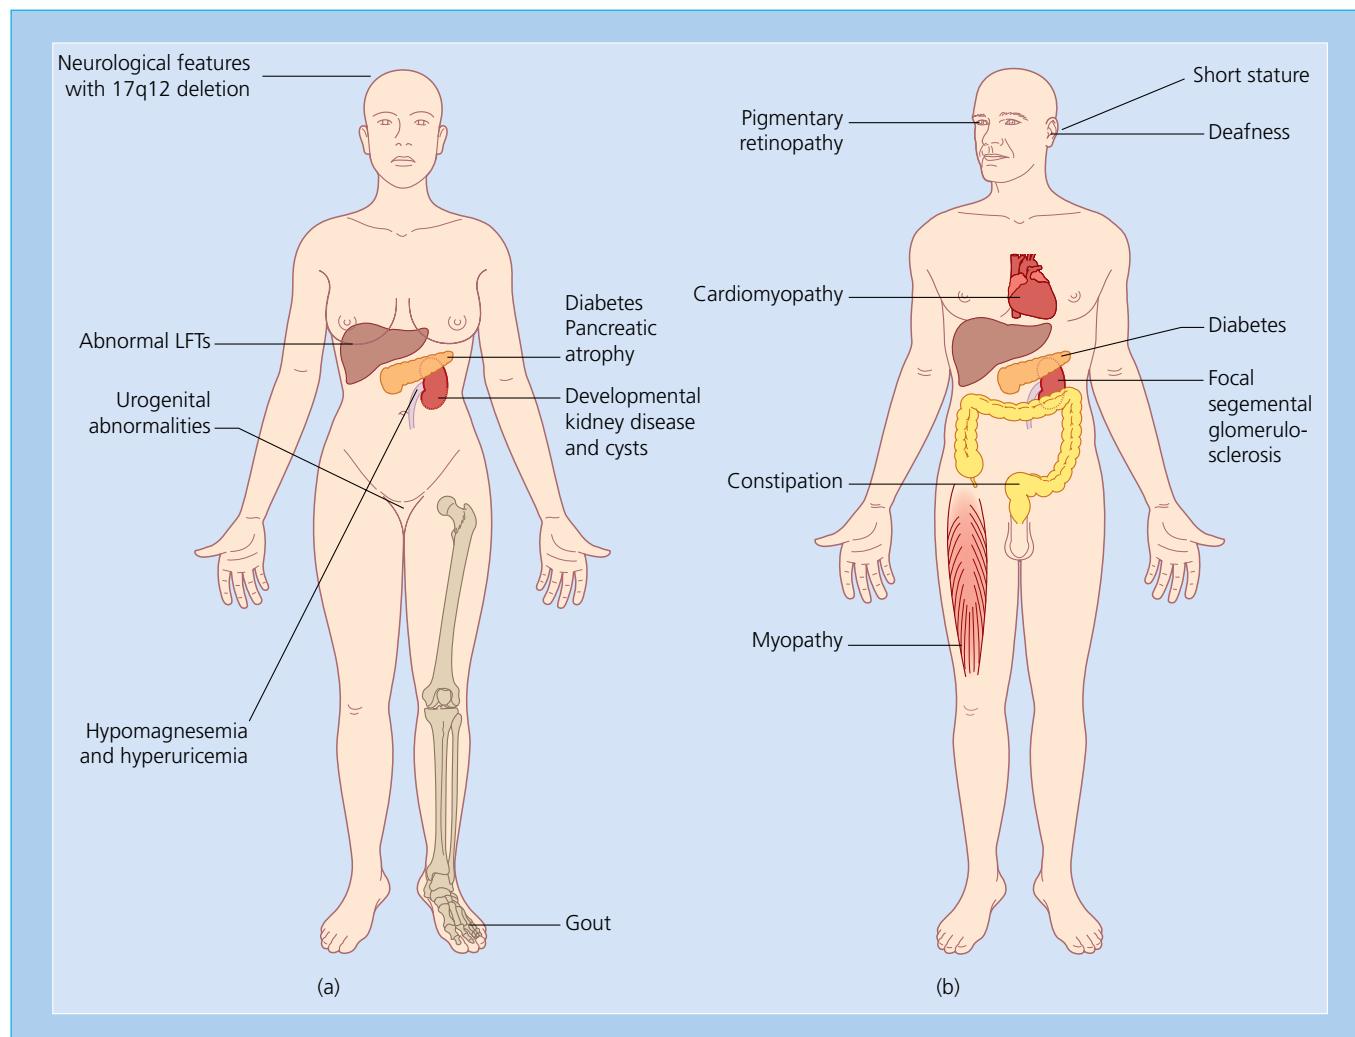

Figure 20.7 Phenotypes of (a) renal cysts and diabetes syndrome due to *HNF1B* variant or deletion; and (b) maternally inherited diabetes and deafness caused by mitochondrial m.3243A>G variant. LFTs, liver function tests. Source: Adapted from Murphy et al. [130] and Clissold et al. [150].

(over 85%) and sensorineural hearing loss (over 75%) [132–136]. Diabetes is progressive but may present acutely, with ketoacidosis occurring in ~8% of cases [132, 133, 137]. Mean age at diagnosis of diabetes is 37 years, but age of diagnosis can range from 11 years to 68 years [133, 137, 138].

Hearing loss typically develops in early adulthood and is more common in men than women [133, 135]. Those with the m.3243A>G variant have a high prevalence of renal failure, with focal segmental glomerular sclerosis found frequently on biopsy [133, 139]. Macular retinal dystrophy is a frequent finding, but rarely causes visual symptoms [130, 133, 139]. Cardiac abnormalities include left ventricular hypertrophy, heart failure, and cardiac arrhythmias [140–143]. Other clinical manifestations of the m.3243A>G variant include short stature, MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), psychiatric disorders, proximal myopathy, and gastrointestinal symptoms, particularly constipation [130].

Differentiating from type 1 diabetes and type 2 diabetes

Diabetes caused by the m.3243A>G variant is difficult to differentiate from type 1 diabetes or type 2 diabetes. The presence of deafness in the individual or clustering of diabetes and/or sensorineural deafness in maternal relatives should prompt investigation for the m.3243A>G variant. The diagnosis can be confirmed by testing for the m.3243A>G variant in blood leucocytes or urine. In rare cases the result may be negative on blood-derived DNA because of heteroplasmy loads in leucocytes. Urine or buccal samples may therefore be preferable [130].

Management

Insulin treatment is usually required within two years of diabetes diagnosis [132, 133, 137, 144]. There is a theoretical basis for avoiding metformin in view of the risk of lactic acidosis [130, 132]. Whether there is benefit for the diabetes from use of coenzyme Q10 supplementation is currently unclear [130, 145, 146]. Monitoring for cardiac manifestations should be considered from a young age. Aggressive blood pressure management and early angiotensin-converting enzyme (ACE) inhibitor treatment may be appropriate in view of the high risk of renal complications. Management of hearing loss involves avoidance of exacerbating factors, prompt treatment of ear infections, hearing aids if necessary, and consideration of cochlear implants where there is profound hearing loss [130, 147, 148].

Maternal relatives of affected individuals and children of a woman with the disease should be assumed to carry the m.3243A>G variant. Therefore, annual HbA_{1c} after 30 years and prompt referral to audiology if suspicion of hearing loss and complications of MIDD may be advisable.

Renal cysts and diabetes (*HNF1B* MODY)

HNF1B is a transcription factor with a role in regulating gene expression in a number of tissues including the pancreas, kidneys, liver, genital tract, and gut [149]. Heterozygous deletions or variants in *HNF1B* can cause developmental abnormalities in all these organs, although the commonest phenotypes are renal abnormalities and diabetes. Renal cysts and diabetes (RCAD) syndrome is used to describe the combination of diabetes and renal cysts related to *HNF1B* variants. *HNF1B* abnormalities may show autosomal dominant inheritance, although up to 50 % of cases arise spontaneously and there is a wide variation in phenotype even with identical variants [150, 151, 152–154].

Clinical features

The clinical features are summarized in Table 20.5 and Figure 20.7. Developmental renal disease is the most consistent feature, with renal cysts being the commonest manifestation [150]. Other possible renal abnormalities include glomerulocystic kidney disease, cystic renal dysplasia, and morphological abnormalities such as horseshoe or single kidney. Renal function can range from normal to dialysis dependent [156, 157]. The mean age of diagnosis of diabetes is 24 years, but the age of diagnosis can vary from infancy to over 60 years old [150]. Diabetes is usually associated with pancreatic hypoplasia and may be associated with exocrine dysfunction, although this can result in mild or moderate symptoms of malabsorption [158–160]. Low birth weight is common and very rarely transient neonatal diabetes has been described [159]. Other clinical manifestations include non-progressive abnormal liver function tests, genital tract malformations, hypomagnesaemia, hyperuricaemia, and familial hyperuricaemia nephropathy [158, 161]. Neurodevelopmental disorders including autism spectrum disorder are identified in ~40 % of individuals with an *HNF1B* whole-gene deletion occurring as part of a chromosome 17q12 microdeletion, but are not associated with *HNF1B* intragenic variants [155, 162]. Mild facial dysmorphic features are also suggestive of a 17q12 deletion and include high forehead, high arched eyebrows, long philtrum, long face, and anteverted nares [155]. An association with chromophobe renal cell carcinoma has been reported, reflecting a probable role for *HNF1B* as a tumour suppressor gene [163, 164].

Table 20.5 Features of people with *HNF1B* variants causing RCAD (renal cysts and diabetes) in a UK cohort.

Clinical features	Details
Renal phenotype	
Renal cysts	Common
Renal impairment	Common (15% require dialysis/transplantation)
Morphological renal abnormalities	Occasional (Horseshoe or single kidney)
Renal histology (includes)	Glomerulocystic kidney disease, cystic renal dysplasia, oligomeganephronia
Hypomagnesaemia	44%, proximal tubular defect
Hyperuricaemia and gout	20% (clinical gout)
Diabetes	58%. Mean age of diagnosis 26 yr, range 0–61 yr Insulin treatment common
Other features	
Liver enzyme derangement	Mild, non-progressive
Subclinical exocrine pancreatic failure	Reduced faecal elastase (may require treatment)
Genital tract malformations	17%
Short stature	20% <2 SD below mean height
Neurodevelopmental disorders	Neuropsychiatric manifestations (autism in ~40% of those with whole-gene deletion)
Uncommon	Joint laxity, hearing loss, prognathism, pyloric stenosis, chromophobe renal cell carcinoma

SD, standard deviation.

Differentiating from type 1 diabetes and type 2 diabetes

Approximately 50% of *HNF1B* variants and deletions are spontaneous and so there may be no family history. Testing for *HNF1B* abnormalities should be considered where there is unexplained cystic renal disease, glomerulocystic disease, or other renal developmental abnormalities with or without a past medical or family history of diabetes. It should also be considered in individuals with genital tract abnormalities associated with renal abnormalities. Both simple renal cysts and diabetes are common in the general population and should not lead to automatic testing for *HNF1B* abnormalities; testing would be considered when the diabetes is young onset and atypical for type 1 diabetes and type 2 diabetes. Testing for *HNF1B* should always include dosage analysis to detect gene deletions, as these are common and will be missed if the laboratory performs sequencing only [165].

Management

Although the majority of individuals with *HNF1B* variants will require insulin treatment [166], some individuals, soon after diagnosis, may be briefly managed with sulfonylurea therapy [167]. Renal management is similar to management of other chronic progressive renal diseases. Our recommendation is that adults with normal renal function should have their serum creatinine and estimated glomerular filtration rate (eGFR) repeated annually. Children with normal renal function should have their serum creatinine and eGFR checked every 2–3 years. All individuals should undergo a renal ultrasound scan to assess for structural anomalies. If initial imaging is abnormal, repeat renal ultrasound imaging every 3–5 years is recommended. If the initial ultrasound scan is unremarkable, we suggest repeating imaging every 3–5 years throughout childhood. In adults, monitoring renal function using serum creatinine and eGFR would be sufficient. Annual assessment of HbA_{1c} in adults without a diagnosis of diabetes is recommended. In children without a diagnosis of diabetes, annual urinalysis to test for glycosuria and monitoring HbA_{1c} when routine blood samples are being collected may be helpful. Faecal elastase should be tested to check for pancreatic insufficiency when there are gastrointestinal symptoms, as treatment with Creon® (AbbVie, North Chicago, IL, USA) may be required. Other tests that may be useful in diagnosis of *HNF1B* include liver function tests, serum magnesium, and serum urate.

Other monogenic β-cell diabetes with extra-pancreatic features

Wolfram syndrome

Wolfram syndrome is a rare autosomal recessive neurodegenerative disorder caused by biallelic variants in the *WFS1* gene, and rarely *CISD2*, and is characterized by diabetes insipidus, diabetes mellitus, optic atrophy, deafness (hence DIDMOAD syndrome), and a variety of central nervous system abnormalities. Consideration should be given to this diagnosis where there is a combination of diabetes and optic atrophy [168–170].

Thiamine-responsive megaloblastic anaemia syndrome

Thiamine-responsive megaloblastic anaemia (TRMA) syndrome is a rare autosomal recessive condition caused by variants in the *SLC19A2* gene and is characterized by megaloblastic anaemia (which may be mild), non-autoimmune diabetes, and sensorineural

hearing loss [171]. Treatment with high-dose thiamine can improve some features, including diabetes [172].

Wolcott–Rallison syndrome

Wolcott–Rallison syndrome is a rare autosomal recessive condition caused by biallelic variants in *EIF2AK3* and is characterized by early-onset diabetes, spondyloepiphyseal dysplasia, and recurrent hepatic and/or renal dysfunction. Diabetes usually presents in infancy and requires insulin treatment [173].

Monogenic diabetes with pancreatic exocrine dysfunction

Variants in the carboxyl ester lipase (*CEL*) gene have been identified as a rare cause of monogenic diabetes with pancreatic exocrine dysfunction. Pancreatic exocrine dysfunction often occurs decades before development of diabetes and can be detected by low faecal elastase levels in early childhood [174, 175].

Primrose syndrome

Primrose syndrome is a rare condition caused by variants in the *ZBTB20* gene and is characterized by macrocephaly, intellectual disability, dysmorphic facial features, large calcified external ears, ectopic calcifications, progressive muscle wasting, and diabetes [176].

Insulin resistance

Monogenic causes of diabetes resulting from insulin resistance include the inherited lipodystrophies, variants affecting the insulin receptor or post-receptor signalling, and other monogenic syndromes associated with insulin resistance where abnormalities of insulin action are not the primary disorder. There can be considerable clinical overlap in clinical presentation between these conditions [177]. The key features of severe insulin resistance likely to be associated with a monogenic cause of diabetes are:

- The presence of acanthosis nigricans (Figure 20.8).
- Ovarian cysts, subfertility, and hyperandrogenism in women.
- Hyperinsulinaemia as evidenced by raised endogenous insulin levels, or in those on insulin treatment very high doses of exogenous insulin.

In a lean person, the presence of some or all of these features should prompt consideration of underlying monogenic causes of

Figure 20.8 Acanthosis nigricans affecting the neck of a 26-year-old woman with severe insulin resistance. Source: Reproduced with permission from Moller and O'Rahilly [178].

insulin resistance. While obesity does not exclude monogenic insulin resistance, it is very hard to detect on the background of obesity-related insulin resistance. The presence of other clinical features (Figure 20.9) is related to the underlying cause. Monogenic forms of insulin resistance are comprehensively reviewed elsewhere [179, 180].

Insulin receptor gene variants

Insulin exerts its effects through binding to a transmembrane receptor. Binding of insulin to the α -subunit of the receptor activates β -subunit tyrosine kinase activity, triggering protein activation cascades that lead to insulin's intracellular effects [181, 182]. Variants in the insulin receptor (*INSR*) gene lead to inherited insulin resistance syndromes. The severity of the resulting clinical phenotype depends on the extent of impairment of signal transduction resulting from the underlying variant [183].

Clinical features

Individuals with severe insulin resistance resulting from insulin receptor variants may have common features of severe insulin resistance, which include hyperinsulinaemia, acanthosis nigricans, ovarian hyperandrogenism, and disturbances of glucose homeostasis, which can include hypoglycaemia (classically post-prandial) as well as impaired glucose tolerance and diabetes [183]. However, they do not have features of ectopic fat, which is seen in lipodystrophy (see later). Three main syndromes resulting from insulin receptor variants leading to severe insulin resistance have been described:

- Type A insulin resistance syndrome/
- Rabson–Mendenhall syndrome.
- Donohue syndrome (previously known as leprechaunism).

These syndromes overlap and represent varying clinical features from a continuum of severity of receptor dysfunction rather than completely distinct syndromes [183]. Many individuals with insulin receptor defects and severe insulin resistance (men in particular) may not fit into the syndromic descriptions.

The commonest presentation is Type A insulin resistance syndrome, where individuals without obesity have severe insulin resistance, acanthosis nigricans, and hyperandrogenism. Affected females present in adolescence with polycystic ovarian disease, hirsutism, and signs of virilization (often termed HAIR-AN syndrome) [180, 184, 185]. Females have more prominent clinical features than males, with the majority of affected males remaining asymptomatic until they develop impaired glucose tolerance, usually in adulthood [180].

The syndromic types of insulin resistance seen with insulin receptor variants are rare and associated with more severe impairment of the insulin receptor function. Rabson–Mendenhall syndrome is an autosomal recessive disorder that presents in childhood with acanthosis nigricans, extreme growth restriction, dysplastic dentition, coarse facial features, lack of subcutaneous fat, pineal hyperplasia, and renal abnormalities including medullary sponge kidney and nephrocalcinosis [185–187]. Affected individuals may develop diabetes several years after diagnosis [188]. Most affected individuals do not survive puberty [185]. The most severe syndrome seen with insulin receptor variants is Donohue syndrome, a rare autosomal recessive disorder characterized by low birth weight, hirsutism, growth restriction, disordered glucose homeostasis, and characteristic dysmorphic features. Individuals usually do not survive infancy [185, 189].

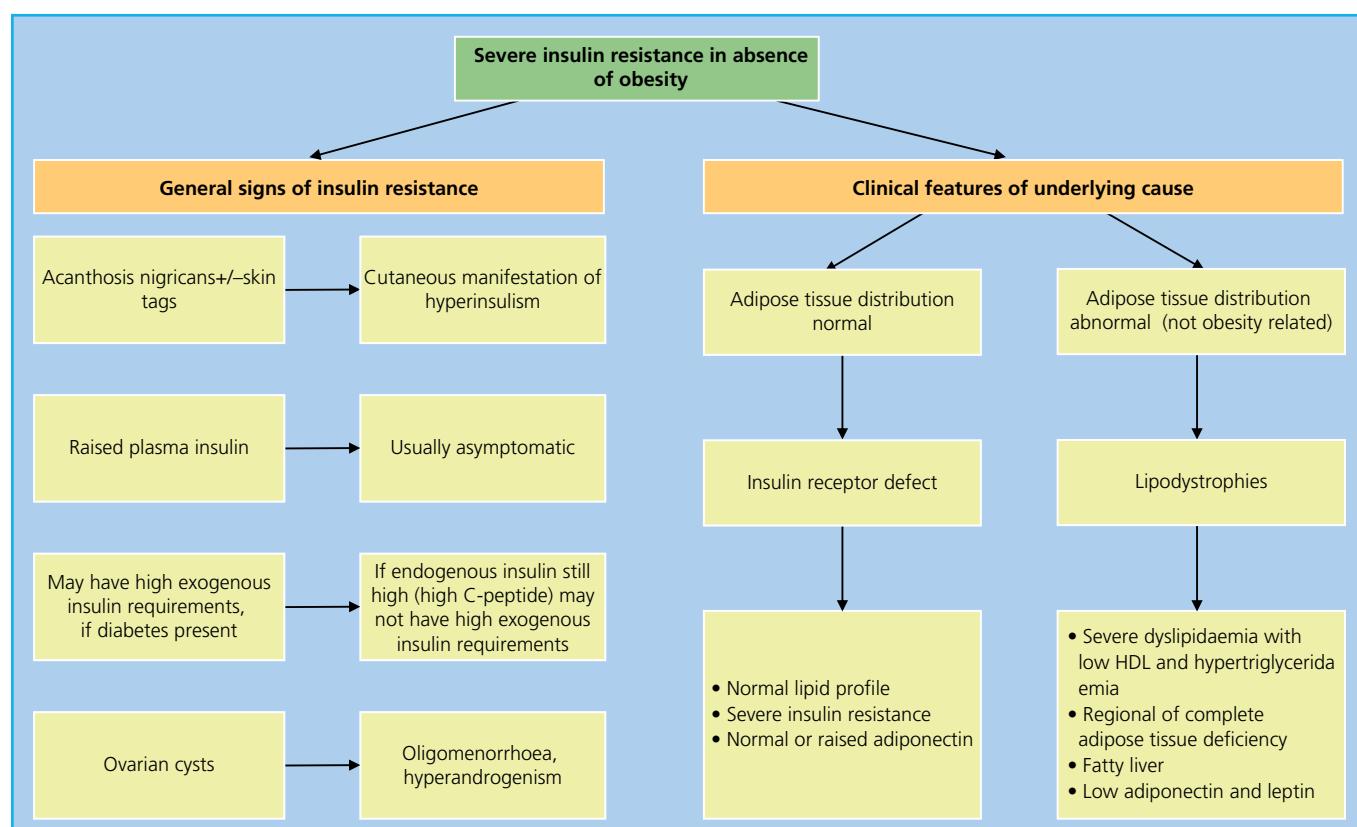

Figure 20.9 Features of monogenic severe insulin resistance. HDL, high-density lipoprotein.

Differentiating from type 1 diabetes and type 2 diabetes

The presence of features of insulin resistance in a slim individual is suggestive of an underlying insulin receptor gene variant. Serum adiponectin levels are typically high with insulin receptor variants, whereas they are low in other forms of insulin resistance. Adiponectin levels could be used as a screening test, with sequencing of the insulin receptor gene reserved for those cases where adiponectin levels are raised [177, 190, 191].

If the affected individual is on a high insulin dose (>3 units/kg/day), does not have obesity, and has elevated glycaemic indices, high non-fasting C-peptide levels can help discriminate insulin resistance from type 1 diabetes. Unlike type 2 diabetes and the lipodystrophies, triglyceride and HDL cholesterol levels are typically normal with insulin receptor variants [185].

Management

When the β cells of the person decompensate and diabetes develops with marked hyperglycaemia, treatment is difficult. While insulin sensitizers, such as metformin and thiazolidinediones, have a role in management, their effect is often limited and insulin therapy is required as β -cell function declines [185]. Glucose levels often remain high despite very large doses of insulin (often in excess of 500 units/day). U500 insulin has a role in reducing the insulin volumes required [185, 192]. Insulin pumps should be considered when very high doses of insulin are required.

Inherited lipodystrophies

Lipodystrophies are rare clinically heterogeneous disorders that are characterized by the selective loss of adipose tissue and accumulation of ectopic fat. They are associated with insulin resistance and other features such as diabetes, acanthosis, dyslipidaemia, hepatic steatosis, and (in women) hyperandrogenism, oligomenorrhoea, and polycystic ovaries [193]. Lipodystrophies may be inherited or acquired.

Familial partial lipodystrophy

Familial partial lipodystrophies are autosomal dominant disorders where insulin resistance in a slim person is associated with the loss of peripheral subcutaneous fat, resulting in ectopic fat. The two main subtypes result from variants in *LMNA* and *PPARG*.

The clinical features of familial partial lipodystrophy are a combination of the features of insulin resistance (acanthosis nigricans, hyperinsulinaemia, polycystic ovarian syndrome, virilization), direct features of lipodystrophy, and indirect features resulting from ectopic fat. Familial partial lipodystrophy associated with *LMNA* variants (also known as Dunnigan lipodystrophy) results in gradual peripheral subcutaneous fat loss from puberty [194, 195]. This, and the associated muscle hypertrophy, gives a muscular appearance of the arms and legs (Figure 20.10). There may be fat loss from the anterior abdomen and chest and excess fat deposition in the face, neck, and intra-abdominally [196, 197]. Ectopic fat accumulates in the liver, muscle, pancreas, and vasculature, resulting in the abnormal metabolism of glucose and lipids [198]. Diabetes is common, particularly in women, and appears in late adolescence or early adulthood [199]. Hypertriglyceridaemia may be marked and associated with pancreatitis. Elevated triglyceride levels and very low HDL cholesterol levels can aid in diagnosis. Cardiovascular mortality is high [200, 201].

Familial partial lipodystrophy associated with *PPARG* variants appears to be phenotypically similar to that caused by *LMNA* variants, although hypertension is more common [202, 203].

Figure 20.10 Familial partial lipodystrophy in a 46-year-old woman. There is truncal and limb lipodystrophy, preserved facial and neck adipose tissue, muscle hypertrophy, and acanthosis apparent in the groin regions.

Diagnosis may be obvious in women, but is more difficult in men where a muscular appearance of limbs is more usual. Early-onset diabetes in an individual without obesity and with acanthosis nigricans, low HDL cholesterol, and hypertriglyceridaemia should raise suspicion of lipodystrophy, particularly if there is marked peripheral fat loss [204]. Many individuals with lipodystrophy are mistakenly thought to have Cushing's syndrome.

Congenital generalized lipodystrophy (Berardinelli–Seip syndrome)

This is a rare (estimated prevalence 1 in 10 million) autosomal recessive disorder characterized by a near-complete absence of subcutaneous fat from birth, giving a muscular appearance [193]. Due to the absence of functioning adipocytes, lipids are stored in metabolically

active tissues. Those affected have features of severe insulin resistance, including often widespread acanthosis, hypertriglyceridaemia, and low HDL cholesterol [205]. Hepatic steatosis occurs early and may lead to cirrhosis; hepatomegaly is seen frequently [206–208]. Childhood growth is accelerated and bone age advanced. Diabetes commonly develops during adolescence. Other associated features include acromegaloid features, hypertrophic cardiomyopathy, skeletal muscle hypertrophy, bone cysts, and intellectual impairment [208]. Serum leptin and adiponectin levels are markedly reduced [209].

Four molecularly distinct forms of congenital generalized lipodystrophy have been identified: type 1 (*AGPAT2* variants); type 2 (*BSCL2* variants); type 3 (*CAV1* variants); and type 4 (*PTRF* variants) [193, 210–212]. *AGPAT2* and *BSCL2* account for the majority of cases and have some difference in phenotype. Some people with this phenotype do not have variants in any of these genes and so it is likely there are further genetic aetiologies to be discovered.

Mandibular hypoplasia, deafness, progeroid features, and lipodystrophy (MDPL) syndrome

MDPL syndrome is an extremely rare autosomal dominant condition caused by variants in the *POLD1* gene on chromosome 19 and is characterized by lipodystrophy, dysmorphic facial features, sensorineural deafness, and metabolic abnormalities including severe insulin resistance and diabetes [213, 214]. In those with diabetes, we recommend using metformin in doses of at least 2 g/d, as this decreases insulin resistance and improves insulin sensitivity.

Other inherited monogenic forms of lipodystrophy

Other inherited subtypes of lipodystrophy associated with dysmorphic features have now had genes discovered, including mandibuloacral dysplasia (*LMNA*, *ZMPSTE24*), SHORT syndrome (*PIK3R1*), neonatal progeroid syndrome (*FBN1*, *CAV1*), atypical progeroid syndrome (*LMNA*), and Keppen-Lubinsky syndrome (*KCNJ6*) [184, 215].

Management of lipodystrophy

Management should address insulin resistance, the main causes of morbidity and mortality, diabetes, cardiovascular and cerebrovascular disease, recurrent pancreatitis (as a result of severe hypertriglyceridaemia), cirrhosis, and psychological distress related to appearance [193]. The key point of management is to treat the ectopic fat. Despite being slim, these individuals have the same problems from ectopic fat as those with morbid obesity and so there are considerable parallels in the management of these two very different groups. The reduction in ectopic fat will result in reduced insulin resistance, reduced hyperglycaemia, lower blood pressure, more favourable lipid profile (lower triglycerides and higher HDL cholesterol), and reduced cardiovascular risk. To reduce ectopic fat the key aim is to reduce oral food intake, which is difficult, but these individuals will see great benefit from even minimal reduction in caloric intake.

Lifestyle changes should include an extremely low-fat diet (<15% total energy from fat) and low caloric intake. Reduced oral intake

will reduce ectopic fat, reducing insulin resistance and improving glycaemic levels. To help reduced oral intake, GLP-1 receptor agonists are helpful as they reduce gastric emptying [216]. Roux-en-Y gastric bypass surgery (RYGB) may also be considered in the management of lipodystrophy. RYGB improves glycaemic indices, enhances insulin sensitivity, and promotes weight loss in familial partial lipodystrophy [217, 218]. Hypertriglyceridaemia that does not respond to measures to reduce ectopic fat may require treatment with fibrates and possibly high doses of fish oils. Given the very high cardiovascular risk, high-dose statins should be used very early and certainly once reaching adult life.

Glycaemic management requires a combination of oral treatments and high-dose insulin in the majority of cases. Early treatment with metformin is commonly used to improve insulin sensitivity [204]. Thiazolidinediones (glitazones) are not recommended as they require normal adipocytes to work well and they can cause further accumulation of fat in the face and neck [179]. Where insulin is needed dose requirements may be very high and both insulin pumps that reduce insulin requirements and U500 insulin should be considered. Where proteinuric renal disease develops, the threshold for renal biopsy should be low as non-diabetic renal disease (e.g. membranoproliferative glomerulonephritis and focal segmental glomerulosclerosis) is increased in lipodystrophy, possibly because of reduced immunoregulatory function of adipocytes [219].

Levels of the adipocytokine leptin are markedly reduced in severe lipodystrophies. Leptin replacement has been associated with marked improvements in glycaemic levels, reduced liver steatosis, and hypertriglyceridaemia in generalized lipodystrophy, but its role is limited in partial lipodystrophy and given the cost of the therapy should only be considered when leptin levels are extremely low [220–222].

Other monogenic conditions associated with insulin resistance

Other monogenic conditions associated with insulin resistance either have marked obesity (e.g. Alström and Bardet-Biedl syndromes), neurological disease including myotonic dystrophy and Friedreich ataxia, or rapid aging (e.g. Werner syndrome) [223].

Conclusion

Monogenic diabetes results from single gene changes that affect β-cell function or insulin sensitivity. Correct diagnosis can help define prognosis and the best treatment and allow screening of family members. Diagnostic testing is now widely available and should be considered where presentation is atypical for type 1 diabetes or type 2 diabetes, where there is an autosomal dominant family history, where there are characteristic associated features, and in all cases where diabetes has been diagnosed within the first six months of life.

21 Drug-Induced Diabetes

Charles D. Ponte¹ and Devra K. Dang²

¹ Robert C. Byrd Health Sciences Center, West Virginia University – Schools of Pharmacy and Medicine, One Medical Center Drive, Morgantown, WV, USA

² University of Connecticut School of Pharmacy, Storrs, CT, USA

Key points

- Many commonly prescribed medications can contribute to hyperglycaemia or cause overt diabetes in predisposed individuals.
- The main mechanism by which glucocorticoids cause hyperglycaemia is by reducing insulin sensitivity in the liver, skeletal muscle, and adipose tissue in a dose-dependent fashion.
- Second-generation antipsychotic use requires scheduled monitoring of glucose, lipids, blood pressure, and body mass index.
- Although combined oral contraceptives are associated with metabolic abnormalities, their use is still recommended for women with type 1 diabetes or type 2 diabetes without vascular complications and in women with a history of gestational diabetes.
- Postmenopausal women can safely take menopause hormone therapy without adversely affecting glucose homeostasis or triggering diabetes.
- Menopause hormone therapy has minimal impact on established type 1 diabetes or type 2 diabetes in postmenopausal women. Continued surveillance of glycaemia is prudent in these women and appropriate adjustments should be made to their anti-diabetes drug regimens as needed.
- Thiazide-diuretics can affect glucose homeostasis in a dose-dependent manner, but the effect appears to be modest. Maintaining normokalaemia is the best defence against this potential metabolic consequence of thiazide use.
- Whether β -blockers affect glucose homeostasis or contribute to the development of overt diabetes is inconclusive. β -blockers with vasodilating properties, such as carvedilol and nebivolol, are the preferred choices for people with diabetes or those at significant risk for diabetes, unless contraindicated by comorbidities such as asthma.
- Statins appear to increase insulin resistance and decrease insulin secretion, with small increases in glycated haemoglobin (HbA_{1c}) and fasting glucose.
- Hyperglycaemia and diabetes have been reported with protease inhibitors and some nucleoside reverse-transcriptase inhibitors (zidovudine, stavudine, and didanosine). The nucleoside reverse-transcriptase inhibitors can cause insulin resistance and promote lipodystrophy and pancreatitis.
- Fluoroquinolone-associated dysglycaemia appears to be much more common with gatifloxacin compared to levofloxacin. Hyperglycaemia tends to occur within 1–2 weeks of therapy initiation. Any changes in glycaemia can be managed with careful adjustment of the anti-diabetes regimen and continued blood glucose monitoring.
- The calcineurin inhibitors cyclosporine and tacrolimus are associated with post-transplant diabetes. Risk factors include older age, obesity, corticosteroid use, other-than-White ethnicity, hepatitis C, and genetic determinants.
- Diazoxide is a long-known cause of drug-induced hyperglycaemia and even diabetic ketoacidosis. Its hyperglycaemic effects have been purported to result from impaired insulin secretion, increased glucose production, and decreased peripheral glucose utilization. Evidence suggests that insulin secretagogues (including the incretin mimetics) may be the drugs of choice to manage this condition.
- Whenever possible, exposure to drugs that could affect glucose regulation or glucose levels should be limited. If a precipitant drug cannot be avoided, careful monitoring for the occurrence of hyperglycaemia is warranted. If a morbid event occurs, the dose should be reduced or the drug discontinued.

Drugs can have countless therapeutic benefits and can be lifesaving. However, the potential also exists for drugs to do great harm. Drug therapy can worsen an underlying disease state, resulting in therapeutic challenges for the clinician. Diabetes is one such example where various drugs can worsen glucose levels and even contribute to hypoglycaemic episodes. Importantly, numerous commonly used medications can also predispose the individual to the development of hyperglycaemia and even overt diabetes. Corticosteroids, second-generation antipsychotics (SGAs), diazoxide, statins, oral contraceptives, and niacin are just a few examples of drugs that have been

associated with hyperglycaemia or drug-induced diabetes. Various mechanisms have been proposed for drug-induced hyperglycaemia, which include insulin resistance, decreased insulin secretion, decreased glucose uptake, pancreatitis, weight gain, and increased hepatic gluconeogenesis. Whatever the cause, the clinician should be ever vigilant to the potential for drug-induced dysglycaemia, taking into consideration individual and drug factors, and be prepared to manage its consequences in the appropriate manner.

This chapter will describe selected drug classes and individual drugs that have been associated with hyperglycaemia or overt diabetes.

Table 21.1 Other medications that can induce hyperglycaemia.

Antidepressants
Gonadotropin-releasing hormone agonists
Fish oil
Growth hormone
Interferons
L-asparaginase
Mammalian target of rapamycin (mTOR) inhibitors (everolimus, sirolimus, temsirolimus)
Megesterol acetate
Niacin
Phenytoin
Rifampin
Ritodrine
Somatostatin analogues – most significant with pasireotide
Teprotumab-trbw
Terbutaline
Thalidomide
Tyrosine kinase inhibitors

Source: Based on Dang et al. 2018 [1]; Wilkins and Sambamoorthi 2011 [2]; Sivendran et al. 2014 [3]; Pan et al. 2011 [4]; Novartis 2015 [5].

Attention will be given to predisposing factors along with the attendant pathophysiological characteristics, utilizing the relevant literature and emerging evidence. The focus will be on medications that are commonly prescribed and those with clear and significant potential for the development of diabetes. Other medications that can induce hyperglycaemia are listed in Table 21.1 [1–5]. The chapter will conclude with a discussion of strategies to prevent and manage drug-induced dysglycaemia.

Glucocorticoids

Of all of the medications that can potentially induce hyperglycaemia, glucocorticoids are the drug class that most consistently leads to this effect. Glucocorticoids have been reported to increase blood glucose when administered via numerous routes. They most commonly induce hyperglycaemia when administered intravenously or orally, at supraphysiological doses because of the high bioavailability potential for these routes. They have also been reported to increase blood glucose when administered by the intra-articular and epidural routes [6, 7], and some, but not all, studies found that inhaled corticosteroid led to hyperglycaemia [8, 9]. A case-control study of a large primary care registry in the UK found no association between inhaled, injected, ophthalmic, or topical glucocorticoids with incident diabetes, but oral glucocorticoids are associated with up to 2% of cases of new-onset diabetes. The authors acknowledged the limitations of the database, which may have provided an underestimation of the risk [10]. Other cohort studies have reported that the odds ratio for glucocorticoids-induced new-onset diabetes ranges from 1.36 to 2.31 [11].

The main mechanism by which glucocorticoids cause hyperglycaemia is through reduction of insulin sensitivity in the liver, skeletal muscle, and adipocyte, by approximately 50–70%, which appears to be dose dependent [11–15]. Glucocorticoid administration leads to decreased glucose transport 4 (GLUT4) expression and migration, decreased glycogen synthesis, and increased hepatic

gluconeogenesis [16]. Glucocorticoids also decrease insulin production and secretion [17, 18].

The most common clinical presentation of glucocorticoid-induced hyperglycaemia is a rise in blood glucose starting in mid-morning and continuing throughout the day until bedtime [19]. Therefore, this adverse drug reaction may not be detected if only the fasting blood glucose is monitored. Oral glucocorticoids are typically administered so that they mimic the physiological pattern of endogenous cortisol secretion, and once-daily glucocorticoids such as prednisone and prednisolone are administered in the morning. Taking into account the peak effect of these medications after a dose (e.g. peak effect of prednisone at 4–6 hours), checking a 1–2 hours post-lunch or a pre-dinner blood glucose starting a few days after treatment initiation will enable detection of any hyperglycaemia [11, 18, 19]. An elevation in the fasting blood glucose can occur with higher doses of once-daily glucocorticoids (prednisone 40 mg or equivalent) and with twice-daily administration [19]. People with pre-existing diabetes should monitor their blood glucose more frequently during the course of glucocorticoid treatment and all treated individuals should also be advised to look out for symptoms of hyperglycaemia. There are no published guidelines on the treatment of glucocorticoid-induced hyperglycaemia with diabetes medications, although various strategies have been advocated [11, 19].

Oral agents that enhance insulin sensitivity (e.g. metformin, thiazolidinediones) or stimulate insulin secretion (e.g. sulfonylureas, non-sulfonylurea secretagogues) address the mechanisms underlying glucocorticoid-induced hyperglycaemia. However, concerns about pre-existing renal impairment and other risk factors for lactic acidosis, long duration of action leading to hypoglycaemia especially overnight, or slow onset of effect plus weight gain and oedema make the use of metformin, sulfonylureas, and thiazolidinediones, respectively, not an ideal option in some individuals [11, 19]. The non-sulfonylurea secretagogues and dipeptidyl peptidase-4 inhibitors may be better choices given their quicker onset of action, effect on post-prandial hyperglycaemia, and lower potential for hypoglycaemia [18]. Insulin therapy offers the flexibility of matching the onset, peak, and duration of action to the pattern and degree of hyperglycaemia; furthermore, the dose can be more easily adjusted when the glucocorticoid dose is changed. Neutral protamine Hagedorn (NPH) insulin or a premixed insulin containing NPH can be the best choice for people with diabetes taking an intermediate-acting glucocorticoid (e.g. prednisone) in the morning [11, 18, 19]. When given once daily at breakfast, NPH insulin's peak effect starting at 4 hours after administration and duration of 10–16 hours closely matches the peak effect and duration of prednisone. In individuals taking a long-acting glucocorticoid, such as dexamethasone, twice-daily dosing of intermediate-acting glucocorticoids, and higher doses (e.g. 40 mg or higher of prednisone or equivalent), fasting hyperglycaemia will likely also be seen and a long-acting insulin analogue (glargine, detemir, or degludec) plus prandial insulin will likely be needed [18, 19]. Many courses of treatment with glucocorticoids comprise an initial high dose with a gradual taper to physiological levels before eventual discontinuation. Careful monitoring of blood glucose and subsequent insulin dose adjustments may be necessary to avoid hypoglycaemia as the medication is withdrawn. The results of an ongoing Danish multicentre randomized control trial comparing NPH insulin with the sodium-glucose cotransporter-2 (SGLT-2) inhibitor empagliflozin (EANITIATE study) for individuals with glucocorticoid-induced diabetes may provide additional insight into management strategies [20].

Second-generation antipsychotics

The SGAs, also known as atypical antipsychotics, constitute another drug class with well-known hyperglycaemic effects (Chapter 65). Numerous case reports as well as studies exist of various SGAs worsening existing diabetes, inducing new-onset diabetes, and leading to hyperglycaemic crises [21–24]. SGAs can cause blood glucose elevations both acutely and chronically [25–27]. Hyperglycaemia has been reported for all currently marketed SGAs in the USA, although the degree of severity varies considerably [26, 28–30]. Olanzapine and clozapine appear to have the highest propensity for this adverse drug reaction [26, 27, 31]. SGAs with the lowest potential for hyperglycaemia include the newer SGAs, aripiprazole, ziprasidone, paliperidone, lurasidone, brexipiprazole, and cariprazine, although data and clinical experience with these agents are more limited [28–30, 32, 33]. Quetiapine and risperidone have moderate potential for hyperglycaemia relative to the other SGAs [29].

The mechanism of SGA-induced hyperglycaemia has yet to be fully elucidated, but is likely multifactorial. SGA-induced weight gain is probably an important contributor, and SGAs with the highest potential for weight gain (olanzapine and clozapine) are also associated with the most clinically significant hyperglycaemia. The binding of SGAs to histamine-1, serotonin, norepinephrine, and dopamine receptors, at different affinities depending on the agent, affects weight gain through regulation of hunger and satiety [29]. However, several studies also demonstrated that hyperglycaemia and insulin resistance occur with some SGAs regardless of body weight and food intake [34, 35]. Animal studies suggest that SGAs may induce hyperglycaemia through inhibition of insulin secretion by antagonism of α -1 adrenergic, muscarinic (M_3), and serotonergic (5HT₂) receptors [36, 37].

Similar to glucocorticoids, SGA administration can lead not only to hyperglycaemia, but also to weight gain and dyslipidaemia, which further contribute to cardiovascular risks. These adverse drug reactions, along with the higher prevalence among individuals with mental illness of overweight or obesity, physically inactivity, and smoking, make monitoring and prompt treatment crucial [38]. A large meta-analysis encompassing 25 692 people with schizophrenia found an overall prevalence of 32% for metabolic syndrome, and 52%, 28%, 28%, and 20% for clozapine, olanzapine, risperidone, and unmedicated individuals, respectively [39].

Recommendations for monitoring for the development of hyperglycaemia, weight gain, and dyslipidaemia were first published in 2004 by the American Diabetes Association, American Psychiatric Association, American Association of Clinical Endocrinologists, and North American Association for the Study of Obesity [29], but other national and international guidelines have also emphasized the importance of regular screening for glucose and lipid abnormalities [40, 41]. In addition to obtaining personal and family history of diabetes, dyslipidaemia, hypertension, obesity, and cardiovascular disease, these guidelines also recommend obtaining baseline measurement for glucose, lipids, blood pressure, and body mass index with periodic reassessment. A proposed monitoring schedule can be found in Table 21.2 [42]. Specific to fasting plasma glucose, this should be monitored at 12 weeks then annually. In addition, if the person gains $\geq 5\%$ of their baseline weight during treatment, it is recommended that clinicians consider switching to another SGA [29]. Several studies have shown an improvement in glucose levels after switching from olanzapine to aripiprazole [43].

Table 21.2 Monitoring schedule for second-generation antipsychotics.

Measurement	Baseline	6 weeks	12 weeks	At least annually
Weight and body mass index	X	Measure weekly in first 6 weeks	X	X
Waist circumference	X	X	X	X
Fasting glucose	X	X	X	X
Fasting lipid profile	X	X	X	X
Blood pressure	X	X	X	X

However, changing to another antipsychotic may not always result in equivalent treatment of the mental illness and other measures (therapeutic lifestyle changes, diabetes medications) may need to be employed.

Oral contraceptive agents

Combination oral contraceptive (COC) preparations are used by more than 100 million women worldwide [44]. These products contain one of two oestrogens, mestranol or ethinyl oestradiol, and a variety of progestins (e.g. norethindrone, norgestrel, norgestimate) in monophasic, biphasic, and triphasic formulations. Despite their proven efficacy, adverse events have been ascribed to their use (especially the oestrogen component), including metabolic abnormalities such as glucose intolerance and overt diabetes. The causes of COC-induced dysglycaemia have been historically associated with alterations in insulin sensitivity and insulin secretion. However, current evidence does not support a significant effect of COCs on glucose metabolism or homeostasis and the development of overt diabetes [45]. Interestingly, a recent analysis of data from the Missouri Pregnancy Risk Assessment Monitoring System (PRAMS) in the USA suggested that women with gestational diabetes were nearly 1.5 times more likely to have used hormonal contraception before conception [46]. A recently published Cochrane Database systematic review sought to answer the question of whether COCs adversely affected carbohydrate metabolism in women without diabetes and in those with overweight or obesity. In analysing 31 trials that met the inclusion criteria, there were no significant differences in carbohydrate metabolism among the different preparations. Surrogate end-points used included fasting and two-hour post-prandial glucose, insulin and glucose area-under-the curve (AUC), and glycated haemoglobin (HbA_{1c}) levels. Due to various study design deficiencies, the authors were unable to elucidate the metabolic risk of oral contraceptives in women with obesity [47].

Whereas the risk of dysglycaemia from COCs in women without diabetes remains negligible, metabolic effects arising from the use of these drugs in women with type 1 diabetes or type 2 diabetes can be consequential. Similarly, unplanned pregnancy in this same population also has significant maternal and fetal consequences, especially when associated with hyperglycaemia. Thus contraceptive options must be chosen that do not contribute to an excess metabolic and cardiovascular risk for these women. Based on the eligibility criteria

for contraceptive use published by the World Health Organization (WHO) in 2009 (adapted by the USA in 2010), the use of COCs is favoured in women with type 1 diabetes or type 2 diabetes without vascular complications and in women with a history of gestational diabetes [45]. A 2013 Cochrane Database systematic review failed to show significant differences between progestin-only, combination hormonal, and non-hormonal contraceptives on carbohydrate and lipid metabolism and vascular complications in women with type 1 diabetes or type 2 diabetes [48]. These results were ascribed to various methodological deficiencies, making interpretation problematic.

Menopause hormone therapy

Menopause hormone therapy (MHT) or hormone replacement therapy (HRT) typically involves the administration of oral oestrogens alone or in combination with an oral progestogen for the treatment of postmenopausal symptoms, especially hot flashes, vaginal atrophy, and mood instability. Transdermal and intravaginal formulations are also prescribed. Given the potential for COCs to affect glucose homeostasis and glycaemic indices in women with diabetes, the use of MHT in postmenopausal women can be viewed with similar concerns, especially with oral preparations, as the doses are typically higher than with other routes of administration [49]. The results of two published randomized placebo-controlled trials have dispelled the concern about whether MHT adversely impacts glucose metabolism or precipitates incident diabetes. The Heart and Estrogen/Progestin Replacement Therapy Study (HERS) studied nearly 2800 postmenopausal women with coronary heart disease who took MHT for approximately four years [50]. At the completion of the trial, there was no significant difference in the fasting blood glucose levels between women with and without diabetes and those with impaired fasting glucose. Importantly, women taking MHT had a 35% reduction in incident diabetes compared to those in the placebo arm of the trial (number needed to treat [NNT] = 30 over 4 years). Likewise, women enrolled in the Women's Health Initiative Hormone Trial and receiving conjugated equine oestrogens plus medroxyprogesterone were found to have a 21% lower risk of diabetes ($p = 0.03$) at one-year follow-up compared to placebo controls (NNT = 143 over 5.6 years) [51]. This difference was ascribed to decreases in insulin resistance. Reduced incident diabetes was also noted in a recent meta-analysis of postmenopausal women on low-dose combination HRT [52]. In the same study women with diabetes experienced improved metabolic measures. The findings suggest that postmenopausal women can safely take MHT without adversely affecting glucose homeostasis or triggering diabetes.

Whether women with diabetes can safely take MHT remains more uncertain and untested. A recently published Cochrane Database systematic review showed that glycaemic levels were not affected by MHT in women with type 1 diabetes [53]. However, this finding was based on only one underpowered placebo-controlled randomized clinical trial, making the results questionable. Previous studies evaluating the effects of MHT on women with type 2 diabetes suggest improved glycaemic levels with its use [54, 55]. In a large observational study, investigators evaluated the impact of MHT (opposed and unopposed oestrogen therapy) on HbA_{1c} in women with type 2 diabetes. HbA_{1c} was significantly lower in women taking MHT versus those not on MHT: age-adjusted mean \pm standard error [SE] $7.9 \pm 0.03\%$ (63 mmol/mol) vs $8.5 \pm 0.02\%$ (69 mmol/mol), respectively, $p = 0.0001$ [55]. Likewise, an assessment of data

from the US National Health and Nutrition Examination Survey, 1988–1994 (NHANES III), indicated that postmenopausal women currently taking MHT had lower fasting blood glucose and HbA_{1c} levels versus women who had never taken MHT: 112 vs 154 mg/dl (6.2 mmol/l vs 8.5 mmol/l) and 6.0% vs 7.1%, (42 mmol/mol vs 54 mmol/mol), respectively. Whereas these observational studies cannot support causation, the evidence does promote the notion that MHT has minimal impact on established type 2 diabetes in postmenopausal women. Continued surveillance of glycaemic indices is prudent in these women and appropriate adjustments should be made to their anti-diabetes drug regimens as needed.

Thiazide diuretics

The thiazide diuretics have been a mainstay for the management of hypertension for over 50 years [56]. Early on it was recognized that this drug class could negatively impact glycaemic measures in persons with diabetes [57]. Despite their widespread use and clinical utility, questions continue to be raised regarding their potential effect on glucose homeostasis and glycaemic levels in those with established diabetes. In a recent systematic review and meta-analysis, thiazide diuretics exhibited a dose-dependent modest effect on fasting blood glucose and a negligible effect on HbA_{1c} in people with hypertension [58]. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), a very large landmark study in hypertension management, found significantly more new-onset diabetes (fasting blood glucose ≥ 126 mg/dl [7 mmol/l]) with chlortalidone compared to amlodipine and lisinopril at the four-year follow-up period (11.6%, 9.8%, and 8.1%, respectively) [59]. In addition, people with pre-existing diabetes or those who developed diabetes during the original Systolic Hypertension in the Elderly Program (SHEP) were evaluated as part of a long term follow-up study (14.3 years) [60]. Individuals with diabetes assigned to chlortalidone had lower cardiovascular and total mortality rates compared to placebo controls (hazard ratio [HR] 0.805, 95% confidence interval [CI] 0.680 to 0.952) [60]. These representative studies, although interesting in their findings, provide little resolution to the ongoing debate surrounding thiazide-induced dysglycaemia.

Historically, thiazide-induced dysglycaemia has been connected to alterations in potassium balance, namely hypokalaemia. Since insulin secretion is linked, in part, to an accumulation of intracellular potassium within the pancreatic β cell, potassium loss would impair insulin release, resulting in hyperglycaemia. In an effort to substantiate this long-held belief, a group of investigators reviewed pertinent intervention trials using thiazides from 1966 to 2004 that measured serum potassium and glucose levels [61]. There were 59 trials that met the inclusion criteria. Analysis of the trial data supported an inverse relationship between potassium balance and blood glucose levels. However, the effects on blood glucose were modest, with an average increase of 7.07 ± 7.38 mg/dl (0.4 ± 0.4 mmol/l) [61]. In a subgroup analysis of the SHEP trial, for every 0.5 mEq/l (0.5 mmol/l) decrease in serum potassium there was a corresponding 45% increase in incident diabetes risk (95% CI 24% to 70%; $p < 0.001$) [62]. This association was only evident during the first year of treatment with chlortalidone. In a more recent subgroup analysis, no correlation was found between fasting serum glucose and serum potassium levels in individuals with hypertension receiving hydrochlorothiazide alone or when added to atenolol [63].

Clinicians need to be aware that the thiazide diuretics can affect glucose homeostasis in a dose-dependent manner, but the effect appears to be modest at best. Maintaining normokalaemia is the best defence against this potential metabolic consequence of thiazide use [62]. Any alteration in glycaemic levels can be managed with careful adjustment of the anti-diabetes regimen and continued blood glucose monitoring.

β-adrenoceptor antagonists

β-blockers are widely used to treat a variety of conditions, including hypertension, angina, arrhythmias, and congestive heart failure. Despite their benefits, these drugs can pose problems for people with pre-existing diabetes. Their propensity to mask the adrenergically mediated signs and symptoms of hypoglycaemia and delay its recovery is well known. Theoretically, non-selective β-blockers could also worsen peripheral vascular disease via unopposed α-receptor stimulation of the vasculature. Whether β-blockers affect glucose homeostasis or contribute to the development of overt diabetes is less certain. In a recent meta-analysis and systematic review, non-selective β-blockers were associated with an increase in fasting blood glucose of ~10 mg/dl (0.5 mmol/l) in persons with diabetes. Importantly, adverse outcomes were not noted [64].

In an older prospective cohort study, the use of β-blockers was associated with a 28% increased risk of new-onset diabetes (relative hazard 1.28; 95% CI 1.04 to 1.57) [65]. A more recent systematic literature review examined the effects of various β-blockers on glucose homeostasis, insulin sensitivity, and diabetes risk [66]. β-blockers with vasodilating properties had less pronounced effects on glycaemic indices and insulin sensitivity in people with diabetes. Whereas the evidence supporting an association between the administration of selective and non-selective β-blockers and diabetes risk is inconclusive, β-blockers with α-blocking properties (e.g. carvedilol) may have a reduced or no risk for diabetes [67]. This discrepancy has been attributed to differences in effects on insulin sensitivity compared to conventional β-blockers. These findings warrant consideration of a β-blocker with vasodilating properties, such as carvedilol and nebivolol, as the preferred choice for people with diabetes or those at high risk for diabetes [66].

HMG CoA reductase inhibitors

The 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors, commonly known as statins, have been the mainstay of hyperlipidaemia and cardiovascular protection for over two decades, but their hyperglycaemic potential has only recently been reported. The US Food and Drug Administration (FDA) changed the product labelling of statin medications to include the findings of elevated fasting glucose and HbA_{1c} in 2012 [68]. Statins appear to increase insulin resistance and decrease insulin secretion, with small increases in HbA_{1c} and fasting glucose [69]. A meta-analysis reported that the lowest risk for new-onset diabetes is with pravastatin at 40 mg/day (odds ratio [OR] 1.07, 95% CI 0.86 to 1.3), followed by atorvastatin 80 mg/day (OR 1.15, 95% CI 0.9 to 1.5), and highest with rosuvastatin 20 mg/day (OR 1.25, 95% CI 0.82 to 1.9) when compared to placebo [70]. Another meta-analysis found that the risk of incident diabetes is 9% (OR 1.09, 95% CI 1.02 to 1.17) and that treatment of 255 individuals for four years would result in one

additional case of diabetes [71]. The authors also reported that statin therapy would prevent 5.4 major coronary events (coronary heart disease death and non-fatal myocardial infarction) in these 255 individuals, and that the potential benefit would be expected to be greater if prevention of strokes and revascularization was also taken into account [71]. The Justification for the Use of Statins in Primary Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) trial reported that, for those with one or more diabetes risk factors, rosuvastatin was associated with a 28% increase in diabetes, but 134 cardiovascular events or deaths were avoided for every 54 new cases of diabetes [72]. The American Diabetes Association Standards of Medical Care in Diabetes guideline noted that the absolute risk of rosuvastatin-induced diabetes is small (1.5% with rosuvastatin compared to 1.2% with placebo over five years) and recommends statin therapy for most people with diabetes with overt cardiovascular disease or cardiovascular risk factors [73, 74].

Antiretroviral therapy for human immunodeficiency virus

The pharmacological treatment of human immunodeficiency virus (HIV)-1 currently includes nucleoside reverse-transcriptase inhibitors (NRTIs), non-nucleoside reverse-transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase strand transfer inhibitors, fusion inhibitors, chemokine receptor antagonists, CD4 post-attachment inhibitors, and gp120 attachment inhibitors. Hyperglycaemia and diabetes have been reported with PIs and some of the NRTIs (zidovudine, stavudine, and didanosine) [75]. In a recent meta-analysis, the incidence of diabetes and pre-diabetes in people taking antiretrovirals was 13.7 and 125 per 1000 person-years. Risk factors included age, obesity, family history, lipodystrophy, and antiretroviral therapy regimen [76]. NRTIs can cause insulin resistance and promote lipodystrophy and pancreatitis [1, 77, 78]. PIs induce hyperglycaemia through increasing insulin resistance and the development of lipodystrophy [79–85]. *In vitro* studies also demonstrated that some PIs can decrease insulin secretion [81, 85]. PI-induced lipodystrophy (Figure 21.1) is characterized by lipohypertrophy (resembling central obesity) with or without lipoatrophy, manifesting as peripheral fat loss (particularly in the extremities, face, and buttocks) [86]. Lipodystrophy, insulin resistance, hyperglycaemia, and the dyslipidaemia (elevated triglyceride and total cholesterol, reduced high-density lipoprotein cholesterol) associated with PIs can increase the risk of cardiovascular events in treated individuals. In 2021, HIV diagnosis was incorporated into the American Diabetes Association's Standards of Medical Care in Diabetes guideline as a risk factor that warrants screening. The guideline specifically recommended that 'Individuals with HIV should be screened for diabetes and prediabetes with a fasting glucose test before starting antiretroviral therapy, at the time of switching antiretroviral therapy, and three to six months after starting or switching antiretroviral therapy. If initial screening results are normal, fasting glucose should be checked annually' [87].

Pentamidine

Pentamidine is an antifungal/antiprotozoal agent, which is FDA-approved for the treatment and prevention of *Pneumocystis jirovecii* pneumonia commonly associated with HIV infection and those

Figure 21.1 Protease inhibitor-induced lipodystrophy. (a, b) 'Buffalo hump' caused by nuchal fat deposition. (c, d) Facial fat atrophy. Source: Courtesy of Professor Munir Pirmohamed, University of Liverpool, UK.

with immunodeficiency or malignancy. The drug is usually administered intravenously or via inhalation for adults and children alike. Importantly, the drug has the propensity to cause both hypoglycaemia and hyperglycaemia. Its well-known dysglycaemic effects are due to impaired insulin secretion and direct cytotoxicity and β -cell apoptosis. In 128 immunocompromised individuals with *P. jirovecii* pneumonia, pentamidine was associated with 7 cases of hypoglycaemia, 23 cases of overt diabetes, and 18 cases of hypoglycaemia followed by diabetes. The drug was administered parenterally in 75% of the individuals. Hyperglycaemia was noted an average of 52 days (20–90 days) following pentamidine administration. Insulin was required in 63% of those with diabetes. Risk factors for the development of diabetes included high doses, impaired renal function, and poor clinical status of the individual [88]. In a retrospective chart review of pentamidine-associated adverse drug reactions in 106 HIV-infected people, 9 experienced hyperglycaemia, with average blood glucose levels of 369 mg/dl (20.4 mmol/l) and a mean time to onset of 14 days [89]. Providers need to be

aware of the development of hyperglycaemia with pentamidine and monitor the individual accordingly for this late-appearing adverse drug reaction.

Fluoroquinolones

The fluoroquinolone class of antimicrobial agents has been available for over 50 years. Despite these drugs' clinical utility, several well-known adverse effects have been reported, most noteworthy being arthropathy and QT prolongation [90]. In retrospective analyses, serious dysglycaemia (both hypoglycaemia and hyperglycaemia) has also been associated with their use, culminating in the voluntary removal of gatifloxacin from the US and Canadian markets in 2006 owing to a significant risk of hospitalization for hypoglycaemic or hyperglycaemic episodes [91,92]. Although oral gatifloxacin is no longer available from many markets (e.g. USA, Canada, Japan, India), it is still sold around the world and is

available via online distributors. In 2018, the FDA announced additional warnings for the fluoroquinolone class to include the potential for hypoglycaemic coma, especially in older people and those taking oral anti-diabetes agents and/or insulin [93]. Inhibition of adenosine triphosphate (ATP)-dependent potassium channels on pancreatic β cells resulting in increased insulin secretion may play an aetiological role [94].

Whereas many drug adverse effects are a class effect, fluoroquinolone-associated dysglycaemia appears to be much more common with gatifloxacin compared to levofloxacin. Ciprofloxacin poses little or no risk [92]. Of the currently available fluoroquinolones in the USA, moxifloxacin appears to have the highest likelihood for causing hyperglycaemia compared to levofloxacin or ciprofloxacin. A recent large population-based cohort study of approximately 78 000 individuals in Taiwan found that the overall risk of hyperglycaemia and hypoglycaemia was greater with moxifloxacin compared to levofloxacin, ciprofloxacin, macrolides, and second-generation cephalosporins [95].

The aetiology of fluoroquinolone-induced hyperglycaemia is unclear, but possible contributing factors include a history of diabetes, failure to adjust doses in renal insufficiency, acute illness, and age. Recent animal studies suggest that hyperglycaemia results from increased drug accumulation in the pancreas of individuals with diabetes, histamine-associated release of the counter-regulatory hormone epinephrine, and the prolonged secretion of glucagon-like peptide 1 (GLP-1), which inhibits insulin secretion and production [96–98].

The risk of hyperglycaemia from fluoroquinolone use (with and without diabetes) warrants careful surveillance by clinicians and those taking the drugs alike. Hyperglycaemia tends to occur within 1–2 weeks of therapy initiation and is dose related. Any changes in glycaemic indices can be managed with careful adjustment of the anti-diabetes regimen and continued blood glucose monitoring. Likewise, hypoglycaemic signs and symptoms must be verified and managed accordingly. Adjustments of oral anti-diabetes and insulin therapy may be required. Recent evidence supports a possible role for octreotide in the management of refractory fluoroquinolone-induced hypoglycaemia [94].

Calcineurin inhibitors

There are various classes of drug that are used as immunomodulators to combat rejection following organ transplantation or to manage autoimmune diseases and other inflammatory conditions. One such class is the calcineurin inhibitors. Well-known representative examples include cyclosporine and tacrolimus. Calcineurin is a protein that is involved in the production of the cytokine interleukin-2 (IL-2) by T-helper cells. IL-2 is responsible for T-cell differentiation, which is important in the maintenance of cellular immunity.

It had been recognized for many years that transplant recipients experience glucose intolerance and also develop type 2 diabetes [99]. Several associated risk factors were implicated in the development of post-transplant hyperglycaemia or diabetes, including the widespread use of corticosteroids in this population. In addition to the transplant itself, immunosuppressant agents administered to counteract rejection were also implicated, namely cyclosporine and tacrolimus [99]. The prevailing belief that cyclosporine is less likely to impair glucose homeostasis than tacrolimus has been questioned [100]. Alterations in insulin sensitivity and

impaired β -cell function are cited as causative factors in the development of glucose intolerance. However, recent evidence corroborates findings that defective insulin secretion is the primary pathological defect [101]. Whether cyclosporine has any advantages over tacrolimus in managing transplant recipients with pre-existing type 2 diabetes has recently come into question, yet remains controversial [102, 103].

Risk factors for new-onset diabetes after transplantation (NODAT) include older age, obesity, corticosteroid use, other-than-White ethnicity, hepatitis C, and genetic determinants [104]. Glucose intolerance or overt diabetes tends to occur within six months of immunosuppressant therapy. Clinicians need to be aware of individual risk factors and aggressively manage dysglycaemia when it occurs. Inattention to NODAT can result in graft failure and other diabetes-related complications [104]. The optimal therapeutic approach remains to be defined, but emerging evidence suggests that insulin secretagogues, the dipeptidyl peptidase 4 (DPP-4) inhibitors, and basal insulin may be suitable drug options [104–106].

Diazoxide

Diazoxide is a thiazide-like drug that had been in clinical use for over 40 years for the management of hypertensive emergencies and hyperinsulinaemic hypoglycaemia (secondary hypoglycaemia). At present, the drug is only available as an oral suspension for the treatment of secondary hypoglycaemia (e.g. insulinoma, islet cell hyperplasias). Importantly, it has been long recognized as a cause of drug-induced hyperglycaemia and even diabetic ketoacidosis [107]. Its hyperglycaemic effects have been purported to result from impaired insulin secretion, increased glucose production, and decreased peripheral glucose utilization [108, 109]. Diazoxide's ability to inhibit insulin secretion results from *opening* the ATP-sensitive potassium (K_{ATP}) channel in the β cell of the pancreas. This ability to inhibit insulin secretion may prove useful in the management of type 1 diabetes and type 2 diabetes by preserving β -cell function [110]. Likewise, diazoxide may improve hypoglycaemic unawareness via opening the sulfonylurea receptor 1 (SUR1)-selective K_{ATP} channels in the central nervous system [110].

Prevention and treatment strategies

The old adage that an ounce of prevention is worth a pound of cure is germane to any discussion involving drug-induced dysglycaemia. Clinicians need to be sensitized to the reality that drug therapy may precipitate hyperglycaemia in predisposed individuals as well as lead to overt diabetes mellitus. It may be best to avoid precipitant drugs whenever possible and choose more appropriate alternatives. When evaluating a possible case of drug-induced dysglycaemia, a careful review of prescription and non-prescription (over-the-counter) medications as well as herbal products and dietary supplements can reveal possible offenders. In addition to a thorough drug history, the clinician should also evaluate the individual person's drug regimen and comorbid conditions that may affect the pharmacokinetics or pharmacodynamics of the suspected drug. When drug-drug interactions are suspected, numerous resources are available to the clinician to facilitate their evaluation. These include various compendia, online references, smartphone applications,

Part 4 Other Types of Diabetes

professional colleagues, and drug and health information centres. As with any reference tool, it is important to corroborate the information found using a second or third source. This ensures that the information is timely, accurate, and reliable.

Clinicians are often stymied when assessing non-prescription medications by the sheer number of products available for consumption. One can overcome this fact by employing a review of systems approach, akin to asking the individual about organ system-based complaints as part of a medical history. In this systematic approach, major product categories are captured and evaluated by asking *head-to-toe* questions. This method has been previously published if more information is needed [111].

Whenever possible, limit an individual's exposure to drugs that could affect glucose regulation. Careful attention should be paid to limiting the numbers of drugs, as well as the doses and duration of therapy whenever possible. Baseline data such as weight, renal function, and fasting blood glucose levels should be obtained when appropriate. This is especially important in individuals taking more than one medication with the potential for hyperglycaemia, prescribed a high dose of the medication, taking concomitant drugs that can increase the concentration or duration of the medication, or those with other risk factors for diabetes (Table 21.3) [1, 74]. Importantly, prospective monitoring of high-risk individuals should be an ongoing process.

In the event that a precipitant drug cannot be avoided in a given person, prudence would dictate careful monitoring for the occurrence of dysglycaemia. If a morbid event occurs, the dose of the

Table 21.3 Risk factors for diabetes.

Age ≥ 35 years
Family history (first-degree relative) of diabetes
Race/ethnicity (e.g. African American, Latino, Indigenous American, Asian American, Pacific Islander)
Physical inactivity
Overweight or obese (body mass index $\geq 25 \text{ kg/m}^2$ or $\geq 23 \text{ kg/m}^2$ in Asians)
Hypertension ($\geq 140/90 \text{ mmHg}$ in adults or on therapy for hypertension)
High-density lipoprotein cholesterol $<35 \text{ mg/dl}$ (0.90 mmol/l) and/or triglyceride level $>250 \text{ mg/dl}$ (2.82 mmol/l)
History of cardiovascular disease
History of gestational diabetes
HIV
Polycystic ovary syndrome
Previously identified pre-diabetes based on laboratory values
Other clinical conditions associated with insulin resistance (e.g. acanthosis nigricans, severe obesity)

offending agent can be reduced or the drug can be discontinued if suitable. If necessary, supportive care may be required for a time dependent on the drug in question and the clinical status of the individual. Most importantly, the clinician should learn from the incident and develop strategies to obviate such happenings in the future.

Diabetes in Hypersecreting Endocrine Disorders

Allan A. Vaag¹, Neil A. Hanley², and Caroline M. Kistorp¹

¹Steno Diabetes Center Copenhagen and Rigshospitalet, Copenhagen, Denmark

²Centre for Endocrinology and Diabetes, University of Manchester, Manchester, UK

Key points

- Hypersecretion of glucocorticoids in Cushing syndrome is associated with insulin resistance and impaired glucose homeostasis in around 70% of cases.
- Hypersecretion of growth hormone from adenomas in the anterior pituitary causes acromegaly, which is associated with impaired glucose homeostasis in up to 38% of all individuals with the disease.
- Hypersecretion of catecholamines from adenomas of the chromaffin cells in the adrenal medulla or paraganglioma causes hyperglycaemia in approximately 50% of cases.
- Hypersecretion of glucagon or somatostatin from pancreatic islet cell adenomas is a rare endocrine cause of diabetes.
- Hypersecretion of thyroid hormones in thyrotoxicosis causes mild and most often transient glucose intolerance.
- Hypersecretion of aldosterone, parathyroid hormone, or vasoactive intestinal peptide due to hyperplasia or adenoma is associated with mild glucose intolerance.
- Hypersecretion of androgenic steroids causes insulin resistance and glucose intolerance in up to 50% of women with polycystic ovarian syndrome.

Diabetes is defined by arbitrary cut-off levels of plasma glucose and/or glycated haemoglobin (HbA_{1c}) levels, thought to reflect the level of glycaemia that differentiates between people with or without risk of micro- and macrovascular diabetes complications. However, with insufficient knowledge of the exact causal or non-causal relationships between glycaemia and each of the multiple distinct vascular and non-vascular complications, and without being able to exactly factor in the time and duration of the diabetes dimension, it is clear that there is a grey zone in which people may be misclassified as either having or not having diabetes. Obviously, this dimension is of higher importance in type 2 diabetes compared with type 1 diabetes. Furthermore, this issue has increasing importance in those with relatively mild diabetes secondary to the general activation of stress responses in individuals with a range of different diseases, including infections, acute severe illness, cancer, and heart failure. Multiple types of cancer as well as heart failure often precede and even may be the primary cause of diabetes in some individuals [1]. An intriguing dimension of this is that the excess morbidity and mortality in people with diabetes secondary to other diseases may not necessarily be due to diabetes *per se* [1], and that the otherwise unexplained U-shaped relationship between HbA_{1c} and mortality in type 2 diabetes could reflect different causes of death in individuals with high versus low HbA_{1c} , with the latter population more likely to die from other diseases than diabetes [1]. The mechanism by which multiple types of endocrine disorders and diseases cause diabetes reflects activation of stress hormones, including growth hormone (GH), catecholamines, steroids, glucagon, and thyroid hormones. In that context, it is not difficult to

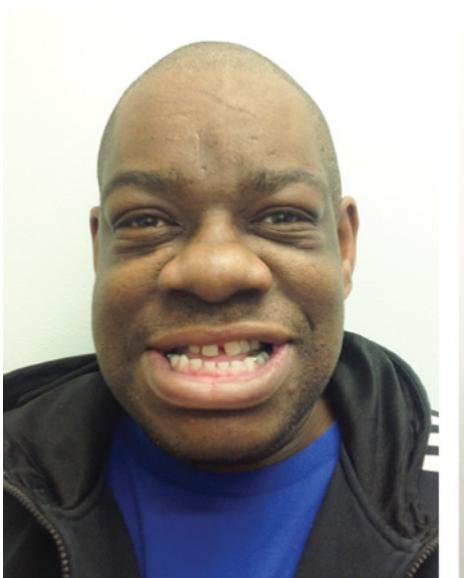

understand why pathological overproduction and hypersecretion of these hormones may cause or precipitate overt diabetes, which for most cases phenotypically resembles type 2 diabetes, but probably more correctly should be classified as secondary diabetes. The aim of this chapter is to provide a brief overview of endocrine disorders that cause secondary and often transient diabetes as a result of uncontrolled excessive secretion of *counter-regulatory hormones* involved in physiological regulation of glucose homeostasis and protection against hypoglycaemia on a daily basis.

Acromegaly

Clinical presentation

Acromegaly is caused by excessive GH secretion leading to bone and soft tissue overgrowth as well as cardiovascular and metabolic complications (Figure 22.1, Table 22.1) [2]. Acromegaly affects between 60 and 240 people per million [2] and is most frequently caused by a pituitary adenoma larger than 1 cm in diameter (a *macroadenoma*; Figure 22.1). Acromegaly may less frequently be caused by a *microadenoma* (diameter less than 1 cm) and a minority (<1%) of cases are caused by excessive secretion of GH-releasing hormone (GHRH) from a hypothalamic gangliocytoma or a carcinoid tumour in the pancreas or the lung [3]. Acromegaly may in rare cases appear as part of the multiple endocrine neoplasia type 1 and type 4 (MEN1) syndrome as a result of a mutation in the tumour suppressor gene, *MENIN* [4]. MEN1 can also include

(a)

(b)

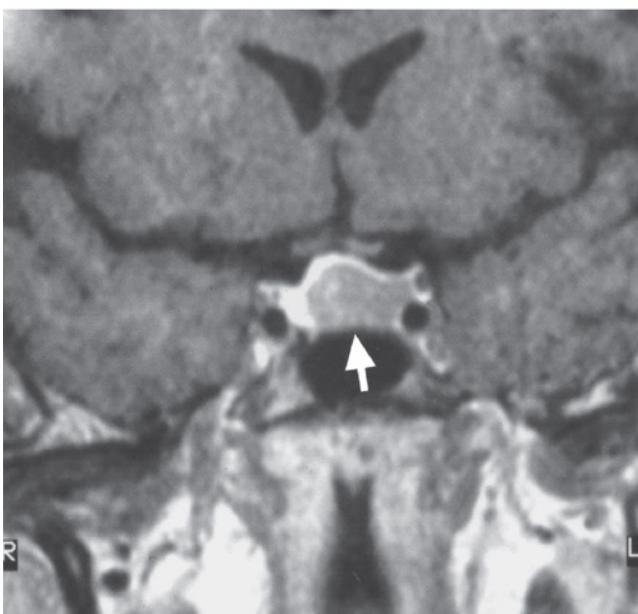

Figure 22.1 (a) Characteristic features of a man with untreated acromegaly. Note the teeth separation, particularly noticeable in the lower jaw, and the associated underbite from the mandibular overgrowth. The hand illustrates soft tissue overgrowth and is often described as spade-like. (b) Magnetic resonance imaging from an individual shows a large adenoma (arrow) in the pituitary extending up to but not in contact with the optic chiasm and also extending out into the left cavernous sinus. Source: Courtesy of Professor Neil Hanley and Rachel Jennings, University of Manchester, UK.

glucagonomas and somatostatinomas, both of which can independently cause secondary diabetes. Acromegaly may in rare cases occur in familial isolated pituitary adenomas as a result of mutations in the aryl hydrocarbon receptor-interacting protein (*AIP*) tumour suppressor gene, which is associated with early onset and a more aggressive disease [5]. Acromegaly has most often been present several years prior to the clinical diagnosis based on the characteristics outlined in Figure 22.1 and Table 22.1 [1]. Onset of acromegaly in adolescence prior to the closure of linear growth results in excessive adult height or *gigantism*. Untreated GH excess

is associated with hypertension, increased morbidity, and mortality from cardiovascular disease as well as glucose intolerance [1].

Glucose intolerance

Abnormal glucose tolerance or overt diabetes occurs in 15–38% of all individuals with acromegaly as a direct result of elevated GH and insulin-like growth factor I (IGF-I) levels (Figure 22.2) [6]. Indeed, the severity of diabetes and to some extent insulin resistance correlates directly with the degree of elevated GH and IGF-I levels in acromegaly [7].

Table 22.1 Clinical features of acromegaly.

Musculoskeletal
Protruding mandible (prognathia) with lower teeth separation
Big tongue (macroglossia)
Enlarged forehead (frontal bossing)
Acral growth of hands and feet (carpal tunnel syndrome, tight rings, increasing shoe size)
Large joint arthropathy and arthralgia
Gigantism (if growth hormone excess prior to epiphyseal closure)
Skin
Irritating, thickened, greasy (increased sebum production)
Excessive sweating
Cardiovascular
Dilated cardiomyopathy, cardiomegaly, and cardiac failure
Hypertension
Metabolic
Glucose intolerance/diabetes
General
Headaches
Tiredness, often very disabling, lowers quality of life and ability to work
Local tumour effects
Compression of the optic chiasm (superior tumour growth) or cranial nerves III, IV, and/or VI (lateral tumour growth into cavernous sinus)

The underlying pathogenic mechanisms of diabetes in acromegaly resemble common type 2 diabetes, including both hepatic and peripheral (muscle) insulin resistance, as well as impaired pancreatic insulin secretion in either a relative or an absolute sense [8]. GH is a strong enhancer of adipose tissue lipolysis generating non-esterified fatty acids (NEFAs), which in turn via the *glucose-fatty acid* cycle (Figure 22.2) cause both hepatic and muscle insulin resistance, as well as with time also impaired pancreatic insulin secretion, eventually resulting in overt hyperglycaemia [8].

Diagnosis and treatment

The simplest and most frequently used screening test for acromegaly is a measurement of the serum IGF-I level [3]. If markedly raised above the reference, and exogenous GH administration is excluded, the test is diagnostic for acromegaly, but is primarily used as a rule-out measure [3]. Subsequent diagnostic tests include a series of random serum GH measurements, and/or a two-hour 75 g oral glucose tolerance test (OGTT), with the latter taking advantage of the negative feedback by glucose on GH secretion. Failure to suppress the GH level to below 0.4 µg/l is diagnostic of acromegaly. Individuals with type 1 diabetes commonly exhibit GH hypersecretion [9] (Figure 22.3), which in turn may reflect GH resistance and the reduced effect of GH to stimulate IGF-I secretion in the liver, resulting in circulating IGF-I levels in the lower normal range (Figure 22.4). Accordingly, an increased circulating IGF-I level above the normal range is a strong diagnostic indicator of acromegaly in type 1 diabetes. The elevated GH levels in type 1 diabetes return to normal with improved glycaemic levels.

Biochemical diagnosis (or suspicion) of acromegaly provides the indication for magnetic resonance (MR) imaging of the anterior pituitary to detect and measure the size of the adenoma (Figure 22.1).

Treatment of acromegaly involves surgery, medical therapy, and in rare therapy-resistant cases radiotherapy (Table 22.2) [3]. A conservative observational strategy may be applied in individuals with acromegaly if the risks of treatment side effects and/or complications exceed the expected beneficial effects on symptoms. Trans-sphenoidal surgery is first-line therapy of a macroadenoma, rapidly lowering GH levels and reducing any increased pressure on the optic chiasm, subsequently resulting in reduced symptoms including improvements of affected visual fields. However, due to the macroadenoma's large size, commonly extending beyond the pituitary fossa, surgery is only curative in around 40–50% of individuals with macroadenomas [12]. In contrast, cure is achievable in more than 85% of individuals with microadenomas [12].

Once-monthly injection of the somatostatin analogues, octreotide long-acting release (octreotide-LAR) and lanreotide, is first-line medical therapy, which lowers circulating GH and normalizes IGF-I levels in 30–50%, and is associated with a reduction in tumour volume in ~60% of individuals with acromegaly [1, 13, 14]. In some cases, increasing doses and/or reduced dose interval may improve clinical and biochemical response. The primary side effects are gastrointestinal, but with neutral long-term impact on glucose tolerance.

Oral octreotide was recently approved in the USA as long-term treatment. Pasireotide is a novel and more potent somatostatin analogue, which primarily inhibits somatostatin receptor type 5 (SST5). The use of pasireotide is associated with a high prevalence of hyperglycaemia (70%) and overt diabetes in up to 40% of individuals with acromegaly, due to inhibition of insulin secretion [15].

Oral treatment with the dopamine agonist cabergoline has only a modest effect on GH secretion in a limited number of individuals

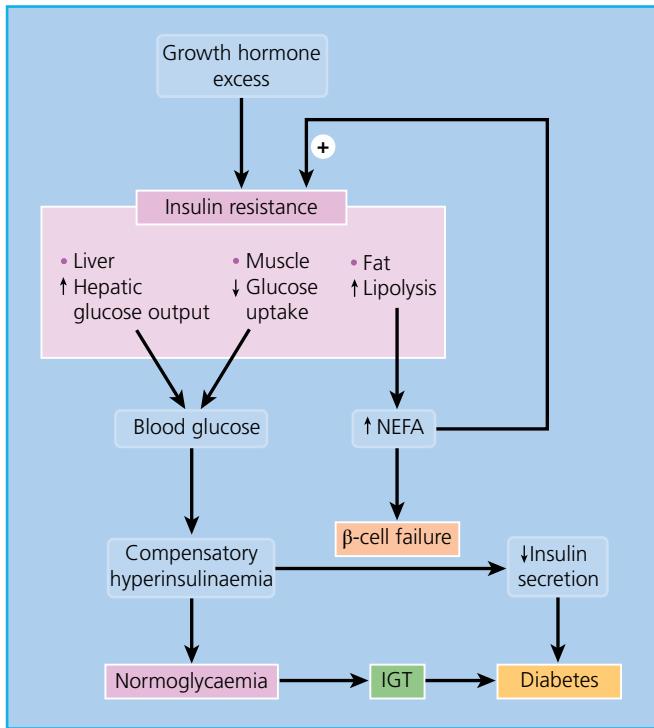

Figure 22.2 Mechanisms of hyperglycaemia and diabetes in acromegaly. Diabetes develops if β cells fail to compensate for the increased demand for insulin. IGT, impaired glucose tolerance; NEFA, non-esterified fatty acid.

Diabetes in acromegaly resembles mild or moderately severe type 2 diabetes. Insulin treatment is rarely required, and most individuals can be treated with diet and oral anti-diabetes drugs [6].

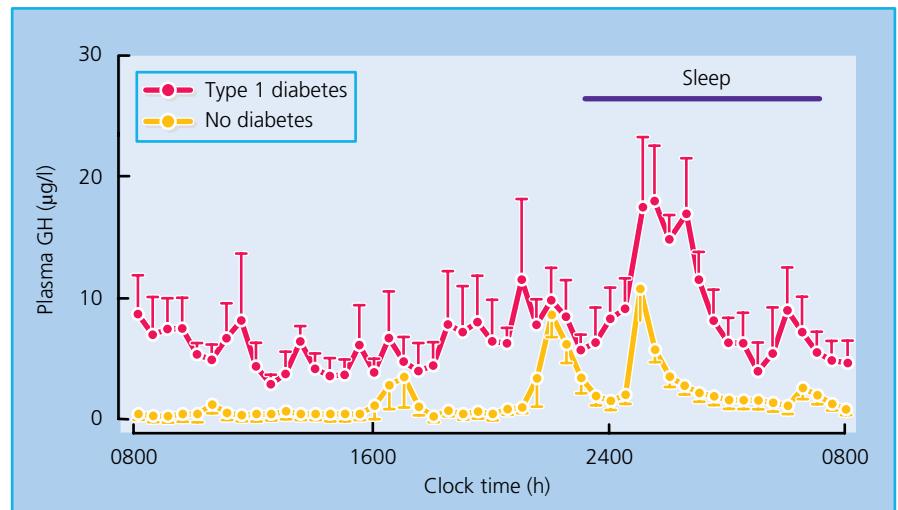

Figure 22.3 Increased growth hormone (GH) secretion in type 1 diabetes. Note the marked hypersecretion during sleep in the early hours of the morning.
Source: Hansen et al. 1970 [10]. Reproduced with permission of John Wiley & Sons.

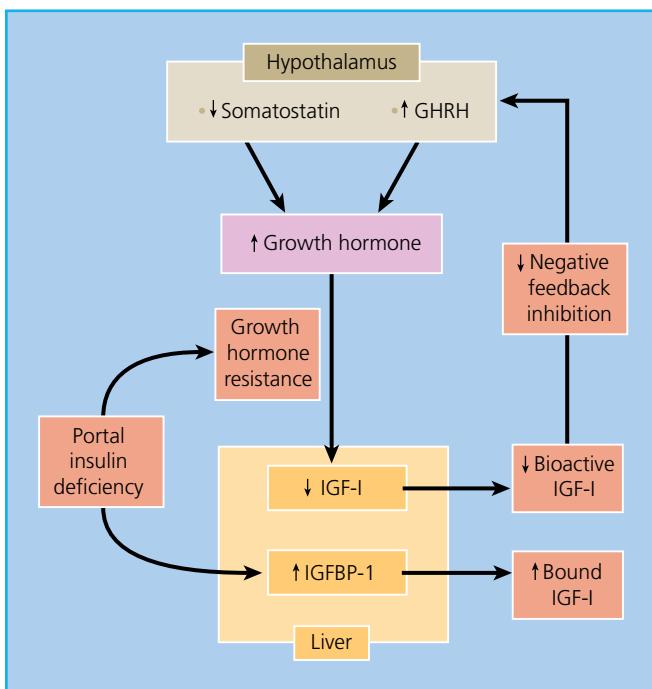

Figure 22.4 Mechanisms of growth hormone (GH) hypersecretion in diabetes. Insulin-like growth factor binding protein 1 (IGFBP-1) binds and reduces the bioavailability of insulin-like growth factor I (IGF-I), which normally decreases GH secretion by negative feedback inhibition on the hypothalamus and pituitary; IGFBP-1 expression is inhibited by insulin. GHRH, growth hormone-releasing hormone.

and is rarely sufficient as mono-therapy. Cabergoline may be a useful adjunct co-treatment to surgery and/or somatostatin analogue injection therapy in the ~25% of individuals with acromegaly with co-secretion of prolactin, indicative of increased expression of dopamine receptors in the adenoma [14]. Besides increased suppression of GH secretion, this allows for reduced doses, and therefore reduced costs, as well as fewer of the gastrointestinal side effects associated with use of somatostatin analogues.

Table 22.2 Treatment of acromegaly.

Advantages	Disadvantages
Transsphenoidal surgery	
Rapid effect Can restore vision in optic nerve compression Might be curative if complete resection	Invasive, requires general anaesthetic Non-curative for large extrasellar tumours
Somatostatin analogue drugs	
Non-invasive May reduce tumour Normal IGF-I in up to 60% of treated individuals	Monthly intramuscular injection Expensive Gastrointestinal side effects (diarrhoea) Unlikely to be curative (i.e. continuous therapy needed) Hyperglycaemia and overt diabetes (pasireotide)
Pegvisomant	
Non-invasive Blocks GH action	Expensive GH concentrations remain elevated
Radiotherapy	
Non-invasive Likely to shrink tumour Likely to reduce GH levels Might be curative	Slow onset of effect (several years) Standard external three-beam radiotherapy likely to cause hypopituitarism by destroying other pituitary cell types

GH, growth hormone; IGF-I, insulin-like growth factor I.

Source: Adapted from Holt and Hanley 2021 [11].

As an alternative to GH-lowering treatments, pegvisomant was developed as a GH antagonist preventing GH dimerization, thereby blocking downstream GH signalling. Pegvisomant effectively results in reversing symptoms and clinical features of acromegaly and is associated with a normalization of IGF-I levels in ~60% of all treated individuals after five years of treatment [3, 16, 17]. As a result of reduced negative feedback inhibition, pegvisomant treatment increases circulating GH levels from the somatotroph

adenoma. This, however, is not associated with increased tumour growth, as otherwise seen in bilateral adrenalectomy in Cushing disease (Nelson syndrome) [16, 17].

Radiotherapy is only used as third-line treatment in rare cases with active disease after surgery and medical therapy. Conventional three-field external beam radiotherapy is highly effective in pituitary tumour destruction and lowering of GH and IGF-I levels [3, 18]. Alternatively, if preservation of adjacent normal pituitary tissue and function has a high priority, stereotactic radiotherapy may be applied. Pituitary radiotherapy is associated with increased risk of subsequent cerebrovascular disease, which needs to be considered when deciding between the available treatment options [19].

Glucose tolerance and acromegaly treatment

Glucose tolerance improves in most individuals after successful treatment with normalization of GH levels using pituitary surgery and/or irradiation [20, 21]. Somatostatin analogues decrease insulin secretion and may therefore be associated with transient deterioration of glucose intolerance in some individuals [22, 23]. However, glucose tolerance improves along with lower GH levels during long term somatostatin analogue treatment in most individuals [13]. Insulin sensitivity and glucose tolerance also improve when blocking GH receptor binding with pegvisomant [24, 25]. Post-surgery or radiotherapy, hypopituitarism and GH deficiency may predispose to increased total and central adiposity, which in turn may cause or precipitate insulin resistance and glucose intolerance [8]. Glucose intolerance in individuals treated for or recovering from acromegaly cannot be differentiated from type 2 diabetes.

GH promotes growth including increased vascularization and excessive GH levels have been linked to proliferative diabetic retinopathy. Increased numbers of retinal vessels have been reported in acromegaly [26], and resolution of diabetic retinopathy has been reported in a few individuals with rapid-onset panhypopituitarism [27, 28]. People with diabetes who have GH deficiency only rarely develop retinopathy [29], and a study in mice showed that inhibition of GH secretion ameliorated diabetic retinopathy [30]. Nevertheless, compared with people with diabetes without acromegaly, individuals with both acromegaly and diabetes do not show an increased incidence of diabetic retinopathy [31, 32].

This may be due to the relatively mild or transient phenotypic presentation of diabetes in acromegaly, or alternatively it may reflect that GH is not a strong driver of diabetic retinopathy.

Cushing syndrome

Origin and clinical features

Cushing syndrome is caused by excessive glucocorticoid levels accompanied by characteristic changes of physical appearance, as well as various pathological metabolic and cardiovascular changes (Figure 22.5, Table 22.3) [33–35]. Cushing syndrome along with Cushing disease (Cushing syndrome caused by adrenocorticotropin [ACTH]-secreting corticotroph pituitary adenomas) are named after Harvey Cushing, who was the first to describe the condition(s) in 1912. The commonest cause of Cushing syndrome is the use of synthetic glucocorticoids to treat or prevent conditions with aberrant activation of the immune system as a core part of the disease pathology, such as rheumatoid arthritis, asthma, and chronic obstructive pulmonary disease (COPD). Two-thirds of all cases with Cushing syndrome arising in the context of a non-iatrogenic state are due to excessive ACTH-secreting adenomas of the anterior pituitary, with an incidence rate of 2–3 new cases per million people per year. In ~20% of individuals with endogenous Cushing syndrome, the cause is an adrenal cortex glucocorticoid-secreting tumour, and in 5–10% the cause is ectopic ACTH secretion from a small cell lung carcinoma or from carcinoid tumours [33–36]. Cushing syndrome is three times more common in women than in men, and the characteristic symptoms, physical appearance, as well as increased cardiovascular morbidity and mortality are caused directly by prolonged excessive cortisol levels and tissue exposure. Cortisol is the predominant glucocorticoid hormone in humans (Figure 22.5, Table 22.3) [33–36].

Disturbance to glucose tolerance

Overt diabetes is observed in 20–50% of individuals with Cushing syndrome, and up to 70% of cases exhibit some degree of glucose intolerance [35, 37, 38]. Individuals with pre-existing diabetes

1 month pre-op : 6 months post-op

Figure 22.5 Cushing syndrome in a woman presenting with glucose intolerance, hypertension, and altered appearance. The original presentation related to subfertility was attributed as polycystic ovarian syndrome. The cause of the glucocorticoid excess was a small adenoma in the right adrenal gland. Six months following its removal by unilateral adrenalectomy, the pronounced changes in physical appearance led to the woman being requested to renew her passport. Blood pressure and glucose homeostasis returned to normal. Source: Courtesy of Professor Neil Hanley and Rachel Jennings, University of Manchester, UK.

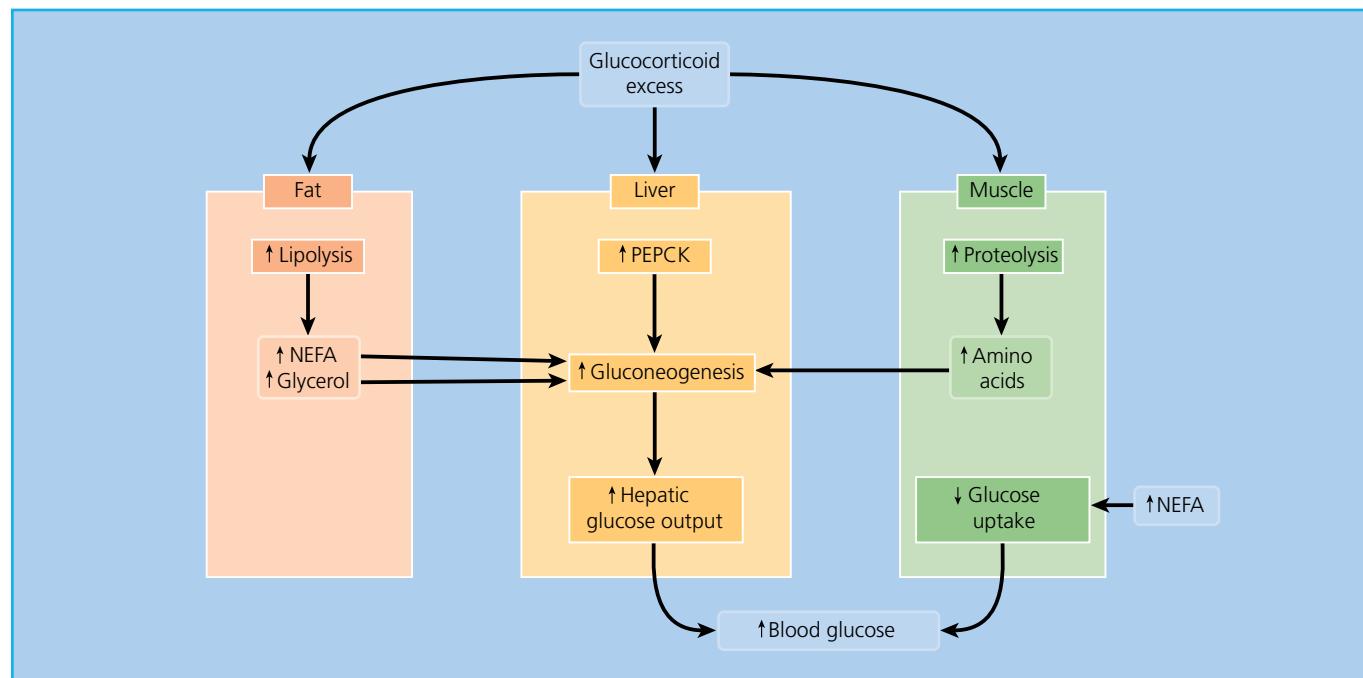

Table 22.3 Clinical features of Cushing syndrome.

Easily bruised, thin skin; poor wound healing
Striae (purple or violaceous rather than white)
Thin (osteoporotic) bones that easily fracture
Glucose intolerance/diabetes mellitus
Central obesity, characteristic rounded facies, buffalo hump
Susceptibility to infection
Predisposition to gastric ulcer
Hypertension
Disturbance of menstrual cycle; symptoms overlap with polycystic ovarian syndrome
Mood disturbance (depression, psychosis)

risk factors such as obesity or a family history of diabetes are at the highest risk. As is the case for almost all types of diabetes secondary to hypersecreting endocrine conditions, diabetes in Cushing syndrome is phenotypically indistinguishable from the clinical presentation of type 2 diabetes. Glucocorticoid excess causes both hepatic and peripheral insulin resistance appearing alongside hyperinsulinaemia as a compensatory phenomenon [37]. The increased hepatic glucose production is predominantly caused by increased gluconeogenesis (as opposed to glycogenolysis) [35, 39]. Glucocorticoid excess is associated with increased proteolysis and release of amino acids in muscle, as well as increased lipolysis and release of glycerol and free fatty acids from peripheral adipose tissue depots, which in turn fuel hepatic gluconeogenic enzymes including phosphoenolpyruvate carboxykinase (PEPCK) (Figure 22.6) [39, 40]. Furthermore, glucocorticoids also increase hepatic glycogen storage [41].

Normalization or improvement of carbohydrate metabolism in Cushing syndrome can be obtained with all types of interventions

and treatments that successfully reduce cortisol levels. Unfortunately, diabetes or glucose intolerance does not disappear completely in all individuals obtaining remission from Cushing syndrome. The extent to which this is due to some degree of non-reversible changes of insulin secretion or action after long-term cortisol exposure, or whether it may be explained by another diabetes-predisposing condition, is unknown. In cases of Cushing syndrome with acute severe hyperglycaemia, intensive insulin therapy with multiple daily insulin injections is indicated, which may be combined with steroidogenesis inhibitor therapy to obtain a fast reduction of serum cortisol levels. In individuals with Cushing syndrome and less severe degrees of diabetes or glucose tolerance, oral anti-diabetes agents, including insulin-sensitizing drugs such as metformin and peroxisome proliferator-activated receptor- γ (PPAR- γ) agonists, are the drugs of first choice. A recent study reported multiple relevant, beneficial effects of metformin on fibrinolysis, inflammatory markers, carotid intima-media thickness, clinical markers of disease activity, frequency of pneumonia, overall rate of moderate to severe infections, as well as all-cause hospitalization and admissions due to adverse events in individuals on systemic glucocorticoid therapy [42]. Thiazolidinediones increase peripheral adipose tissue lipid storage capacity and reduce visceral fat and have ACTH-lowering effects *in vitro*. However, increased total weight and body fat content, as well as unclear overall cardiovascular risk/benefit ratio, make thiazolidinediones a less attractive choice than metformin. Sodium-glucose cotransporter-2 (SGLT-2) inhibitors may be useful to reduce glucose and weight, and in addition provide increased cardiovascular and renal protection. On the downside, glucocorticoid excess may further increase the risk of urogenital infections with SGLT-2 inhibitor treatment. Glucagon-like peptide 1 (GLP-1) receptor agonists and dipeptidyl peptidase 4 (DPP-4) inhibitors may be used to increase glucose-dependent insulin secretion and reduce glucagon secretion, and GLP-1 receptor agonists may also reduce appetite and exhibit favourable effects on fat distribution. Finally,

**Figure 22.6** Mechanisms of hyperglycaemia and diabetes in Cushing syndrome. NEFA, non-esterified fatty acids; PEPCK, phosphoenolpyruvate carboxykinase.

sulfonylureas may be used, but have in general lost attractiveness compared with modern type 2 diabetes therapies due to inferior long-term effectiveness, weight gain, risk of hypoglycaemia, as well as lack of convincing cardiovascular benefits.

Diagnosis and treatment

Cushing syndrome caused by exogenously administered glucocorticoids is easily diagnosed and treated by reducing the dose of or removing the medication. The earliest symptoms and signs of Cushing syndrome, including fatigue and weight gain, are relatively vague and unspecific, and explain why the diagnosis is often missed or delayed. Accordingly, it is important to consider Cushing syndrome as an underlying cause or differential diagnosis in all individuals with type 2 diabetes. Undiagnosed Cushing syndrome is present in up to 2% of all individuals with type 2 diabetes [43]. A thorough interrogation and objective clinical examination are critical in the diagnosis of Cushing syndrome and clinicians should pay attention to symptoms, such as changes in psychological well-being and proximal myopathy, as well as specific signs such as violaceous stretch marks (*striae*), a round *moon face*, thin extremities in the context of an extended abdomen, and disposition of increased adipose tissue in the neck (*buffalo hump*) [33–35].

With a clinical suspicion of Cushing syndrome, the first goal is to determine the extent to which circulating cortisol levels are increased above normal as a result of uninhibited autonomous secretion [33–35]. Usually, a combination of the available tests is used to ensure sufficient diagnostic accuracy for Cushing syndrome (Table 22.4). Cortisol exhibits clear diurnal variation, with high serum concentrations during the day and low levels at bedtime and night. The midnight serum cortisol level is used as a measure of the extent to which there is a lack suppression of daytime cortisol, implying glucocorticoid excess. Individuals with Cushing syndrome are usually admitted to hospital in quiet surroundings 24 hours prior to testing to avoid artificial high cortisol measurements occurring with even low-stress situations, although increasingly testing may be performed at home. Salivary cortisol measurement may be used and posted by the person from home to the laboratory. However, this requires careful validation of the assay for salivary cortisol measurements, and contamination with blood, for instance from teeth brushing, must be avoided, as salivary cortisol levels are 10-fold lower than in serum. A low-dose dexamethasone suppression test administered at midnight with serum cortisol measurements at 8 a.m. is used to test the physiological negative feedback loop of glucocorticoids suppressing pituitary ACTH secretion. If inconclusive or positive, the low-dose test is followed by the slightly more specific 48-hour dexamethasone suppression test [33]. False-positive tests may occur in individuals with increased dexamethasone metabolism, as seen with antiepileptic medication. Oral contraceptive medication increases the production of glucocorticoid-binding proteins, resulting in artificial high total serum cortisol levels, and should therefore be paused for at least one month prior to serum cortisol measurements. Endogenous cortisol production can also be examined from total cortisol urine excretion as measured over 24 hours, typically over two or three days.

When the suspicion of excessive endogenous cortisol production and Cushing syndrome has been confirmed, different tests are available to determine the underlying aetiology (Table 22.4) [33–35]. Although MR imaging is the state-of-the-art method to visualize a pituitary adenoma, this should not be performed until firm biochemical evidence of a pituitary source of Cushing syndrome

Table 22.4 Diagnosis of endogenous Cushing syndrome.

Test	Interpretation
Screening tests to diagnose Cushing syndrome	
Midnight serum cortisol or salivary cortisol measurement	Maintained daytime levels at midnight indicates autonomous cortisol production of Cushing syndrome. Normal value <50 nmol/l in a sleeping patient, grey zone 50–138 nmol/l. Cortisol <207 nmol/l in an awake person may exclude Cushing syndrome
1 mg overnight DST. Oral dexamethasone taken at midnight	Serum cortisol <50 nmol/l at following 9 a.m. is considered a normal value
Formal low-dose DST (0.5 mg × 8 doses 6-hourly ending at 3 a.m.)	Serum cortisol <50 nmol/l following 9 a.m. is considered a normal value
24 h urinary free cortisol measurement	Elevated values support diagnosis of Cushing syndrome
Tests to localize cause of cortisol excess	
Serum ACTH measurement	If suppressed, indicates autonomous adrenocortical overproduction of cortisol (e.g. an adrenocortical adenoma)
If serum ACTH detectable	
High-dose dexamethasone suppression test (2 mg × 8 doses 6-hourly ending at 3 a.m.) ^a	Above 50% suppression of 9 a.m. serum cortisol from pre- to post-test indicates anterior pituitary source; <50% suppression indicates extra-pituitary ectopic source of ACTH
Bilateral IPSS ^a	Gradient from inferior petrosal sinus to periphery of >2:1 supports anterior pituitary source (test can also incorporate CRH administration; see text)
MRI	Should only be considered once biochemical evidence of pituitary source obtained. Helpful for surgeon in planning trans-sphenoidal surgery

ACTH, adrenocorticotrophic hormone; CRH, corticotropin releasing hormone; DST, dexamethasone suppression test; IPSS, inferior petrosal sinus sampling; MRI, magnetic resonance imaging.

^aLarger centres may progress straight to bilateral IPSS if available and conducted by experienced operators rather than perform a high-dose dexamethasone suppression test.

has been established. Thus, neither a positive nor a negative finding of a pituitary tumour can be used in isolation to confirm or exclude Cushing disease. Measurement of serum ACTH levels is considered mandatory to determine whether Cushing syndrome is ACTH dependent. A concentration below the detection limit suggests primary adrenocortical cortisol overproduction, with compensatory pituitary suppression of ACTH release. In individuals with detectable or raised cortisol levels above normal, there is a need to exclude ectopic (non-pituitary) ACTH production before the diagnosis of the classic Cushing disease can be made and treatment can be determined. In contrast to ectopic causes of ACTH overproduction, corticotroph pituitary adenomas usually sustain some degree

of negative feedback inhibition by cortisol, which defines the basis for the high-dose dexamethasone suppression test (Table 22.4). Suppression of serum cortisol by at least 50% after the administration of 16 mg dexamethasone in total over 48 hours suggests Cushing disease. Due to lack of negative feedback inhibition, ectopic ACTH production in non-pituitary tumours is in general associated with higher circulating cortisol levels resistant to such degree of suppression during a 16 mg dexamethasone test. The commonest cause of ectopic ACTH production is an aggressive bronchial carcinoma, while a minority is caused by a less severe carcinoid tumour. Binding of ACTH to the type 1 melanocortin receptor (MC1R) leads to increased skin pigmentation, which accordingly is commoner in individuals with ectopic ACTH production compared with other causes of Cushing syndrome.

Bilateral inferior petrosal sinus sampling (IPSS) is a more sensitive as well as specific diagnostic procedure to differentiate between pituitary versus ectopic ACTH overproduction. In this test, central (sinus petrosis) and peripheral (venous) ACTH levels are measured simultaneously before and after intravenous injection of 100 µg corticotropin-releasing hormone (CRH). The finding of a central versus peripheral baseline ACTH gradient of at least 2:1, or of 3:1 after the CRH injection, is consistent with pituitary ACTH overproduction. IPSS may furthermore help lateralize a pituitary adenoma by identifying clear differences in ACTH levels between right and left sinuses. IPSS is associated with increased thrombosis risk (affecting around 1% of procedures) and is therefore a procedure restricted to endocrine clinics with high expertise.

In Cushing syndrome with a primary suspicion of ectopic ACTH production, various imaging technologies are used to screen for tumours, including computerized tomography (CT), MR imaging, and/or somatostatin receptor isotope scintigraphy. Somatostatin receptors are detectable in around two-thirds of ACTH-secreting carcinoid tumours. Adrenal cortex tumours with high lipid contents (indicative of increased steroid production) can be detected with abdominal CT or MR imaging.

Due to the severe symptoms, complications, and comorbidity of Cushing syndrome [33–35], curative treatment approaches always have the highest priority. Unilateral adrenalectomy is the preferred treatment option in individuals with a primary adrenocortical source of cortisol overproduction. Surgery may be curative in some individuals with ectopic ACTH-secreting carcinoid tumours, whereas the overall severity and poor prognosis in individuals with ACTH overproduction from a bronchial carcinoma commonly make palliative care the right choice. Trans-sphenoidal removal of the corticotroph adenoma is the first-line treatment in individuals with established Cushing disease. Trans-sphenoidal surgery is curative in approximately two-thirds of individuals with Cushing syndrome, due to ACTH-secreting adenomas more often being microadenomas. Indications, side effects, and risks of radiotherapy in Cushing disease resemble those described for acromegaly.

Currently medical treatments are generally inferior to surgery and therefore remain second-line treatments in Cushing syndrome and Cushing disease. However, several new drugs are under investigation, and medical therapy is therefore gradually gaining increased importance. Pharmacological suppression of adrenocortical steroidogenesis with ketoconazole or metyrapone has been used to relieve symptoms and improve glucose homeostasis temporarily if surgery is delayed [33, 34]. However, long-term experience with these drugs is limited due to efficacy and safety concerns.

Metyrapone is currently under investigation in a large international multicentre trial to establish its efficacy and safety more broadly in Cushing syndrome.

Most corticotroph adenomas express various somatostatin receptor subtypes at their surface, and treatment with the somatostatin multiligand analogue pasireotide provides effective lowering of pituitary ACTH secretion, as well as serum and urinary cortisol levels, in people with Cushing disease. Pasireotide administered either twice daily subcutaneously or once monthly intramuscularly using an LAR formulation is an effective as well as safe long-term treatment in Cushing disease [44, 45]. However, inhibition of somatostatin receptors in gut and pancreas simultaneously blocks the secretion of incretin hormones and insulin, resulting in the development of glucose intolerance in more than 70% of individuals on pasireotide treatment [44, 46]. Close monitoring of glucose is therefore imperative in individuals on pasireotide treatment [47]. Osilodrostat and levoketoconazole are novel steroidogenesis inhibitor agents with mechanisms of action resembling metyrapone and ketoconazole, respectively, currently under investigation for Cushing disease. Among novel glucocorticoid receptor-directed or antagonist drugs under development, mifepristone and relacorilant both have promising effects on blood pressure and glucose metabolism, and there is an unexplored future potential in combining current and new therapies with different modes of action in Cushing disease.

In a small fraction of therapy-resistant individuals, bilateral adrenalectomy provides a rapid resolution of excessive cortisol secretion. However, total loss of negative feedback inhibition of pituitary ACTH secretion can result in treatment-refractory pituitary tumour growth with severe adverse local pressure effects, including visual impairments and panhypopituitarism (Nelson syndrome). Adjunct radiotherapy directed against the anterior pituitary gland can be used to prevent or treat individuals with imminent or overt Nelson syndrome.

Glucose tolerance following treatment of Cushing syndrome

Most individuals with Cushing syndrome improve or fully regain their adrenal cortisol production within weeks to months after successful trans-sphenoidal surgery. Nevertheless, long-term suppression of normal corticotrophs (pituitary or ectopic ACTH-secreting tumours), or of adrenocortical cells (cortisol-secreting tumours), is associated with secondary degenerative changes in the remaining normal endocrine tissue. This causes a state of hypocortisolism and all individuals with Cushing disease will need exogenous glucocorticoid substitution after trans-sphenoidal surgery. The need for exogenous glucocorticoids is highest in the period immediately after surgery due to the acute stress situation and because the body needs time to adjust from the situation of excessive endogenous cortisol exposure. A large proportion of individuals will never fully recover a normal diurnal adrenal function [47] and will require life-long exogenous glucocorticoid substitution.

Insulin action and glucose tolerance improve rapidly after successful treatment of Cushing syndrome (Figure 22.5). Prescribed anti-diabetes treatments therefore require careful monitoring and adjustment during and after pituitary surgery. Care needs to be taken to avoid hypoglycaemia when reducing the total glucocorticoid exposure after surgery, especially among those individuals who are dependent on replacement doses of hydrocortisone. Conversely, other individuals will need continued care and treatment for diabetes due to persistent changes in body composition

and features of the metabolic syndrome [40]. A study reported persistent visceral obesity and glucose intolerance in ~60% of individuals who fulfilled criteria for remission of Cushing syndrome [48].

Phaeochromocytoma and paraganglioma

Epidemiology, clinical features, and genetics

Catecholamine-secreting phaeochromocytomas and paragangliomas are tumours arising from the neural crest-derived chromaffin cells of the adrenal medulla (phaeochromocytoma, 80–85%) (Figure 22.7) [49,50] or from the paravertebral sympathetic chains in the chest, abdomen, or pelvis (paragangliomas). Approximately 10% of phaeochromocytomas are bilateral. They can secrete epinephrine, norepinephrine, dopamine, or various combinations thereof. Around 40% of phaeochromocytomas and paragangliomas occur on a hereditary basis either as part of syndromes such as MEN2, von Recklinghausen neurofibromatosis, or von Hippel–Lindau disease [51], or as the single disease manifestation of known mutations in at least 17 known genes [52] (Table 22.5). For instance, succinate dehydrogenase subunit B (*SDHB*) and succinate dehydrogenase subunit D (*SDHD*) mutations are more frequent in extra-adrenal tumours [51,52], and mutations in *SDHB* are more commonly associated with a malignant phenotype [51,52]. The risk of malignancy also increases with tumour size [51,52].

The clinical symptoms of catecholamine-secreting phaeochromocytomas and paragangliomas are classically described as a triad: headaches, sweating, and tachycardia [53, 54]. Hypertension is the commonest clinical finding and occurs in 80–90% of cases. It can be paroxysmal or sustained, the latter occurring especially in children and in norepinephrine-secreting tumours [55]. Other symptoms may be secondary to the co-secretion of various other peptide hormones such as vasoactive intestinal peptide (VIP), substance P, atrial natriuretic factor, endothelin-1, CRH, and GHRH [55]. The normal adrenal medulla predominantly secretes epinephrine, converted from norepinephrine by methylation. This reaction is governed by the adrenal specific enzyme phenylethanolamine-*N*-methyltransferase (PNMT), the expression of which is dependent on high concentrations of cortisol draining centripetally from the outer adrenal cortex towards the adrenal vein [53]. For this reason, larger tumours with more marked disturbance of the normal anatomy or paragangliomas along the sympathetic chain are notable for predominantly secreting norepinephrine as conversion to epinephrine is compromised.

Glucose intolerance

Approximately 50% of individuals with phaeochromocytomas and paragangliomas exhibit various degrees of glucose intolerance, with ~16% of individuals having overt diabetes [56]. Diabetes is more common in phaeochromocytomas than in paragangliomas. The presence of both hypertension and diabetes in a young person of normal

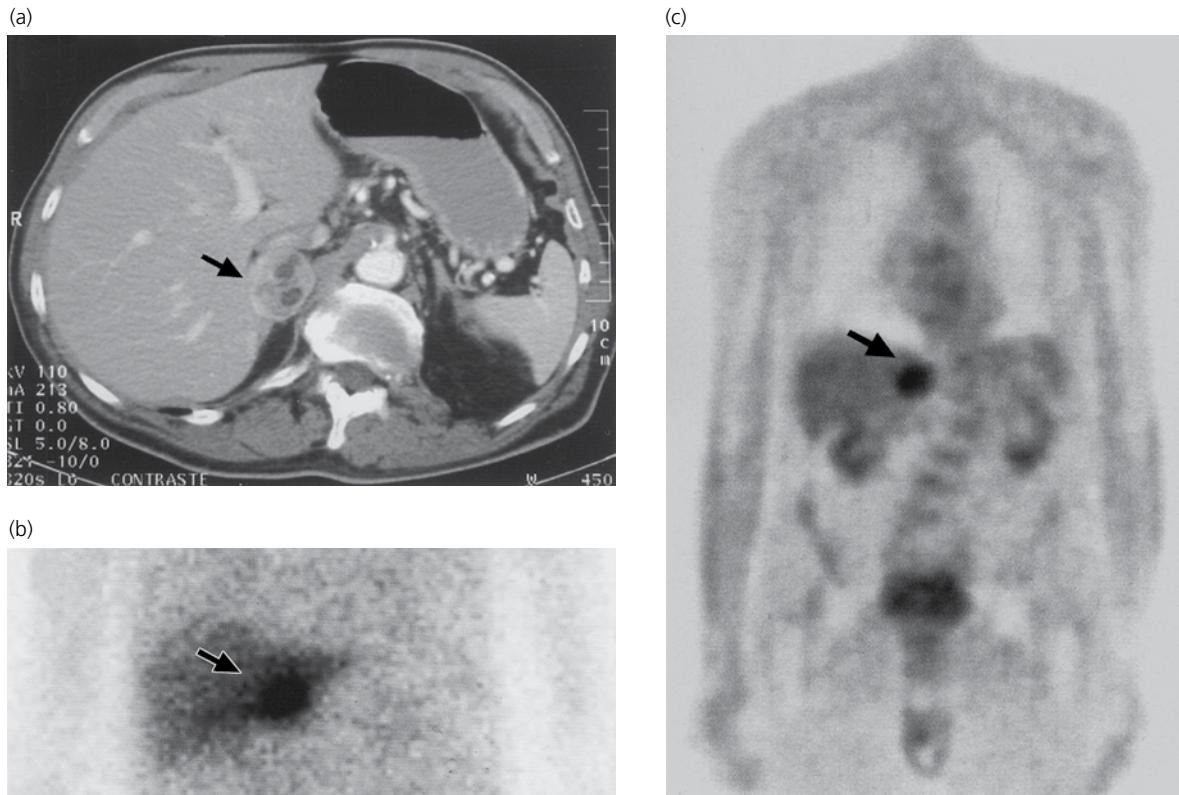

Figure 22.7 Phaeochromocytoma in a 75-year-old man with recent-onset type 2 diabetes treated with a sulfonylurea, who was admitted on an emergency basis with severe chest pain and hypertension (blood pressure 240/130 mmHg). Blood glucose on admission was 27 mmol/l. Urinary catecholamine excretion was greatly increased, and a phaeochromocytoma of the right adrenal was demonstrated by (a) computed

tomography; (b) scanning with ^{131}I -metaiodobenzylguanidine, which is taken up by catecholamine-synthesizing tissues; and (c) positron emission tomography with ^{18}F -fluorodeoxyglucose. After laparoscopic removal of the tumour, diabetes and hypertension both resolved. Source: Courtesy of Professor Neil Hanley and Rachel Jennings, University of Manchester, UK.

Table 22.5 Genes associated with catecholamine-secreting phaeochromocytomas and paragangliomas.

Gene	Germline mutation rate (% detected in all PPGL)	Key characteristics and associations
<i>SDHB</i>	10.3	Extra-adrenal tumours; malignant phenotype
<i>SDHD</i>	8.9	Extra-adrenal tumours; paternal inheritance
<i>VHL</i>	7.3	von Hippel–Lindau disease
<i>RET</i>	6.3	Multiple endocrine neoplasia type 2

body weight should raise suspicion of phaeochromocytoma and paraganglioma. Catecholamines, together with GH and glucocorticoids, belong to the class of *glucose counter-regulatory hormones* that impair insulin action and secretion (Figure 22.8) [57–59]. Epinephrine inhibits insulin secretion via stimulation of α_2 -adrenergic receptors on pancreatic β cells [60]. In the liver, epinephrine stimulates β_2 -adrenoceptors to enhance glycogenolysis transiently and gluconeogenesis in a more sustained fashion [61–63].

Hepatic gluconeogenesis is fuelled by the precursors lactate, alanine, and glycerol, which in turn are partly generated by β_2 -adrenergic stimulation of muscle and adipose tissue lipolysis. Lipolysis in adipose tissue is also stimulated via the β_1 - and β_3 -adrenoceptors. To this end, epinephrine can impair glucose utilization in muscle through direct β_2 -adrenergic effects. The predominance of these β_2 -adrenergic effects probably explains why epinephrine, with its higher affinity for β_2 -receptors, is more potent than norepinephrine in producing hyperglycaemia [61–63]. Activation of epinephrine release is an important component in correcting hypoglycaemia, following inhibition of insulin and increased glucagon secretion, in the hierarchy of counter-regulatory responses (Chapter 40).

Diagnosis and treatment

Phaeochromocytomas and paragangliomas are diagnosed by demonstrating an excess of circulating catecholamines. This is most accurately achieved by measuring their metabolites, metanephrenes, derived by the enzymatic action of catechol-O-methyl transferase in the urine over 24 hours or more commonly in the plasma [49]. These measures are superior to historical

measurement of the metabolite, vanillylmandelic acid, and the catecholamines themselves in terms of sensitivity and specificity [49]. Imaging the tumour can be performed by either MR or CT. Treatment is surgical removal of the tumour as an adrenalectomy, increasingly performed laparoscopically unless malignancy is suspected [49]. Preoperative preparation must be meticulous to prevent both a hypertensive crisis during manipulation of the tumour and cardiovascular collapse after its removal. This is achieved by initial α -receptor blockade, most commonly using the irreversible agent phenoxybenzamine, followed by a β -blocker if needed. The order of implementation is important to prevent a hypertensive crisis from unopposed α -adrenoceptor stimulation. The preoperative α -adrenergic blockade often controls hypertension, but has less effect on glucose intolerance [61, 64]. In malignant phaeochromocytoma where surgery is not possible, adrenolytic drugs, such as mitotane, can be used palliatively.

Glucose tolerance in response to treatment of phaeochromocytomas and paragangliomas

Removal of the tumour in most cases also corrects the metabolic abnormalities, including hypertension and glucose intolerance [61, 64–66]. Clinical genetics input to guide treatment, diagnosis of comorbidities, follow-up, as well as identifying which family members should be screened, is important and required in all individuals, even in seemingly isolated tumours [49, 51]. Hyperparathyroidism and MEN1 can be excluded simply by measuring serum calcium and parathyroid hormone. Annual measurements of plasma metanephrenes are required after surgery to exclude recurrent phaeochromocytomas and paragangliomas.

Glucagonomas

Glucagonomas are tumours derived from the α cell of the pancreatic islet that, along with somatostatinomas and VIP-producing tumours (VIPoma), represent a rare group of hypersecreting gastroenteropancreatic endocrine tumours associated with glucose intolerance or diabetes. Glucagonomas may occur sporadically or as part of the MEN1 syndrome caused by mutations in the tumour suppressor gene, *MENIN* [67]. The most striking clinical features of excessive glucagon secretion (the *glucagonoma syndrome*) are weight loss, necrolytic migratory erythema, diabetes, cheilosis or stomatitis, and diarrhoea [68]. Necrolytic migratory erythema is recognized as an intermittent blistering rash that spreads across the skin, usually involving the skin around the mouth, buttocks, groin, thighs, as well as distal extremities [69, 70] (Figure 22.9a). Hyperglucagonaemia may contribute to the rash, as may hypoaminoacidaemia through glucagon's enhancement of amino acid uptake by the liver and zinc deficiency [70]. The glucagonoma syndrome is also characterized by a normochromic normocytic anaemia, a tendency to thrombosis (pulmonary embolism is a common cause of death), and neuropsychiatric disturbances [69].

Approximately three-quarters of individuals with glucagonoma have overt diabetes [69], which is explained by glucagon's effect to enhance net hepatic glucose production through increased gluconeogenesis and glycogenolysis [70]. The degree of hyperglycaemia in people with glucagonomas is usually mild and in most cases responds to oral anti-diabetes drugs, although insulin treatment may be required in the most severe cases [69]. Reasons for the relatively mild degree of diabetes in individuals with glucagonoma

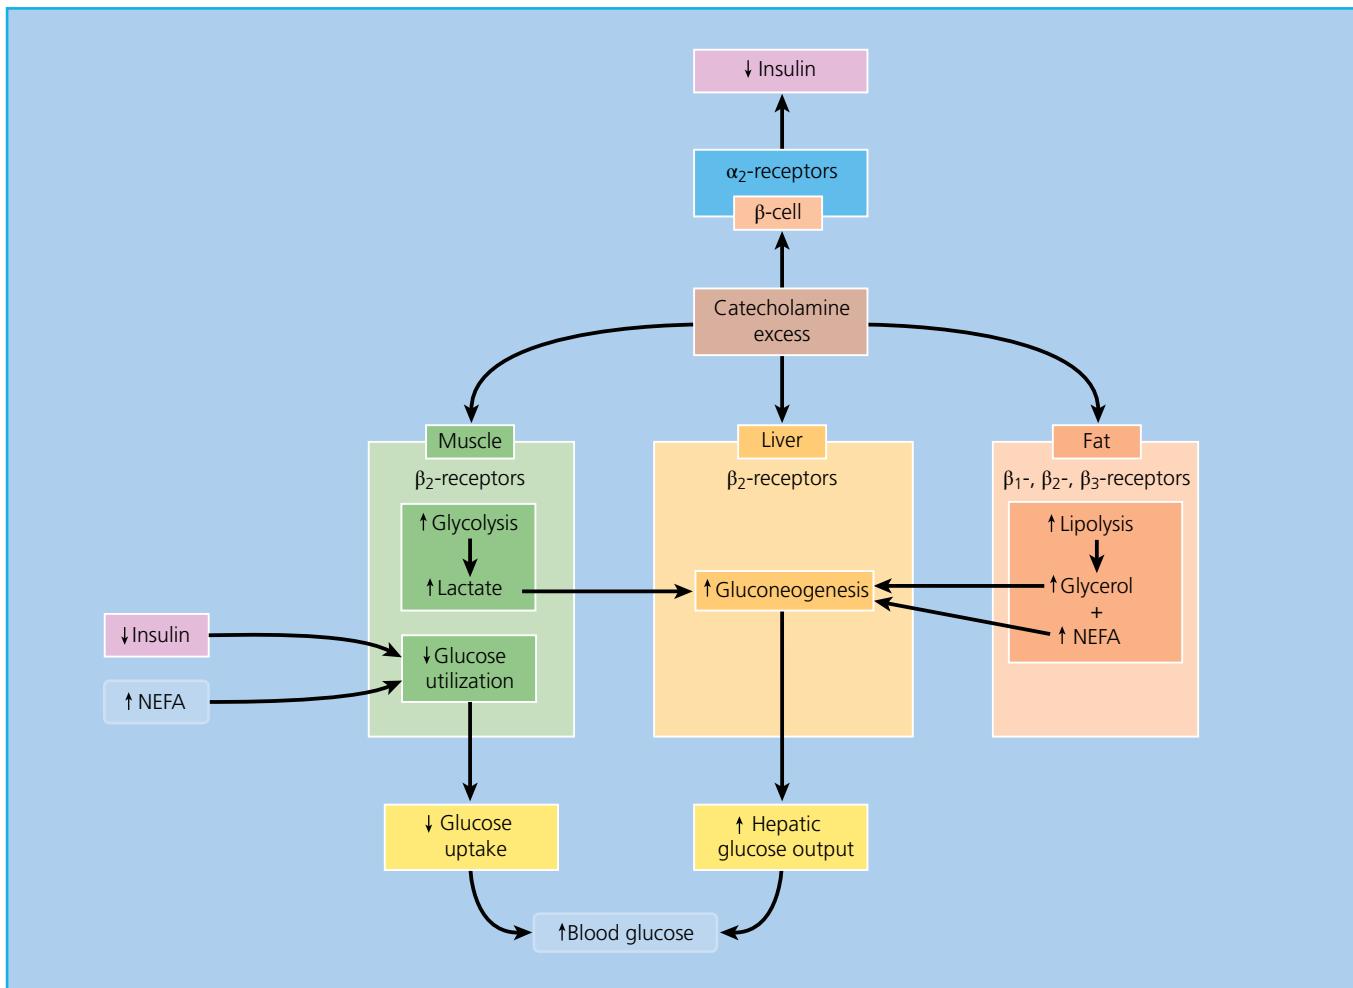

Figure 22.8 Mechanisms of hyperglycaemia in phaeochromocytoma. NEFA, non-esterified fatty acid.

include a diminished effect of glucagon to increase hepatic glucose production with time, as well as compensatory hyperinsulinaemia partly brought about by glucagon's paracrine effect to stimulate insulin secretion in the pancreatic β cells [71]. Differential post-translational processing of tumour-derived proglucagon may lead to concomitant or even predominant overexpression and secretion of other proglucagon-derived peptides, including GLP-1, GLP-2, glicentin, and oxyntomodulin. This, in turn, may cause different gastrointestinal as well as general symptoms including hypoglycaemia [72].

The diagnosis is suggested by the symptoms of the glucagonoma syndrome, particularly the combination of weight loss, a blistering rash, and diabetes. Visualization of an increased pancreatic mass and high fasting plasma glucagon concentration strengthen the diagnosis. However, other causes of hyperglucagonaemia such as severe stress, hepatic and renal failure, hyperglycaemia, small-bowel malabsorption, and synthetic androgenic drugs needs to be excluded [69, 70, 74]. The treatment of first choice is surgery; however, 50% of tumours have metastasized to the liver by the time of diagnosis (Figure 22.9b), limiting the options for cure [68]. Supplementary treatment options include embolization of the hepatic artery, chemotherapy, and/or use of somatostatin analogues to suppress glucagon secretion. The rash usually disappears when

glucagon levels are normalized. Additional symptomatic treatments include administration of zinc and/or a high-protein diet [68–70, 73].

Somatostatinomas

Somatostatinomas are extremely rare tumours arising in 1 in 40 million individuals from 8 cells of the pancreatic islet or enteroendocrine cells of the duodenum and ampulla of Vater [74]. Somatostatinomas may occur sporadically or as part of genetic syndromes including MEN1, neurofibromatosis type 1 (*NFI* gene with malfunction of RAS/MAPK pathway), or Pacak-Zhuang syndrome (*EPAS1* gene encoding HIF) [74–76]. Somatostatin has widespread inhibitory effects on endocrine and exocrine secretory functions in the gastroenteropancreatic system [77], explaining the symptoms and clinical findings in individuals with somatostatinomas, which include diabetes, steatorrhoea, gallstones, and hypochlorhydria [75]. Dual inhibition of insulin and glucagon secretion explains why hyperglycaemia is usually mild and non-ketotic, and why some individuals may even present with hypoglycaemia rather than hyperglycaemia [75]. Insulin treatment is rarely required.

Figure 22.9 Glucagonoma showing characteristic necrolytic migratory erythema (a) and multiple hepatic metastases (b). This man had non-ketotic diabetes, managed with low dosages of insulin; the rash recurred many times despite treatment with somatostatin analogue. He died from pulmonary embolus. Source: Courtesy of Professor Stephen Bloom, Imperial College School of Medicine, London, UK.

Diagnosis is suspected by the symptoms described, and further investigated by measuring circulating somatostatin levels. Visualization of the tumour is by CT or MR imaging, or octreotide scintigraphy, subsequently followed by a biopsy. Surgical resection is usually curative when tumours are small and without metastasis [74]. Supplementary or adjunct treatment options in non-radically operated individuals include debulking, embolization, and/or chemotherapy (including radiolabelled somatostatin analogues) [74].

Vasoactive intestinal peptide-producing tumours

Verner and Morrison first reported a clinical case of a VIP-secreting tumour in 1958 [78]. The classic symptoms of Verner–Morrison syndrome caused by increased circulating VIP levels include watery diarrhoea (pancreatic cholera), hypokalaemia, and achlorhydria [73,79]. Hypercalcaemia and glucose intolerance occur in half of the individuals, but overt diabetes is unusual. Unlike glucagonomas and somatostatinomas, the physiological explanation for hyperglycaemia in VIPomas is unknown, but may be secondary to the glycogenolytic effect of VIP and/or hypokalaemia, which can

impair both insulin secretion and insulin sensitivity. VIPomas usually are large and have metastasized at the time of diagnosis, suggesting that the explanation may be less specific and stress related, and thus more likely to be categorized with the type of unspecific diabetes occurring secondary to multiple types of non-endocrine cancers [1]. Diagnosis is obtained by measuring circulating VIP levels, and the treatment of choice is debulking surgery [79].

Hyperthyroidism

Hyperthyroidism is defined by increased production and circulating levels of thyroid hormones, whereas the state of thyrotoxicosis represents the clinical manifestation of hyperthyroidism (Table 22.6) [80,81]. Autoimmune hyperthyroidism (Graves' disease) is associated with an increased risk of type 1 diabetes, but thyrotoxicosis *per se* is more associated with impaired glucose tolerance in approximately one-third of individuals [82]. The hypermetabolic state of hyperthyroidism causes or worsens hepatic and peripheral insulin resistance, subsequently unmasking glucose intolerance, particularly in people with a pre-existing risk factor, such as obesity or a family history of diabetes [83]. Similarly, hyperthyroidism worsens glucose levels in people with

Table 22.6 Clinical features of thyrotoxicosis plus features associated with Graves' disease.

Clinical features of thyrotoxicosis

Weight loss despite full, possibly increased, appetite
Tremor
Heat intolerance and sweating
Agitation and nervousness
Palpitations, shortness of breath/tachycardia ± atrial fibrillation
Glucose intolerance
Amenorrhoea/oligomenorrhoea and consequent subfertility
Diarrhoea
Hair loss
Easy fatigability, muscle weakness, and loss of muscle mass
Rapid growth rate and accelerated bone maturation (children)

Specific features associated with Graves' disease

Bruit in a diffuse, firm goitre
Thyroid eye disease, also called Graves' orbitopathy
Pretibial myxoedema – thickened skin over the lower tibia
Thyroid acropachy (clubbing of the fingers)
Other autoimmune features (e.g. vitiligo)

secondary to hypersecreting endocrine disorders [90,91]. Treatment of diabetes in individuals with hyperparathyroidism does not differ from general diabetes treatment recommendations.

Polycystic ovarian syndrome

Polycystic ovarian syndrome (PCOS) qualifies as a hypersecreting endocrine disorder through its definition as a clinical or biochemical state of hyperandrogenism in women with oligo- or anovulation, in which other more distinct causes such as Cushing syndrome have been excluded [92,93] (Figure 22.10). The prevalence of PCOS in women of reproductive age is 5–10% and is characterized primarily by hyperinsulinaemia and insulin resistance [93,94]. Approximately 40% of women with PCOS have impaired glucose tolerance and up to 10% overt type 2 diabetes [94]. The risk of PCOS is closely associated with increased obesity, but PCOS also occurs among normal-weight women [93]. Indeed, lifestyle intervention with weight loss represents the treatment of first choice in PCOS women.

Primary hyperinsulinaemia, even to a level higher than required to compensate for the ambient degree of insulin resistance, is likely to take centre stage for the development of PCOS [95]. The raised insulin levels are subsequently the key driver of increased androgen production by both the ovary and the adrenal cortex [96,97]. PCOS is a diagnosis of exclusion, in the sense that clinical and biochemical findings are only supportive of the diagnosis [98]. Increased serum levels of luteinizing hormone (LH) relative to follicle-stimulating hormone (FSH) levels (e.g. the LH : FSH ratio), as well as increased circulating androstenedione and testosterone concentrations, are among the key diagnostic criteria. Serum oestradiol is detectable and usually >200 pmol/l, whereas serum sex hormone-binding globulin (SHBG) levels are usually low. Ovarian ultrasound is indicated to exclude the presence of an androgen-producing tumour [98]. In addition to lifestyle intervention, metformin is indicated in PCOS women both with and without glucose

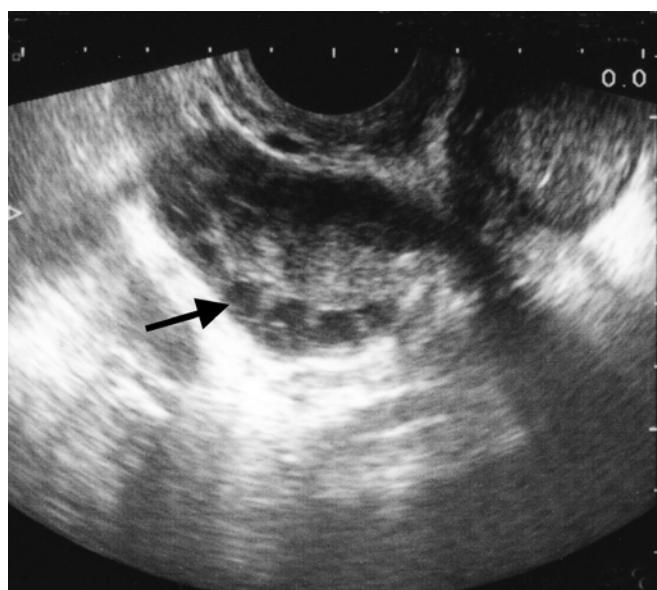

Figure 22.10 Polycystic ovary syndrome, showing characteristic ultrasonographic appearance of large, mainly peripheral cysts (arrow).

pre-existent diabetes [84]. Hypothyroidism is associated with faster intestinal absorption, contributing to increased post-prandial plasma glucose levels [59]. Conversely, restoration of euthyroidism rapidly improves or normalizes glucose metabolism [82]. Guidelines for the use of diabetes treatments in individuals with hyperthyroidism do not differ from conventional treatment of type 1 diabetes and type 2 diabetes.

Primary hyperaldosteronism

Primary hyperaldosteronism was first described first by Conn in 1955 and is characterized by hypertension, hypokalaemia, and neuromuscular symptoms [53]. Benign adrenocortical secreting aldosterone adenomas account for ~65% of cases, whereas bilateral hyperplasia accounts for 30% of cases of primary hyperaldosteronism. Glucose intolerance occurs in ~50% of individuals with primary hyperaldosteronism, whereas overt diabetes is rare [85]. As for suspected pathogenic mechanisms, low serum potassium levels are associated with impaired insulin secretion, while elevated aldosterone levels is associated with reduced peripheral insulin sensitivity [65]. Removal of the adenoma or potassium loading increase insulin secretion and normalise glucose metabolism [85].

Primary hyperparathyroidism

Primary hyperparathyroidism characterized by hypersecretion of parathyroid hormone may occur as a result of a parathyroid adenoma or less frequently due to parathyroid hyperplasia [86]. Increased intracellular calcium levels cause insulin resistance and reduced cellular glucose uptake [87], explaining the approximately threefold higher prevalence of diabetes in individuals with more severe degrees of primary hyperparathyroidism compared with the general population [87–89]. The extent to which parathyroidectomy normalizes glucose tolerance is less clear for primary hyperparathyroidism compared with most other types of diabetes

intolerance to improve insulin action, lower circulating insulin levels, and eventually to improve menstrual regularity and increase the chance of ovulatory cycles [99]. Other anti-diabetes agents that improve insulin action and/or reduce weight, including GLP-1 receptor agonists, SGLT-2 inhibitors, as well as thiazolidinediones, improve clinical symptoms [100, 101].

Glucose intolerance in hyposecreting endocrine disorders

Although diabetes is much more common in hypersecreting endocrine disorders, the inverse scenario of increased prevalence of diabetes in individuals with hyposecreting endocrine disorders is not uncommon. Thus, both subclinical and overt hypothyroidism is associated with an increased prevalence of diabetes, and to some extent with an increased prevalence of diabetes complications [102, 103]. The mechanisms underlying the link between hypothyroidism and diabetes are less clear than for diabetes and hyperthyroidism, but reduced tissue blood flow, glucose uptake, and insulin clearance have been proposed to play a role [77, 104]. Hypothyroidism has also been linked with an increased risk of hypoglycaemia [105], and the increased prevalence of diabetes in hypothyroidism may to some unknown extent be explained by physical inactivity, weight gain, and/or elevated plasma triglycerides.

Although GH excess is a recognized cause of insulin resistance, increased hepatic glucose production, and diabetes, long-standing GH deficiency is also associated with insulin resistance and increased risk of diabetes [106, 107]. Increased insulin resistance in adults with GH deficiency is largely explained by changes in body composition, with increased total and abdominal fat mass at the expense of reduced lean body mass [107]. GH is a potent activator of adipose tissue lipolysis, and the changes in body composition are

therefore readily explained by long-term relative or absolute under-stimulation of adipose tissue lipolysis. The delicate homeostatic balance between GH's diabetogenic and anti-diabetogenic effects may also explain the conflicting outcomes of long-term GH substitution on glucose tolerance in individuals with GH deficiency [108–112]. Accordingly, there is general consensus that individuals on GH therapy need regular monitoring of glucose metabolism to avoid overtreatment and development of overt diabetes [106, 112].

Other endocrine disorders associated with diabetes

Type 1 diabetes is an autoimmune disease with common or overlapping aetiology and pathophysiological mechanisms with diseases such as Addison disease (autoimmune adrenalitis) and autoimmune thyroid disease. Accordingly, clinicians need to consider the onset of new autoimmune pathology in people with these disorders. In individuals with type 1 diabetes, screening can be justified to exclude hyperthyroidism or hypothyroidism by measuring serum thyroid-stimulating hormone (TSH) annually. The development of Addison disease in people with type 1 diabetes markedly increases insulin sensitivity such that unanticipated hypoglycaemia may occur despite reduced dose requirement. Rare conditions resembling type 1 diabetes with associated endocrinopathies may occur, such as the autoimmune polyglandular syndromes or POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin abnormalities) syndrome. Monogenic causes of diabetes may affect other endocrine organs. Examples (and their respective endocrine disorder) include the various types of haemochromatosis (primary hypogonadism), Wolfram syndrome (diabetes insipidus), and Kears–Sayre syndrome (hypoparathyroidism, hypogonadism, and hypopituitarism).

Pancreatic Disease and Diabetes

Ranjit Unnikrishnan^{1,2} and Viswanathan Mohan^{1,2}

¹Dr. Mohan's Diabetes Specialities Centre, IDF Centre of Excellence in Diabetes Care, Chennai, India

²Madras Diabetes Research Foundation, ICMR Center for Advanced Research on Diabetes, Chennai, India

Key points

- Pancreatic disease is a rare cause of diabetes.
- Acute pancreatitis is associated with transient hyperglycaemia that rarely persists.
- Chronic pancreatitis secondary to any cause can lead to permanent diabetes that is typically difficult to manage; imaging studies reveal dilated ducts and pancreatic calculi.
- Tropical calcific pancreatitis is a disease of unknown aetiology found in low- and middle-income countries associated with large pancreatic calculi and diabetes (fibrocalculus pancreatic diabetes).
- Hereditary haemochromatosis is an inherited disorder that produces diabetes secondary to iron deposition in the pancreatic islets and subsequent islet cell damage.

- Pancreatic carcinoma may complicate type 2 diabetes, diabetes secondary to chronic pancreatitis, and, most commonly, fibrocalculus pancreatic diabetes. It is important to suspect malignancy in any person who complains of back pain, jaundice, or weight loss in spite of optimal glycaemic levels.
- Pancreatic surgery can lead to diabetes that is insulin requiring and often difficult to manage.
- Cystic fibrosis is a relatively common genetic disorder affecting the lung, pancreas, and other organs. Up to 75% of adults with cystic fibrosis have some degree of glucose intolerance, and the prevalence of cystic fibrosis diabetes is increasing in parallel with the improved survival of people with cystic fibrosis.

The pancreas plays an important role in carbohydrate metabolism and is a key player in the pathophysiology of the different types of diabetes. It is therefore surprising that pancreatic disease is a rare cause of diabetes, accounting for less than 0.5% of all cases of diabetes. The prevalence of undiagnosed disease, however, may be much higher [1]. The rarity of diabetes in pancreatic disease may be explained, in part, by the presence of considerable β -cell reserve in most individuals. It has been estimated that nearly 80–90% of the pancreas has to be destroyed or removed for diabetes to develop in otherwise healthy individuals.

Several disease processes affecting the pancreas can lead to diabetes, some of which are listed in Table 23.1. Most of these conditions damage the exocrine as well as endocrine components of the pancreas. The exocrine parenchyma and islet tissue lie in intimate contact with each other and are functionally related. This may explain why parenchymal disease can impair β -cell function [2,3].

Acute pancreatitis

Acute pancreatitis varies considerably in its impact on the gland and its metabolism. Pathological findings vary from mild oedema to haemorrhagic necrosis, and the clinical presentation spans a wide spectrum from mild to fulminating or fatal illness.

The most common causes of acute pancreatitis are alcoholism and gallstone disease. Table 23.2 sets out the causes of acute pancreatitis.

It is of interest that diabetes is, in itself, a risk factor for acute pancreatitis, and the use of certain classes of glucose-lowering agents, particularly the glucagon-like peptide-1 receptor agonists and the dipeptidyl peptidase-4 inhibitors, has been reported to be associated with acute pancreatitis [4,5]. Recent systematic reviews have either failed to confirm a link between the use of these agents and acute pancreatitis or have shown only a minor increase in risk [6]. The US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) continue to state that the currently available data do not support a causal relationship between incretin-based drugs and pancreatitis [7].

Classically, the disease presents with sudden onset of epigastric pain, associated with nausea and vomiting, aggravated by food and partially relieved by sitting up and leaning forward. Physical examination reveals low-grade fever, tachycardia, and hypotension. Jaundice may also be found infrequently. Cullen sign (periumbilical discolouration) and Grey Turner sign (flank discolouration) indicate severe necrotizing pancreatitis.

Commonly found metabolic abnormalities include hyperglycaemia, hypocalcaemia, hyperlipidaemia, hypoalbuminaemia, and coagulation disorders [8]. Serum levels of amylase and lipase are elevated, but these are neither sensitive nor specific. Computed tomography (CT) or magnetic resonance imaging (MRI) shows oedema of the pancreas. Loss of the normal enhancement on dynamic CT scanning indicates pancreatic necrosis.

Most patients with acute pancreatitis develop transient hyperglycaemia, which mostly results from a rise in glucagon levels rather

than from β -cell injury [9]. Hyperglycaemia is usually mild and resolves within days to weeks without needing insulin treatment. Permanent diabetes is rare and occurs mostly in cases with fulminant disease and multiorgan failure, in which the incidence approaches 25% [10]. Blood glucose levels exceeding 11.1 mmol/l (200 mg/dl) during the first 24 hours indicate a poor prognosis [11]. Following an episode of acute pancreatitis, individuals have a greater than twofold increased risk of developing diabetes over the next five years [12].

Non-specific elevations of serum amylase and lipase may also be found in diabetic ketoacidosis [13]. Acute pancreatitis, however, may affect up to 11% of individuals with ketoacidosis, usually with mild or even no abdominal pain [11].

Chronic pancreatitis

This condition is characterized by progressive and irreversible destruction of the exocrine pancreatic tissue, leading to exocrine pancreatic insufficiency and varying degrees of glucose intolerance, which often require insulin. The causes of chronic pancreatitis vary according to the geographical location (Table 23.3).

Alcohol misuse accounts for most of the cases (>85%) in European and North American populations. Alcohol alters the composition of pancreatic secretions, leading to the formation of proteinaceous plugs that block the ducts and act as foci for calculi formation. Tropical chronic pancreatitis is a distinct form of the disease that is not associated with excessive alcohol intake and is prevalent in low- and middle-income countries [14, 15].

Hereditary chronic relapsing pancreatitis is a rare entity, inherited in an autosomal dominant fashion. Mutations in a number of genes have been implicated, including *PRSS1* (encoding cationic trypsinogen), *SPINK1* (serine protease inhibitor, Kazal type 1), and *CFTR* (cystic fibrosis transmembrane conductance regulator) [16–19].

Obstructive chronic pancreatitis is a rare condition that follows occlusion of pancreatic ducts by tumours, scarring, pseudocysts, or congenital anomalies. Stones are not seen. Surgery or endoscopic dilatation may occasionally be curative.

Idiopathic pancreatitis, which accounts for 10–20% of all cases, affects two distinct age groups, one with onset at 15–25 years and the other at 55–65 years [20]. Cigarette smoking is a risk factor and mutations in specific genes have also been postulated [19, 21, 22].

Epidemiology

Chronic pancreatitis is prevalent worldwide. The incidence varies between 7 and 14 cases per 100 000 population per year, with significant differences between populations and countries. The incidence appears to have increased over time in many parts of the world [23–27]. Tropical chronic pancreatitis is confined to tropical and subtropical regions of the world, with the highest prevalence rates reported in southern India.

Pathological features

The term chronic calcific pancreatitis accurately describes the pathological changes in over 95% of cases of chronic pancreatitis in European and North American countries. The ductal and acinar lumina are filled with proteinaceous plugs that later calcify, forming small stones composed chiefly of calcium carbonate or calcite. Huge stones can occur, but are more characteristic of tropical pancreatitis. The stones are found diffusely throughout the affected organ. Microscopically, there is atrophy of the ductal epithelium and stenosis of the ducts, associated with patchy fibrosis. There may also be foci of necrosis, with infiltration by lymphocytes, plasma cells, and histiocytes [28]. Ultimately, the pancreas shrivels and develops an opaque capsule that may adhere to surrounding organs.

Table 23.3 Causes of chronic pancreatitis.

Common (90% of cases)	Rare
Alcohol abuse	Hereditary relapsing pancreatitis
Idiopathic	Obstructive chronic pancreatitis
Tropical chronic pancreatitis	

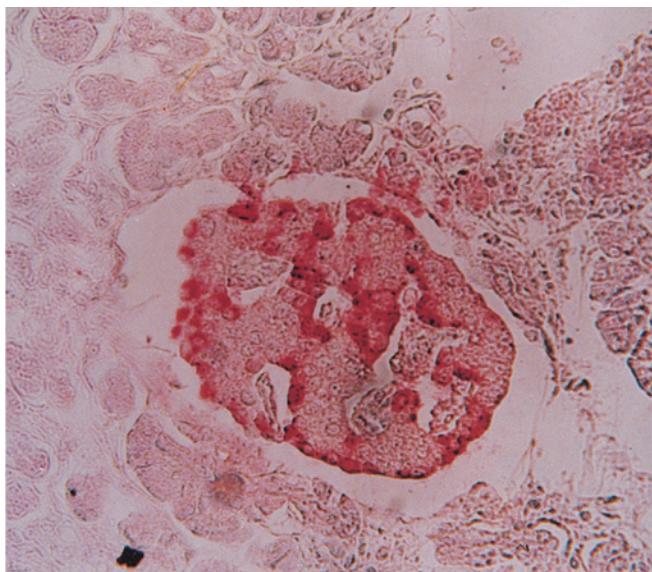

Figure 23.1 Nesidioblastosis, from a case of fibrocalculous pancreatic diabetes, showing islet tissue arising from ductal remnants. Stain aminoethylcarbazole; magnification $\times 40$.

As fibrosis progresses, the acini atrophy and eventually disappear, leaving clusters of islets surrounded by sclerosed parenchyma. Neof ormation of islet cells from ductal tissue can occur (nesidioblastosis) (Figure 23.1). Immunohistochemistry studies reveal a generalized decrease in the number of islets, accompanied by overall reduction in β -cell density and insulin immunoreactivity, which correspond to disease duration and C-peptide levels (Figure 23.2; Table 23.4) [30,31].

Clinical features and diagnosis

Abdominal pain is the predominant symptom and the usual reason for seeking medical care. The pain is usually steady, boring, and agonizing, and located in the epigastrium or left hypochondrium with radiation to the dorsal spine or the left shoulder. Bending forward or assuming the knee–chest position relieves the pain. The cause of the pain is unknown, but may relate to increased intrapancreatic or intraductal pressure, or to ischaemia of the pancreas. It tends to remit and relapse and follows an unpredictable course. The development of end-stage pancreatic disease is associated with disappearance of the pain in many cases.

Exocrine pancreatic insufficiency may manifest with steatorrhoea and features of fat-soluble vitamin deficiency, although steatorrhoea may not be apparent on a low-fat diet. The combination of oily and greasy stools with diabetes should raise the suspicion of chronic pancreatitis.

Investigations

Demonstration of pancreatic calculi on a plain X-ray of the abdomen is diagnostic (Figure 23.3). In cases where obvious calculi cannot be found, ultrasonography, CT scanning, or endoscopic retrograde cholangiopancreatography (ERCP) will help to confirm the diagnosis (Figure 23.4). ERCP is considered the gold standard and usually reveals irregular dilatation of the pancreatic ducts with filling defects caused by stones (Figure 23.4a). CT scanning shows patchy increases in parenchymal density and, ultimately, atrophy of the gland.

Exocrine pancreatic function can be assessed by measuring the urinary excretion of compounds that are liberated in the gut by pancreatic enzyme action on orally ingested precursors such as

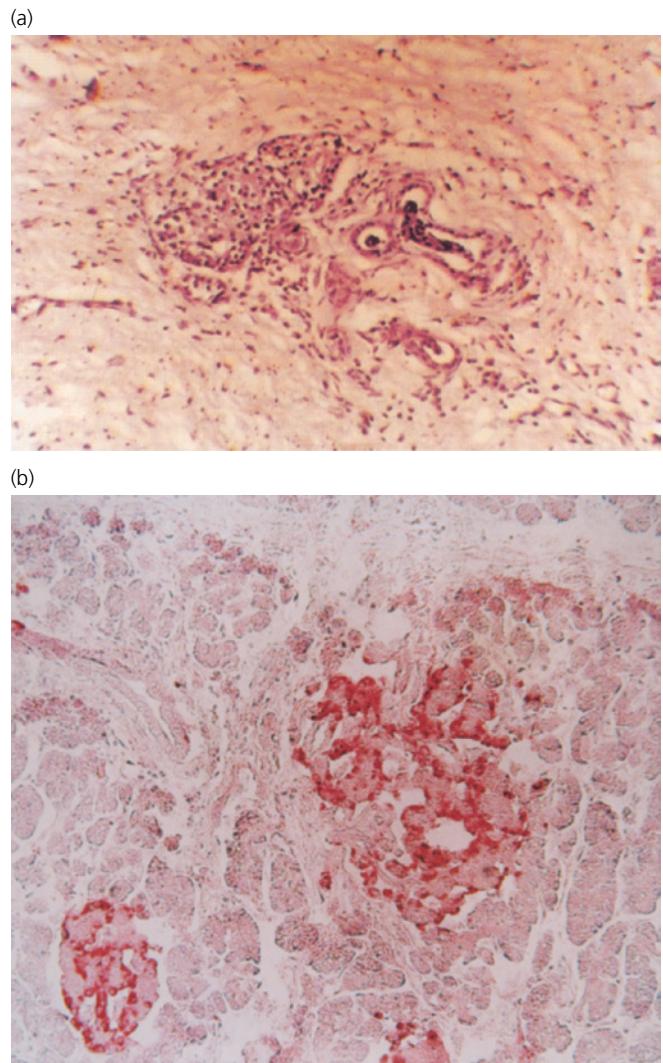

Figure 23.2 Histological features of chronic pancreatitis, from cases of fibrocalculous pancreatic diabetes. (a) Exocrine tissue is entirely replaced by dense fibrosis that spares the islets. N-benzoyl-L-tyrosyl-p-aminobenzoic acid (NBT-PABA) or fluorescein dilaurate (pancreolauryl). Screening tests of pancreatic enzymes (faecal chymotrypsin, faecal elastase) are also used, as they are simpler to perform but are less specific. Measurement of pancreatic output (via a tube placed in the duodenum) following ingestion of the Lundh test meal may also be helpful. Serum amylase is usually normal, except during acute attacks.

Diabetes in chronic pancreatitis

Abnormal glucose tolerance and diabetes complicate around 40–50% of cases of chronic pancreatitis. Unlike acute pancreatitis, the cause here is damage to the β cells, owing to loss of trophic signals from the exocrine tissue [2, 32], although some authors have postulated a role for reduced insulin sensitivity as well [33]. The diabetes is of insidious onset and usually occurs several years after the onset of pain. The prevalence has been assessed at 60% after 20 years [34]. Half or more of patients require insulin for optimal glycaemic management [35, 36], but ketoacidosis is rare, even if insulin is withdrawn. Possible explanations include better preservation of β -cell function (compared with type 1 diabetes) [37], reduced glucagon secretion, and lower body stores of triglyceride, the major substrate for ketogenesis [29, 37]. On account of the lower glucagon reserve, these people are also prone to severe and prolonged hypoglycaemia, and often diabetes is difficult to manage with wide fluctuations of blood glucose levels.

Chronic diabetic complications

It was originally thought that people with pancreatic diabetes were not at increased risk of microvascular complications; however, retinopathy [38] and nephropathy [39] occur at frequencies similar to those with type 2 diabetes, while the prevalence of neuropathy might be higher [40, 41]. The risks of macrovascular complications, nevertheless, are relatively low. This may partly be explained by the favourable blood lipid profile that often accompanies the malnutrition commonly seen in these people [42].

Management of diabetes in chronic pancreatitis

Removal of obvious causes, such as alcohol and hypertriglyceridaemia, will help to prevent progression of the damage to the gland. Pain can be very difficult to manage. Measures include total abstinence from alcohol, dietary modification (small frequent meals with low fat content), analgesics, and the somatostatin analogue octreotide, which suppresses pancreatic exocrine secretion. In a subgroup of individuals, massive doses of non-enteric-coated preparations of pancreatic enzymes may reduce pain. Surgical interventions include sphincterotomy, internal drainage of pancreatic cysts, endoscopic removal of calculi (via ERCP), insertion of duct stents, and denervation procedures. Total resection of the pancreas followed by whole pancreas or islet cell transplantation is an option for intractable cases. Malabsorption can be effectively treated with a low-fat diet with pancreatic enzyme supplements (along with histamine H₂ blocker or proton pump inhibitor to block gastric acid secretion) taken at meal times.

Diabetes should be managed along conventional lines, with a few caveats. High carbohydrate and protein intakes are encouraged along with fat restriction in order to prevent steatorrhoea while preventing weight loss. Over 80% of these individuals require insulin; however, the required doses are typically low, around 30–40 units/day [35, 36]. Despite this, frequent and severe hypoglycaemia may occur as a result of reduced glucagon secretion.

Individuals with type 2 diabetes exhibit evidence of reduced exocrine pancreatic function, albeit not to the degree found in ‘pancreatic’ diabetes. In a study from India, the prevalence of exocrine pancreatic insufficiency (measured by the faecal chymotrypsin assay) was 4.5% in type 2 diabetes, as compared to 88% and 24% in fibrocalculus pancreatic diabetes and type 1 diabetes, respectively [43]. Pancreatic insufficiency has been postulated to occur due to loss of the trophic action of insulin on the exocrine tissue; however, autonomic neuropathy affecting the enteropancreatic

reflexes may play a role in the pathogenesis [44]. Routine screening of persons with type 2 diabetes for exocrine pancreatic insufficiency in the absence of symptoms is not recommended.

Tropical chronic pancreatitis

This is a distinct variety of chronic pancreatitis seen predominantly in low- and middle-income countries in the tropical and subtropical regions of the world [45, 46]. This entity was first reported in 1959 by Zuidema [46] in people from Indonesia, but the disease was subsequently reported in several countries in Africa and Asia. The highest prevalence appears to be in southern India, particularly in the states of Kerala and Tamil Nadu [47]; however, the prevalence seems to be declining even in these areas.

The disease usually starts in childhood with recurrent abdominal pain and during adolescence progresses to large pancreatic calculi and ductal dilatation (Figures 23.3 and 23.5). By adulthood, frank diabetes is found in more than 90% of these individuals [48]. Nevertheless, it remains a rare cause of diabetes, constituting less than 1% of all cases of diabetes (and a slightly higher proportion of all young-onset diabetes) even in regions where it is most prevalent [49, 50]. A recent population-based study in urban southern India reported a prevalence of 0.36% among people with self-reported diabetes and 0.019% among the general population [51].

The term tropical chronic pancreatitis is used to denote the pre-diabetes stage of the disease, whereas the term fibrocalculous pancreatic diabetes is used to describe the clinical picture once diabetes has supervened (Figure 23.6).

Figure 23.5 Calcite stones of various sizes removed from the pancreas of a person with fibrocalculous pancreatic diabetes.

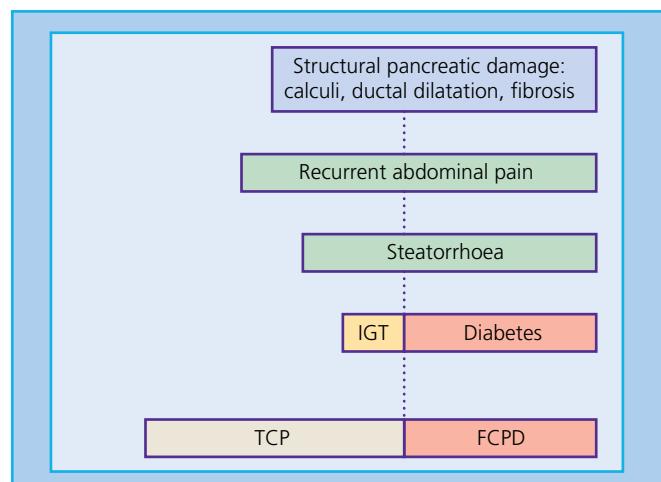

Figure 23.6 Natural history of tropical calcific pancreatitis (TCP) and fibrocalculous pancreatic diabetes (FCPD). IGT, impaired glucose tolerance.

The aetiology of the condition remains unknown. Poor nutrition has been implicated as a possible factor; however, this may be a consequence rather than a cause of the pancreatopathy. The condition may also affect well-nourished individuals [52]. In the past, attention was focused on the role of dietary toxins such as cyanogens (found in cassava), but this link has not been substantiated. Cases tend to cluster in families, which may suggest a genetic aetiology for the disease [53–56]. Several studies have reported an association of tropical chronic pancreatitis with the *SPINK1* gene [57–63], as also with the cathepsin B (*CTSB*) gene [64,65]. A role has been suggested for oxidant stress and free radical-mediated injury, but this has not been proven conclusively [66].

Salient differences between alcoholic chronic pancreatitis and tropical chronic pancreatitis are summarized in Table 23.5. The classic clinical triad of tropical chronic pancreatitis comprises abdominal pain, steatorrhoea, and eventually diabetes. The disease often progresses steadily from euglycaemia through impaired

glucose tolerance to frank diabetes. Most people require insulin but are generally not prone to ketosis; some can be managed with oral anti-diabetes agents (Figure 23.7). The risk of developing pancreatic carcinoma in tropical chronic pancreatitis is 100-fold greater than in those without the disease and is much higher than in other forms of chronic pancreatitis [67]. Pancreatic malignancy should be suspected in individuals with tropical chronic pancreatitis if they complain of intractable pain or significant weight loss even after attaining optimal glycaemic levels. Management of tropical chronic pancreatitis and fibrocalculus pancreatic diabetes is similar to that outlined for chronic pancreatitis.

Hereditary haemochromatosis

This condition, also called idiopathic or primary haemochromatosis, is the most common autosomal recessive genetic disorder in people of northern European ancestry, with a prevalence of 4–5 per 1000 [68,69]. The classic triad of diabetes, cirrhosis, and bronzed hyperpigmentation of the skin was first described by Troussseau in 1865 and called ‘haemochromatosis’ by von Recklinghausen in 1889 [70].

Aetiology and pathology

Genetic basis

Most cases of primary haemochromatosis arise from mutations in the haemochromatosis gene (*HFE*), located on the short arm of chromosome 6, close to the major histocompatibility complex (MHC), which explains the linkage with human leucocyte antigen (HLA) A3 [71]. The *HFE* protein encoded by this gene is expressed on the cell surface of various tissues, including the enterocytes of the duodenal brush border, where iron is chiefly absorbed. The *HFE* gene modulates iron absorption by binding to the transferrin receptor. In two-thirds of cases, a C282Y mutation (substitution of cysteine by tyrosine at position 282) in the *HFE* gene is responsible [68]. Another mutation, H63D, seems to act synergistically with C282Y [72]. These mutations inhibit the binding of *HFE* to transferrin, leading to an excessive and inappropriate increase in intestinal iron absorption and greatly increased body iron stores. Non-*HFE* mutations are also rarely found to be responsible in some cases.

Table 23.5 Differences between tropical chronic pancreatitis and alcoholic chronic pancreatitis.

	Tropical chronic pancreatitis	Alcoholic chronic pancreatitis
Demographic features		
Male : female	70 : 30	90 : 10
Peak age at onset (years)	20–30	30–50
Socioeconomic status	Poor > affluent	All groups
Alcohol abuse	Absent	Present
Pancreatic morphology		
Prevalence of calculi	>90%	50–60%
Features of calculi	Large; in large ducts	Small, speckled; in small ducts
Ductal dilatation	Usually marked	Usually moderate
Fibrosis	Heavy	Variable
Risk of pancreatic cancer		
Markedly increased		Increased
Diabetes		
Prevalence	>90%	50%
Time course	Faster evolution	Slower evolution

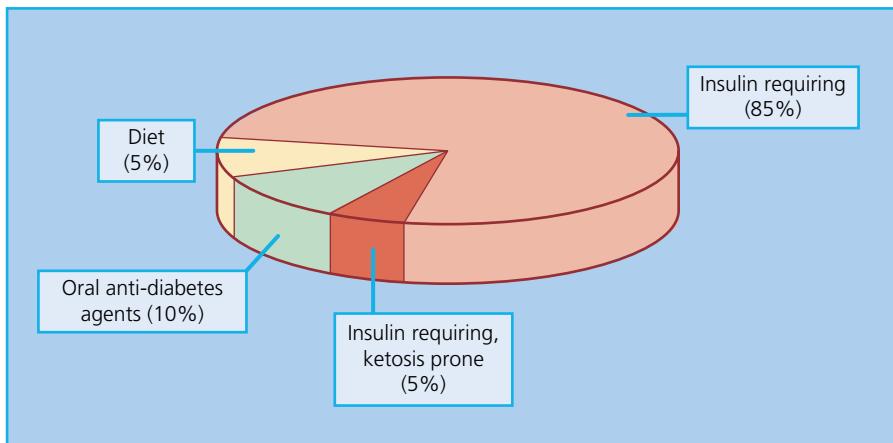

Figure 23.7 The spectrum of diabetes in fibrocalculus pancreatic diabetes. Source: Data from Mohan et al. 1989 [42].

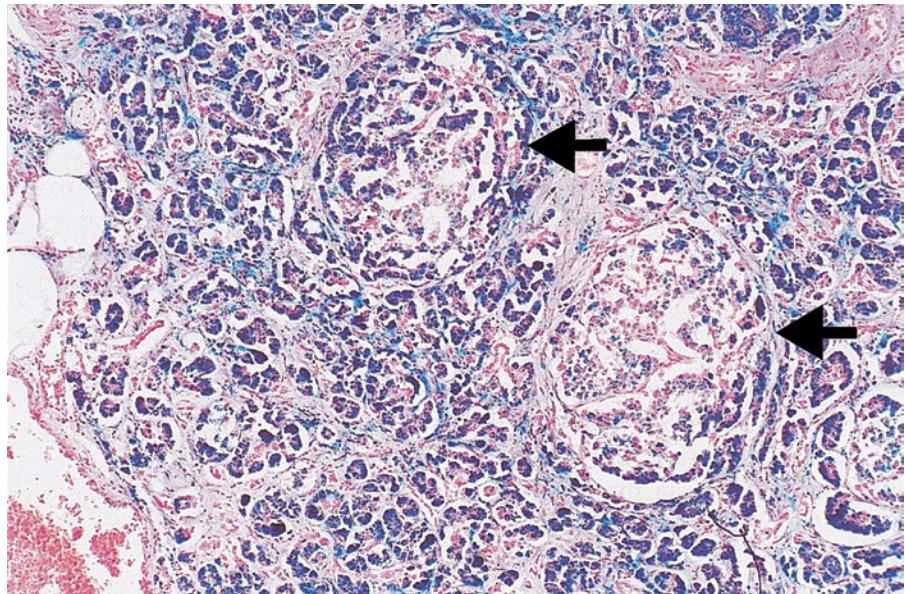

Figure 23.8 Hereditary haemochromatosis. Perls stain shows heavy iron deposition (blue) in exocrine and islet tissue in the pancreas (arrows). Original magnification $\times 375$. Source: Courtesy of Dr A. Clark, Wirral Hospital, UK.

Pathophysiology

The primary defect is excessive iron absorption across the mucosa of the proximal small intestine, which continues even in the setting of greatly increased total body iron stores (often 15–20 g; cf. normal adult iron stores of 1–2 g). Excess iron is deposited preferentially in the liver, pancreas (exocrine tissue as well as islets), pituitary, heart, and parathyroids (Figure 23.8). Tissue injury is postulated to occur as a result of rupture of iron-laden lysosomes, generation of free radicals (by decomposition of hydrogen peroxide catalysed by the ferrous and ferric ions – the Fenton reaction), and the stimulation of collagen synthesis by activated stellate cells.

Clinical features

The classic clinical features are hepatic cirrhosis, diabetes, and skin hyperpigmentation ('bronzed diabetes') (Figure 23.9). Hepatic fibrosis and cirrhosis usually only develop in those aged over 40 years, unless other factors such as alcoholism are present. Portal hypertension, hepatic failure, and hepatocellular carcinoma (in 15% of cases) are late sequelae [73]. Bronzing of the skin, which

occurs in 70% of cases but may be less evident in darker-skinned races, is caused by both iron deposition in the subcutaneous tissue and increased melanin in the basal dermis. Hypopituitarism, hypogonadism, hypoparathyroidism, and chondrocalcinosis with pseudogout are less common features.

Presenting symptoms include weakness, weight loss, diabetes symptoms, arthralgia, erectile dysfunction, and skin pigmentation. Signs include hepatosplenomegaly, heart failure, skin pigmentation, testicular atrophy, arthropathy, hypogonadism, and occasionally hypothyroidism. Many people with haemochromatosis, however, are asymptomatic and may be detected during investigation for unrelated reasons or through genetic screening of family members of those with haemochromatosis.

Diabetes in primary haemochromatosis

The prevalence of diabetes depends on the severity of iron overload and presence of cirrhosis [74]. Up to 50% of these individuals have glucose intolerance and 25% have overt diabetes [75], although the disease is an extremely rare cause of diabetes in the

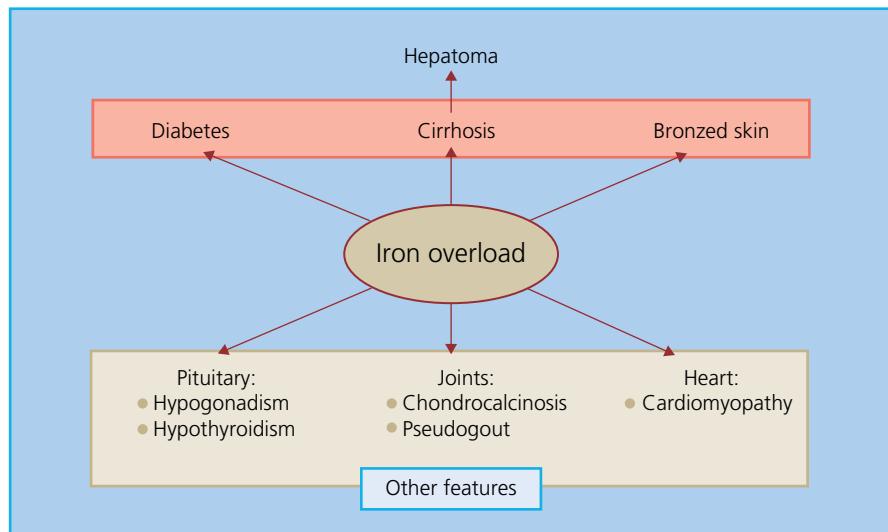

Figure 23.9 Clinical features of hereditary haemochromatosis. The classic triad comprises diabetes, cirrhosis, and hyperpigmentation of the skin ('bronzed diabetes').

general population. The prevalence is steadily declining as the diagnosis is being made earlier, before significant pancreatic damage has occurred. Both insulin resistance and β -cell failure contribute to the development of diabetes, and most individuals eventually require insulin. These individuals are prone to both microvascular and macrovascular complications [73], the risk of nephropathy being particularly high in those carrying the H63D mutation [76].

Investigations and diagnosis

The diagnosis should be suspected in any person with diabetes, hepatomegaly or liver disease, skin pigmentation, arthritis, and hypogonadism. A high index of suspicion is required to make an early diagnosis, because significant iron overload can exist with few or none of these clinical manifestations.

The total-body iron stores can be assessed using measurement of serum ferritin and percent saturation of transferrin. Serum ferritin is a useful screening test for relatives of affected individuals, but because ferritin is an acute-phase reactant, the levels of which can be elevated in inflammatory states, abnormally high results should be confirmed by other tests (Table 23.6) [77]. Serum iron and percentage saturation of transferrin are elevated early in the course of the disease, but lack specificity. A combined measurement of the percentage transferrin saturation and serum ferritin levels provides a simple and reliable screening test for hemochromatosis. A positive test mandates genetic testing.

The role of liver biopsy in the diagnosis and management of haemochromatosis has significantly diminished following the development of genetic testing for the C282Y mutation. The major role of liver biopsy at the present time is to exclude the presence of cirrhosis, which is a major risk factor in the development of hepatocellular carcinoma. Hepatic iron overload can also be detected using imaging techniques such as CT scanning or MRI.

All first-degree adult relatives of individuals with haemochromatosis should be tested for C282Y and H63D mutations in an attempt to detect disease in the early pre-cirrhotic phase, at which stage treatment can prevent further progression.

Treatment

Treatment of hereditary haemochromatosis is by repeated venesection, which must be started as early as possible. Removal of excess iron by venesection prevents diabetes and cirrhosis and prolongs survival [74]. Chelating agents such as desferrioxamine and deferasirox are more expensive, less safe, and less effective

than venesection. Diabetes may be improved by venesection, but usually requires insulin treatment. Management is often complicated by hypoglycaemia caused by concomitant α -cell damage and glucagon deficiency. Hepatic transplantation for hereditary haemochromatosis was previously associated with a poor prognosis, but survival rates have improved of late. Diabetes tends to worsen after transplantation because of the use of immunosuppressant drugs [78]. Hepatocellular carcinoma is a late complication and may be an indication for transplantation if the disease remains localized.

Secondary haemochromatosis

Iron overload can also occur as a consequence of repeated blood transfusion and disorders of erythropoiesis such as thalassemia and sickle cell anaemia, in which case the condition is termed secondary haemochromatosis or hemosiderosis. Pancreatic damage and diabetes frequently result. The duration of disease and number of transfusions correlate well with the degree of glucose intolerance. Iron overload may induce autoimmune attack against the β cells, thereby contributing to the development of diabetes [79].

Pancreatic neoplasia

Adenocarcinoma of the pancreas is the fifth most common cause of cancer death and is increasing in its incidence [80]. It has a poor prognosis, with a five-year survival rate of less than 3%. Although diabetes has long been associated with pancreatic adenocarcinoma, the nature and strength of the association remain controversial. A meta-analysis of 20 epidemiological studies showed a twofold increased risk of pancreatic cancer among people with diabetes of more than five years' duration [81], suggesting that diabetes is a risk factor for the neoplasm. Other studies, however, have concluded that the cancer preceded and caused the diabetes [82], a view supported by observations that diabetes may improve after resection of the tumour. Some studies have even suggested that diabetes protects against pancreatic cancer [83]. Tropical chronic pancreatitis is associated with a 100-fold increase in the risk of developing pancreatic carcinoma [65]. Currently available data do not support an association between the use of incretin-based therapies for diabetes and the risk of pancreatic carcinoma [7, 84, 85].

The diagnosis of pancreatic carcinoma should be suspected in any person with type 2 diabetes who complains of unexplained weight loss (despite insulin therapy and apparently good glucose levels), back pain, or jaundice.

Pancreatic surgery and diabetes

Diabetes is a frequent complication of pancreatic resection performed for various indications. The incidence and severity of diabetes depend on the extent of resection of the distal segment, where the islets are most abundant. In one study, diabetes developed in 56% of cases following distal resection [86]. Diabetes is more likely to follow subtotal pancreatectomy than procedures such as lateral pancreaticojjunostomy and pancreaticoduodenectomy (Whipple procedure). Diabetes is obviously inevitable following total pancreatectomy.

Table 23.6 Diagnostic tests in hereditary haemochromatosis.

	Haemochromatosis	Normal
Serum iron ($\mu\text{g/dl}$)	180–300	50–150
Transferrin saturation	80–100	20–50
Total iron-binding capacity ($\mu\text{g/dl}$)	200–300	250–370
Serum ferritin ($\mu\text{g/dl}$)		
Men	500–6000	20–300
Women	500–6000	15–250
Hepatic iron concentration ($\mu\text{g/g dry weight}$)	10 000–30 000	300–100

1 $\mu\text{g/dl}$ of serum = 5.6 $\mu\text{mol/l}$. The calculated total iron binding capacity in $\mu\text{g/dl}$ is converted to $\mu\text{mol/l}$ by multiplying by 0.1791.

Source: Based on Fried Hagedorn 2000 [77].

Management of diabetes caused by pancreatic surgery

The diabetes is usually difficult to manage, with wide excursions in blood glucose levels. Individuals are exquisitely insulin sensitive and prone to hypoglycaemia as a result of the loss of glucagon function. Frequent small meals and multiple small doses of insulin can minimize these problems to an extent. Use of a subcutaneous insulin infusion pump may be beneficial in some cases. People with diabetes following pancreatectomy are ideal candidates for whole pancreas or islet cell transplantation. Any associated exocrine pancreatic insufficiency should also be addressed. Meals should be low in fat and high in carbohydrate and protein. Pancreatic enzyme therapy will help in controlling steatorrhoea and stabilizing blood glucose [87].

Cystic fibrosis

Cystic fibrosis is a multisystem disease characterized by recurrent airway infection leading to bronchiectasis, pancreatic insufficiency, abnormal sweat gland function, and urogenital dysfunction. It is an autosomal recessive disorder caused by mutations in the *CFTR* gene located on chromosome 7q22. This gene encodes a protein, CFTR, which regulates the chloride secretion across epithelial surfaces. Various mutations have been described, of which deletion of the phenylalanine residue at position 508 ($\Delta 508$) is the most common [88]. The defect produces unusually viscous secretions that lead to pancreatic ductular obstruction, dilatation, and pancreatic insufficiency. The incidence is 1 in 2500 live births in populations of white northern European ancestry, but the disease is much less common in Africans and Asians [89].

The most common clinical features are steatorrhoea, failure to thrive and growth retardation, recurrent lung infections, hepatobiliary complications, osteoporosis, and symptoms of fat-soluble vitamin deficiency such as night blindness. The diagnosis is confirmed by the presence of an elevated sweat chloride concentration in excess of 60 mmol/l.

Diabetes in cystic fibrosis

The incidence of diabetes in children with cystic fibrosis is 2–3% (about 20 times higher than in the general population). The incidence rises steadily through adolescence, with up to 25% of individuals in their 20s developing diabetes and a further 50% having glucose intolerance [90]. Up to 50% of adults develop diabetes by the age of 35–40 years. Occasionally, diabetes is the first manifestation of cystic fibrosis. As the treatment of the lung disease in cystic fibrosis has improved, more and more people are surviving into adulthood, leading to an increase in the prevalence of cystic fibrosis diabetes.

The major factor in the pathogenesis of diabetes is damage to the pancreatic β cells secondary to exocrine pancreatic degeneration. There is a progressive decrease in insulin secretion with increasing age, and a decrease in the number of β cells associated with inflammation, fibrosis, and amyloidosis of the pancreas. There may also be a direct effect of the cystic fibrosis mutation on insulin secretion, as the *CFTR* has a role in β -cell function and insulin secretion. Other postulated mechanisms include enhanced absorption of glucose [91], lowered chloride levels within the β cell leading to reduced glucose responsiveness [92], and autoimmune attack against the β cell, which may explain why type 1 diabetes is more common in

relatives of people with cystic fibrosis [93]. The physiological insulin resistance of normal puberty may also contribute. Interestingly, diabetes develops more commonly in people homozygous for $\Delta 508$ than in heterozygotes [94].

Diabetes is usually insidious in onset and characterized by a delayed, flattened, and prolonged insulin secretory response to glucose [95]. Insulin secretion in people with cystic fibrosis declines from childhood, even in those with normal glucose levels. Insulin sensitivity is usually normal, but reduced insulin sensitivity contributes to hyperglycaemia in situations where there is another cause of insulin resistance, such as infection or systemic corticosteroid treatment. Basal insulin secretion is relatively preserved, but the insulin response to a glucose load is reduced and delayed. Consequently, fasting blood glucose levels are normal initially and the individual may only have intermittent elevations of post-prandial glucose to begin with. There is a characteristic pattern of abnormal glucose levels, with glucose levels being lowest before breakfast and rising after meals, with the highest levels in the evening. In time, post-prandial hyperglycaemia becomes established and fasting glucose levels subsequently rise to levels diagnostic of diabetes [96]. Ketoacidosis is rare, although insulin treatment is usually required.

As persons with cystic fibrosis diabetes now survive longer [88], chronic microvascular complications are also frequently seen, although macrovascular disease is virtually unknown. The major impact of cystic fibrosis diabetes, however, is on lung function and mortality. Studies dating back to the 1980s demonstrated significant increases in mortality in those with cystic fibrosis diabetes even after adjustment for other risk factors. Health appears to start to deteriorate two to six years prior to a diagnosis of diabetes, with decreases in weight, body mass index, and markers of lung function up to six years prior to the diagnosis of diabetes. The reasons why worsening glycaemia adversely affects clinical status are not fully understood, but are likely to be multifactorial and include the gradual loss of the anabolic effect of insulin and elevated airway glucose levels that may promote bacterial growth.

Management

The International Society for Paediatric and Adolescent Diabetes (ISPAD) and the American Diabetes Association (ADA) recommend that all children with cystic fibrosis be screened annually for diabetes with an oral glucose tolerance test, starting from 10 years of age [96, 97]. Currently the diagnostic criteria are the same as for other forms of diabetes, but there have been calls to lower the thresholds to recognize that levels of glycaemia that are below the standard thresholds may still be associated with worsening lung function and weight loss. The oral glucose tolerance test is the diagnostic test of choice, but this should not be performed during acute exacerbations of pulmonary disease, particularly if the treatment includes glucocorticoids. There is some evidence that glycated haemoglobin (HbA_{1c}) may be useful for diagnosing cystic fibrosis diabetes, although this is not currently recommended. The utility of continuous glucose monitoring is being assessed. Although some people initially respond to sulphonylureas, most ultimately need insulin and this is reflected in most guidelines for treatment, which recommend insulin as the treatment of choice [98]. In addition to managing diabetes, insulin may also improve body weight and pulmonary and pancreatic function [90, 99, 100]. Early diagnosis and treatment of cystic fibrosis diabetes may help to preserve lung function [101]. Annual monitoring for complications of diabetes is recommended, starting five years after the diagnosis of diabetes [97].

Part 4 Other Types of Diabetes

Dietary modification in people with cystic fibrosis who also have diabetes presents much the same difficulties as in people with chronic pancreatitis. A diet rich in carbohydrates and protein but restricted in fat is recommended. Oral pancreatic enzyme therapy helps to improve nutrient digestion and absorption. Enteric-coated preparations of lipase can control steatorrhoea. Fibrosing colonopathy is a concern in individuals receiving higher strengths of lipase [102].

Conclusion

Although rare, diabetes secondary to pancreatic disease is potentially important. The underlying pancreatic disease may need treatment in its own right, while disorders with a genetic basis

must be identified so that other family members can be screened. Diagnosis of pancreatic diabetes requires a high index of suspicion. Suggestive symptoms include features of pancreatic disease (steatorrhoea, unexplained weight loss, or back pain) and severe diabetes, which is difficult to manage, in the absence of a family history of diabetes.

Clinical Presentations of Diabetes

Ee Lin Lim¹ and Roy Taylor²

¹ Royal Preston Hospital, Preston, UK

² Diabetes Research Group, Institute of Translational and Clinical Research, Newcastle University, Newcastle upon Tyne, UK

Key points

- The classic symptoms of diabetes are thirst, polydipsia and polyuria, weight loss, and tiredness.
- People with type 1 diabetes usually present with classic symptoms and occasionally diabetic ketoacidosis.
- People with type 2 diabetes may present with classic symptoms or the presentation may be asymptomatic and discovered on routine examination or laboratory test.
- Type 2 diabetes may present with complications of diabetes that may be either microvascular or macrovascular.
- Initial diagnosis of type 2 diabetes during acute myocardial infarction or stroke is common.
- The mode of presentation may help distinguish the type of diabetes.
- With advancing age, the renal threshold for glucose increases and thirst perception diminishes.
- Consideration of the impact of the initial consultation on the individual is important.
- Diabetes of onset in pregnancy is important and ideally detected by an effective screening programme.

Diabetes has long since taken over from syphilis as the great imitator, and nowhere is this more apparent than in the wide variation of possible modes of initial presentation. The classic triad of thirst, polydipsia, and polyuria accounts for only a modest proportion of new diagnoses of diabetes. The relatively acute onset of such symptoms associated with loss of weight is the hallmark of type 1 diabetes with ketoacidosis at the extreme. Hyperosmolar hyperglycaemic syndrome (HHS) may precipitate a dramatic presentation of type 2 diabetes to emergency services. Non-specific symptoms including tiredness, general malaise, and repeated or persistent skin infections may lead to a biochemical diagnosis of diabetes. Screening of at-risk groups or individuals allows early diagnosis. Regrettably, the nature of the condition is such as to allow it to remain asymptomatic for years, allowing the clinical presentation to be a long-term complication of diabetes. This could be in the form of macrovascular disease (myocardial infarction, stroke, black toe) or in the form of microvascular disease (loss of visual acuity, nephropathy, neuropathy). Pregnancy may cause gestational diabetes mellitus (GDM) that, although it may remit after delivery, does indicate a high risk for future type 2 diabetes.

diabetes need to be established if the diagnostic consultation is to be therapeutic. In an era of medicine by numbers, often traduced as *evidence-based medicine*, it is easy to overlook the impact of the consultation itself on the person who will live with diabetes. ‘Where were you when the Twin Towers fell?’ – ‘What was it like when you were told you have diabetes?’ The moment is likely to be memorable and influential.

The therapeutic consultation will involve listening, a process that need not be unduly time consuming. ‘Do you know of anyone with diabetes? What do you know of diabetes just now?’ The information received will allow the person’s likely type of diabetes and immediate prognosis to be put into perspective. Together with other aspects of sound clinical history taking, it will also transform that person’s view of the consultation. Individuals with diabetes rate *listening* as the most valued attribute of a doctor. Although others may listen too, this cannot be delegated.

At what stage of diabetes is the person in front of you? The implications for the person who was identified on routine screening are quite different from those of someone presenting with a black toe. The former is likely to be at an early stage of a long process with a good chance of modifying disease progression, whereas the latter is likely to have other established tissue complications. Clearly, genetic susceptibility to develop complications plays a part as well as natural history time course. The former individual may never develop more than microaneurysms in the eye and be resistant to diabetic nephropathy. Even if they are to be susceptible to complications, these are amenable to intervention over a period of many years. The latter individual, however, requires clear explanation of what can be done and how future trouble can be avoided. Hippocrates summed it up nicely: ‘Cure sometimes, relieve often, comfort always’.

Clinical considerations at presentation

At the heart of any consultation involving the presentation of diabetes there is a patient. Depending on prior knowledge, *diabetes* may be associated in their mind with blindness and amputation, disability, and premature death. Alternatively, it may be associated with vague concepts of malaise. The individual’s beliefs and thoughts on

The possibility of cure should not be overlooked. Diabetes has long been regarded as incurable, but this is not so. Recent advances in our understanding of type 2 diabetes reveal that it is a simple condition of accumulating more fat than can be tolerated by the individual. Durable remission of short-duration type 2 diabetes by substantial and sustained weight loss is possible for those who have the determination and ability to change long-standing behaviour patterns [1]. For such people, this knowledge is life changing and normoglycaemia continues as long as weight regain is avoided [2]. Only 50% of individuals with diabetes of duration longer than eight years can reverse their diabetes, compared with around 90% of those with diabetes for less than four years [3]. Bariatric surgery produces dramatic and long-term cure of type 2 diabetes in the early years of the condition by enforced calorie restriction [4, 5]. However, can the remission results be translated to the diabetes population in the community and is the delivery of such significant weight loss feasible? The Diabetes Remissions Clinical Trial (DiRECT) showed that more than a third of people with type 2 diabetes who took part in a weight management programme delivered through primary care surgeries in England and Scotland remained in remission of their diabetes two years later [6]. Weight loss led to reduced levels of intra-pancreatic fat, which in turn was associated with the recovery of pancreas function and insulin production [7].

Rare causes of diabetes should not be overlooked. Look out for the slatey grey person with large liver and haemoglobin level of 190 g/l. Haemochromatosis is rare as a cause of diabetes, but it is treatable and therefore important (Chapter 23). The hyperglycaemia of a person taking a combination of thiazide diuretic and β -blocker may be ameliorated by use of alternative agents (see Chapter 21). Cushing syndrome may include curable diabetes (Chapter 22). Few people taking systemic steroid therapy can stop treatment just because of the development of diabetes, but diabetes will go away or become much easier to manage when the steroid course finishes.

Types of diabetes

The classification of diabetes has attracted much debate, although most people follow well-defined clinical courses. Currently, those people who appear to have primary, major β -cell failure are classified as having type 1 diabetes. Type 1 diabetes does not present clinically until 80–90% of the β cells have been destroyed. As type 2 diabetes is caused by fat accumulation in liver and pancreas that exceeds a personal threshold [8, 9] and removal of this by substantial weight loss will restore long-term normoglycaemia if done within six years of diagnosis [6, 7], any doubt about type 2 diabetes having a single weight-related aetiology has been removed. Typically, type 2 diabetes presents beyond the age of 30 years in those with an elevated body mass index (BMI). Around 1 in 10 people with newly diagnosed type 2 diabetes have a BMI in the normal range but have gained weight during adult life. The younger the age of onset, the greater is the weight at presentation. The monogenic causes of diabetes are capable of precise genetic description and are clearly separate (Chapter 20). Similarly, pancreatic disease such as chronic pancreatitis, pancreatic carcinoma, and haemochromatosis is capable of precise diagnosis (Chapter 23). Type 2 diabetes, however, is often used to cover conditions that do not fit into the other, more easily defined categories. More subtypes will be identified in due course (Chapter 2).

The important practical question at the initial presentation is whether insulin therapy is necessary. In some circumstances there is no doubt, such as diabetic ketoacidosis (DKA) or severe weight loss with ketonuria and glycosuria in a child (Figure 24.1). More usually in adult practice, the question must be carefully considered. Table 24.1 lays out the common and distinguishing features from the clinical history, examination, and urinalysis to help the clinician come to the answer. The subsequent sections consider the separate features in context.

Thirst, polydipsia, and polyuria

These symptoms result from an osmotic diuresis caused by hyperglycaemia. The symptoms are common to all types of diabetes, although the time course is likely to be shorter and the symptoms more severe in type 1 diabetes. Not infrequently, sugar-containing carbonated drinks are selected to slake thirst, leading to worsening of symptoms. A careful history documenting the time course of symptoms and any change in intake of specific drinks is important. Remembering how many times per day urine is passed is not easy, but nocturia is more clear-cut and the number of times urine is passed at night should be quantified. ‘Do you need to drink water when you get up at night?’ is a reasonably objective measure of thirst.

For glucose to escape into the urine, plasma glucose concentration must exceed the renal threshold for tubular reabsorption of glucose and the absolute amount of glucose delivered to the renal tubules must exceed the maximum absorptive capacity. The renal threshold averages 11 mmol/l, but displays a wide individual variation of around 6–14 mmol/l [10]. Additionally, the maximum absorptive capacity varies with age, such that older people exhibit glycosuria at higher plasma glucose levels [11].

The rise in maximum renal tubular absorptive capacity with increasing age is clinically significant, as older people will only develop osmotic symptoms at higher plasma glucose levels. Conversely, a negative urine test is even less likely to exclude a diagnosis of diabetes than in younger people. In addition to the need for higher plasma glucose levels in older people to produce osmotic symptoms, the threshold for triggering the sensation of thirst rises with advancing years [12]. This is important because, once the maximum renal absorptive capacity has been exceeded, dehydration will become considerably more advanced before thirst is sensed. These age-related changes are highly relevant to the development of severe hyperosmolar states.

The presence of chronic hyperglycaemia itself changes the renal sensitivity to vasopressin such that thirst is not appreciated despite rising plasma osmolarity [13]. Hence, the combination of undiagnosed diabetes and advanced age is particularly potent in delaying appropriate action to increase oral fluid intake as dehydration progresses. The clinical features identified from the history at presentation will vary in relation to the factors mentioned. In older people, thirst may not be experienced despite an osmotic diuresis and polydipsia will be absent. The most reliably quantitated feature of an osmotic presentation is therefore frequency of nocturia, and specifically an increase from habitual levels.

In children, enuresis may be the first symptom of polyuria. Sudden onset of enuresis should always prompt testing of urine for glucose. A urine test is entirely appropriate as an initial screen in this situation, as the absence of glucose from the urine absolutely excludes hyperglycaemia as a potential cause of polyuria.

Part 4 Other Types of Diabetes

Figure 24.1 A 3-year-old boy before and after three months of insulin therapy (1922). (a) The severe wasting of muscle and adipose tissue due to the insulin deficiency of type 1 diabetes is painfully evident. There is no more dramatic reminder of weight loss as a prominent presenting feature of type 1 diabetes, especially if presentation is delayed. (b) The speed of restoration of body mass on replacing insulin is impressive. Source: Reproduced with permission from Eli Lilly & Co.

Table 24.1 Clinical features at presentation of type 1 diabetes, type 2 diabetes, and monogenic diabetes.

	Type 1 diabetes	Type 2 diabetes	Monogenic diabetes	Pancreatic
Weight loss	Yes (not essential, e.g. in slow-onset type 1 diabetes)	Usually no	No	Possible. If marked consider pancreatic carcinoma
Ketone formation	Yes (not essential in slow-onset type 1 diabetes)	Unusual, but may occur in ketosis-prone type 2 diabetes	No, unless recent fasting	Yes, but not necessary for diagnosis
Time course of symptoms	Weeks or days	Months	Months	Weeks or months
Severity of symptoms (e.g. nocturia >3)	Can be marked	Variable, but not usually extreme unless fuelled by sugary drinks to assuage thirst	Not usually severe	Depends on clinical situation
Family history	Possibly of insulin dependence at a young age	Present in 30% with onset in adult life	Present in almost all with onset in childhood or adult life	Only by chance, except in association with haemochromatosis
Age	Peak age in preschool and teenage years, but can present at any age	Typically after the age of 20 yr	Childhood, adolescence, or adult	Usually middle aged and older

Note: This is a diagnostic guide, with exceptions because of specific circumstances. It is not exhaustive and does not include rarer forms of diabetes, including syndromic diabetes.

Weight loss

Establishing whether significant weight loss has occurred is the most important aspect of history taking in those with newly presenting diabetes. Unless secondary to concurrent disease, the symptom strongly suggests insulin deficiency and hence newly presenting type 1 diabetes. Its absence does not exclude type 1 diabetes, as the speed of onset of insulin deficiency and the presence of intercurrent illness, which may have exacerbated osmotic symptoms, may mean that weight loss has not yet commenced.

Weight loss at presentation of type 2 diabetes may occur from dietary restriction, often undertaken because of suspicion of impending health problems. Such deliberate changes in eating habit are readily established from the history. Typically, weight does not change, or even continues to rise, prior to the symptomatic onset of type 2 diabetes.

The weight loss mainly reflects the relative loss of the anabolic actions of insulin. Muscle wasting may be prominent, especially in young men. Associated loss of muscle strength may be reported. As an anabolic hormone, insulin acts principally to inhibit protein degradation [14]. Its relative absence allows the balance between continuous protein synthesis and breakdown to be disturbed. There is an additional effect of insulin deficiency in the failure of normal promotion of lipogenesis and inhibition of lipolysis. Excess non-esterified fatty acids accumulate in plasma, forming substrate for ketogenesis. If the clinical presentation of diabetes is acute, a component of the weight loss will reflect the loss of both intracellular and extracellular water.

Blurred vision

Major changes in plasma glucose will be followed over a period of days and weeks by blurring of vision. The symptom is typically present after a relatively acute glucose change, usually in the context of presentation of type 1 diabetes or in the specific circumstance of a hyperosmolar presentation of type 2 diabetes. It is most important to explain that the visual blurring will become worse following the relatively rapid correction of gross hyperglycaemia. This explanation is vital to avoid the supposition that diabetes-related blindness is already progressing, with consequent unnecessary worry. It also prevents the unnecessary purchase of spectacles that will be redundant once the hyperglycaemia is treated.

It is reasonably assumed that shifts in osmotic pressure between plasma and inside the eyeball account for the visual change. Certainly, this provides a practical and immediately understandable explanation. Detailed tests, however, have not tied down any identifiable refractive change [15].

Infections

Exposure of leucocytes to glucose concentrations above 11 mmol/l impairs phagocytic and other functions [16]. This effect, together with other possible effects on immune function (Chapter 61), explains the impaired ability to fight off bacterial and fungal infections. Susceptibility to viral infections appears to be little changed, although clear data are lacking.

Recurrent or refractory yeast infections may draw attention to previously undiagnosed diabetes. Most frequently this involves

vaginal candidiasis in women or balanitis in men. Normalization of blood glucose levels will permit clearance of the infection with continued antifungal application. Staphylococcal pustules, boils, and carbuncles may be present at the diagnosis of diabetes, especially type 1 diabetes. This clinical observation was supported by a prospective study of 482 individuals with skin or mucous membrane sepsis presenting to an accident and emergency department who were found to have a greater than threefold increased incidence of capillary blood glucose >7.8 mmol/l compared with a background population [17].

Very rare but serious infective presentations of diabetes must be considered. Necrotizing fascitis is considerably more common in people with diagnosed and undiagnosed diabetes [18]. Fournier gangrene (gangrene of the perineum and genitalia) is associated with diabetes in almost 50% of cases [19]. The rare and often fatal facial and/or maxillary sinus fungal infection mucormycosis is most often associated with diabetes [20].

The important new topic of susceptibility of people with diabetes to more severe illness with Covid-19 is considered later.

Diabetic ketoacidosis

DKA occurs as a result of marked insulin deficiency associated with an increase in circulating levels of counter-regulatory hormones. It is characterized by hyperglycaemia, acidosis, and ketosis (identified by the presence of ketonuria or ketonaemia). It mainly occurs in people with type 1 diabetes, but it is not uncommon in type 2 diabetes. Ketosis-prone type 2 diabetes tends to be more common in older, overweight, people of other-than-white ethnicity, and DKA may be their first presentation of diabetes [21].

The prevalence of DKA at initial disease presentation in children and young people is well documented [22] and remains high – data from the registry component of the SEARCH for Diabetes in Youth Study reported a prevalence of 29–31% in 2002–2010, with those from other-than-white ethnic backgrounds and a low income threshold more likely to be affected [23]. In adults, data from the UK National Diabetes audit showed that while nearly 4% of people with type 1 diabetes experience DKA each year, only about 6% of cases of DKA occur in adults newly presenting with type 1 diabetes [24]. The overall mortality rate from DKA ranges from 2% to 5%, but is higher in older people.

DKA typically presents with the symptoms of hyperglycaemia (i.e. thirst, polyuria, and polydipsia). Other symptoms include malaise or lethargy and muscle cramps. Abdominal pain and vomiting may be sufficiently severe to mimic an acute surgical problem. It is critically important to recognize this, as the administration of an anaesthetic is almost invariably fatal. All doctors dealing with emergencies should be aware of the potential pitfall of missing this tell-tale sign of DKA.

Clinical signs include dehydration, deep sighing respirations (air hunger or Kussmaul respiration), and a sweet-smelling fetor (like nail varnish remover) caused by the ketones on the breath. As the ability to detect the smell of ketones is genetically determined, and approximately one-third of people are unable to do this, it is important that individual doctors are aware if they are not equipped with this additional diagnostic tool. Consciousness may be clouded. If the condition has progressed to the stage of coma, the associated signs of dehydration must lead to urgent checking of blood glucose and urinary or blood ketones and blood pH to expedite definitive treatment. If bedside

blood ketone testing is not available, then the semi-quantitative urine test to detect +++ ketonuria is entirely satisfactory.

The marked deficiency or absence of insulin in this condition means that insulin-mediated glucose uptake into tissues such as muscle and fat cannot occur and hepatic glucose output is unrestrained. In the meantime, the dysregulated secretion of counter-regulatory hormones (glucagon, growth hormone, and catecholamines) enhances the breakdown of triglyceride into free fatty acids and increases the rate of gluconeogenesis, which is the main cause for the high blood glucose level in diabetic ketoacidosis. β -oxidation of these free fatty acids leads to the formation of ketone bodies (β -hydroxybutyrate, acetoacetate, and acetone). Acetone is volatile and is released from the lungs, giving the characteristic sweet smell to the breath. Metabolic acidosis ensues when the ketone bodies are released into the circulation and deplete the acid buffers.

The hyperglycaemia-induced osmotic diuresis further depletes sodium, potassium, phosphates, and water. Individuals with DKA are often profoundly dehydrated and have a significantly depleted total body potassium at presentation. Sometimes, a normal or even elevated serum potassium level is seen as a result of the extracellular shift of potassium with severe acidosis. Great care must be taken to monitor serum potassium levels repeatedly once insulin treatment is started, as the concentration can drop precipitously (Chapter 41).

Hyperosmolar hyperglycaemic syndrome

HHS occurs exclusively in people with type 2 diabetes. Often there is a history of several days of ill health, in contrast to DKA, which presents within hours of onset. The principal clinical feature in HHS is profound dehydration. Confusion is usual, and focal neurological symptoms such as weakness on one side or hemi-sensory abnormalities may develop and be easily confused with stroke. HHS was previously termed hyperosmolar non-ketotic (HONK) coma. This terminology has been changed, as coma is a relatively rare feature (<10%) and mild ketosis may be present at diagnosis (sometimes leading to misdiagnosis of ketoacidosis).

HHS shares many features in common with DKA, the major exceptions being the absence of significant ketoacidosis. This is likely because of the residual low-level insulin secretion, which suppresses lipolysis sufficiently to avert ketogenesis, but not sufficiently to prevent hyperglycaemia. Additionally, hyperosmolarity itself may decrease lipolysis, limiting the amount of free fatty acids available for ketogenesis. HHS accounts for 10–30% of hyperglycaemic emergencies. As the prevalence of type 2 diabetes rises inexorably, it is becoming an increasingly common hospital admission and presenting in ever-younger adults and teenagers [25]. Up to two-thirds of those affected have not previously been diagnosed as having diabetes. Mortality rates in HHS have been reported to be 5–20%, a rate that is 10-fold higher than that reported for DKA [26,27] and increases significantly when the patient is above the age of 70 years.

Macrovascular presentations

Acute coronary syndromes

As the risk of ischaemic heart disease is linearly related to fasting and post-prandial blood glucose concentrations, it is unsurprising that both impaired glucose tolerance and diabetes are over-represented

in populations presenting with acute coronary syndromes, which include acute myocardial infarction and unstable angina [28]. Consequently, type 2 diabetes frequently presents for the first time at hospitalization with acute coronary syndromes. This presentation is complicated by stress hyperglycaemia resulting from elevations of catecholamines and cortisol. Stress hyperglycaemia is defined as 'hyperglycaemia resolving spontaneously after dissipation of an acute illness,' which can also occur in people with pre-existing diabetes [29]. Although this may cause problems for the purist wishing to evaluate an effect of diabetes *per se*, from the perspective of the patient with a life-threatening condition exacerbated by dysglycaemia, exact definitions of diabetes are irrelevant. Stress hyperglycaemia and established diabetes have similarly increased mortality from myocardial infarction. In a New York municipal hospital cohort of individuals with acute myocardial infarction, three-year mortality was 52% in those with stress hyperglycaemia (defined as admission blood glucose >7.0 mmol/l) compared with 42% in those with diabetes [30]. The three-year death rate in those with normal glucose levels was 24% in the same study. A meta-analysis has confirmed this effect, with a 3.9-fold increased risk of death associated with stress hyperglycaemia, compared with a 1.7-fold increased risk of death associated with established diabetes [31]. In this context, one of the most important findings of the Diabetes mellitus Insulin Glucose infusion in Acute Myocardial Infarction (DIGAMI) study is often overlooked. The effect of reasonable glycaemic management (blood glucose <10 mmol/l) for those with no prior insulin therapy and stratified as having low coronary risk factors produced a 52% improvement in mortality [32]. This group would have included those with stress hyperglycaemia. In contrast, the DIGAMI study showed no significant benefit of acute blood glucose control for individuals previously treated with insulin.

Estimates of the incidence of stress hyperglycaemia at presentation of acute coronary syndromes range from 10% to 16% [33,34]. This compares with estimates of the prevalence of diabetes at presentation of myocardial infarction of 10–24% [35,36]. Variation in these figures is likely to reflect the influence of racial affiliation on the prevalence of pre-diabetes and type 2 diabetes in the population, as well as increased awareness and effective screening processes to identify previously undiagnosed type 2 diabetes.

Good clinical practice demands measurement of plasma glucose on diagnosis of an acute coronary syndrome. If plasma glucose is raised (7 mmol/l may be quoted, but in the individual case interpretation depends on time since last meal), then both fasting plasma glucose and glycated haemoglobin (HbA_{1c}) should be measured. Raised plasma glucose should indicate a need for particular attention to adequate glucose management during the acute event. Given that the HbA_{1c} result is unlikely to be available immediately, hyperglycaemia indicates a need for rapid control in the acute situation when the first few hours are critical. A fasting plasma glucose of >5.6 mmol/l during the acute admission and/or an admission plasma glucose of >7.8 mmol/l yielded a sensitivity of almost 90% and a positive predictive value of 44% for detecting diabetes [37].

Where there is diagnostic uncertainty, targeted screening in the post-acute setting with a standard 75 g oral glucose tolerance test (OGTT) is acceptable. But when is the optimal time to perform this test? In a group of individuals with myocardial infarction and no previous diagnosis of diabetes, both pre-discharge and six weeks post-discharge OGTTs were performed, showing a good correlation between the two OGTTs [38]. There was 49% concordance between classifications to which an individual was assigned in both OGTTs. The best predictor of abnormal glucose handling

(impaired glucose tolerance or diabetes) being diagnosed at three months was observed to be the 60-minute blood glucose level during the pre-discharge OGTT. The National Institute of Health and Care Excellence (NICE) guideline (2020) recommends that all individuals with acute coronary syndrome and admission blood glucose $>11.0\text{ mmol/l}$ should have fasting plasma glucose no earlier than day 4 after the onset of the acute coronary event or have an HbA_{1c} test before discharge [39].

Acute stroke

The prevalence of previously diagnosed diabetes in individuals with acute stroke is 8–28%, but an additional 6–42% have unrecognised pre-existing dysglycaemia [40]. Plasma glucose at presentation is a major prognostic factor. One series of 86 individuals with acute stroke demonstrated that full functional recovery at four weeks was only seen with those with presenting blood glucose levels $<8\text{ mmol/l}$ [41]. The extent to which this reflects the metabolic stress response in proportion to the severity of the cerebrovascular insult as opposed to hyperglycaemia itself impairing subsequent recovery from ischaemic damage cannot be ascertained from these observational data.

The observations on poorer outcome in those with stress hyperglycaemia following myocardial infarction have been reproduced in respect of acute stroke disease. In a systematic review of observational studies examining the prognostic significance of hyperglycaemia in acute stroke, the unadjusted relative risk of in-hospital or 30-day mortality was 3.07 (95% confidence interval [CI] 2.50 to 3.79) in people without diabetes but with admission plasma glucose level $>6\text{--}8\text{ mmol/l}$ and 1.30 (95% CI 0.49 to 3.43) in those with known diabetes [42]. The relative risk of poor functional outcome in hyperglycaemic individuals without diabetes was 1.41 (95% CI 1.16 to 1.73). Sudden increases in plasma glucose levels appear to impair tissue function more in those individuals who have not been habituated to hyperglycaemia.

Persistent hyperglycaemia (defined as blood glucose $>7.0\text{ mmol/l}$) in the 72 hours after acute stroke is associated with an increase in infarct size, measured using magnetic resonance imaging, and worse stroke outcome [43]. Nonetheless, currently there are no satisfactory outcome studies of control of plasma glucose on the outcome of stroke [44]. The largest study to date, which included 993 individuals, failed to achieve normalized plasma glucose at 24 hours [45]. Importantly, no assessment has yet been conducted of plasma glucose management during the first few hours after presentation with acute stroke, and it is likely that it is in this window of time that this particular presentation of hyperglycaemia may most beneficially be managed.

Microvascular presentations

Eye presentations

Symptomatic loss of vision may occasionally be the presenting feature of type 2 diabetes, where hyperglycaemia has been present for an uncertain number of years, silently causing tissue damage and retinopathy. Loss of vision as a diagnostic event is most often a consequence of macula oedema, but may also be secondary to vitreous haemorrhage. Central or branch retinal vein occlusion is more common in diabetes and may also cause symptomatic presentation of the condition.

Around the time of diagnosis of type 2 diabetes, marked retinopathy with cotton-wool spots or intraretinal microvascular abnormalities

was present in 8% of men and 4% of women in the UK Prospective Diabetes Study (UKPDS) [46]. The critical importance of arranging full retinal examination, preferably by digital retinal imaging, is illustrated in Figure 24.2. Approximately 1% of individuals presenting with symptomatic type 2 diabetes have sight-threatening retinopathy at that time. Very early recognition is essential, as the initial treatment of the diabetes will decrease blood glucose levels, cause retinal blood flow to return acutely to normal levels, and may result in marked worsening of the retinopathy.

In the UKPDS, the severity of retinopathy was related to higher fasting plasma glucose levels. In addition, in men increased alcohol consumption was related to increased severity of retinopathy, while leaner women had more severe eye lesions. Visual acuity was normal in most individuals, but in men there was a trend for those with more severe retinal lesions to have worse visual acuity.

The potential severity of diabetic retinopathy at the time of diagnosis of type 2 diabetes is illustrated by the observation that 15% of those with moderate background retinopathy progress to require photocoagulation therapy within three years [47]. The specific reason for photocoagulation therapy was maculopathy alone in 72% and proliferative retinopathy in 11% in this group of individuals

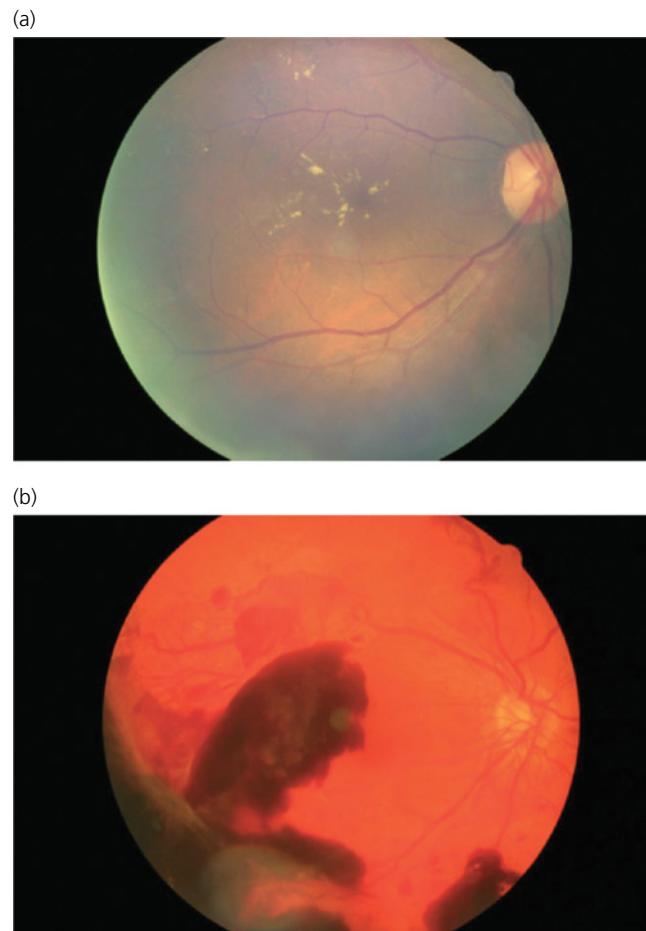

Figure 24.2 (a) Immediate laser therapy was required for the macular oedema associated with the severe exudative maculopathy present at the time of diagnosis. (b) New vessels are present, arising both from the optic disk and from the peripheral retina. Bleeding from the latter caused the prominent pre-retinal haemorrhages that obscure the fovea and in this case caused presentation because of loss of visual acuity.

with type 2 diabetes. Although it is likely that the prevalence of retinopathy of all grades of severity is lower if type 2 diabetes is diagnosed at routine screening rather than symptomatic presentation, this has yet to be quantified.

Diabetes kidney disease

Approximately 20–40% of all people with diabetes develop diabetes kidney disease [48]. In type 1 diabetes, 20–30% will have moderately increased albuminuria after a mean duration of 15 years of diabetes [49, 50], but it is unlikely to be present at diagnosis. In contrast, diabetes kidney disease may be present at diagnosis of type 2 diabetes or shortly thereafter, as diabetes may have been present for many years before the actual diagnosis.

Data from the US National Health and Nutrition Examination Survey (NHANES) 1992–2002 found that those with undiagnosed diabetes had a prevalence of nephropathy of 26.5%, determined from a spot urine albumin–creatinine ratio [51]. Similarly high prevalence of microalbuminuria was reported in the UKPDS in UK and the Hoorn Screening Study in Dutch populations [52, 53]. The prevalence of microalbuminuria has also been reported to be high in pre-diabetes [54, 55].

Although rare as a presenting feature for type 2 diabetes, the observation of unexplained albuminuria should lead to tests for hyperglycaemia.

Neuropathic syndromes

Although any of the neuropathic syndromes of diabetes may precipitate the initial presentation, symmetrical distal sensory neuropathy, mononeuropathies, and amyotrophy are the most likely candidates. The possibility of diabetes underlying most presentations of neurological symptoms must be considered.

Diffuse symmetrical sensory neuropathy is the most common neuropathy. A precise estimate of the true prevalence of this neuropathy has been difficult to ascertain, and reports vary from 7% to 60% in people with diabetes, depending on the criteria and methods used to define the neuropathy [56, 57]. The prevalence increases with both age and duration of diabetes. At 12-year follow-up in the UKPDS, 64% of men and 44% of women who were free of neuropathy at baseline developed at least one neuropathic abnormality [58].

Any nerve may be affected by an acute diabetic mononeuropathy, but palsy of cranial nerves III, IV, VI, and VII presents most often. It is a rare mode of presentation of type 2 diabetes, but not type 1 diabetes.

Diabetic amyotrophy may present as weight loss, and unless pain in the thighs is prominent, the clinical picture may resemble that of malignant disease. Weakness of quadriceps, with visible wasting and absence of the knee tendon reflex, should allow recognition and lead to the measurement of plasma glucose. Such presentation is likely to be associated with type 2 diabetes, but again is rare.

Diabetes-related foot disease

A foot lesion can be a presenting sign of diabetes, and it is estimated that the lifetime risk of developing a foot ulcer in people with diabetes may be as high as 25% [59]. Presentation with a black toe is particularly associated with type 2 diabetes. Peripheral neuropathy leads to sensory motor and autonomic dysfunction, with loss of the protective pain sensation, dry skin, and callus formation. Loss of pain sensation in the feet is usually unnoticed and subsequent trauma does not come to attention until obvious injury is apparent. In approximately half of those with foot ulcers, concomitant peripheral arterial disease is present [60]. In the European Study Group on

Diabetes and the Lower Extremity (EURODIALE) study, foot ulcers with peripheral arterial disease were associated with considerably lower healing rates, and higher major amputation and mortality rates [61].

Pregnancy

The time course of presentation of GDM may be predicted from knowledge of its pathogenesis. The key variable is the physiological insulin resistance that develops during pregnancy. Although several, necessarily small, studies have quantitated this, it is most clearly illustrated by the change in exogenous insulin requirements during pregnancy in women with type 1 diabetes. During steady glycaemic levels and food intake, insulin requirements do not change until ~18 weeks' gestation, whereafter there is a linear increase until around 28–30 weeks' gestation [62]. The extent of change varies between pregnancies from none to over a threefold increase, with an average increase in daily insulin dose of 40% [63]. The range is assumed to be a function of the placenta (fetal-derived tissue), as considerable variation is exhibited between successive pregnancies in the same woman. Predisposed women cannot mount an adequate β-cell response if the degree of insulin resistance becomes too great.

In the light of this information, it can be understood why the elevated blood glucose levels of GDM are not seen in the first half of pregnancy. Screening for GDM will be most sensitive later in pregnancy, but this sensitivity must be balanced with the opportunities to intervene. The current NICE guideline (2015, updated December 2020) on diabetes in pregnancy therefore recommends testing at 24–28 weeks' gestation of women with risk factors [64].

Even mild degrees of elevation of plasma glucose may be deleterious to the fetus, and these are far less than those that could produce osmotic symptoms. The multinational Hyperglycaemic and Pregnancy Outcome (HAPO) study of over 23 000 women found a continuous linear relationship between maternal glucose and fetal growth, with no apparent threshold effect by which to easily guide precise values at which GDM should be diagnosed [65]. Screening for GDM is therefore essential. Symptomatic presentation of GDM is unusual in the context of a healthcare system that provides universal screening for GDM, as per the International Association of Diabetes and Pregnancy Study Group (IADPSG) consensus panel [66]. However, there are practical concerns about implementing universal screening with the one-step 75 g OGTT recommended by international consensus, as well as a lack of high-quality health economic analysis of the costs of delivering the lifestyle and pharmaceutical interventions and benefits.

Where osmotic symptoms and superficial fungal infections are part of the clinical presentation, however, it is important to ask whether this is new-onset type 1 diabetes or type 2 diabetes. The former tends to be associated with higher plasma glucose levels and ketonuria. Both are associated with clearly elevated HbA_{1c} levels, as the hyperglycaemia has been present for several weeks or months. If the presentation is in the first half of pregnancy, it is likely that it will not remit after delivery. If the presentation is in the first half of pregnancy and is associated with raised HbA_{1c}, then a diagnosis of pre-existing diabetes may confidently be made and discussed with the woman [67].

Following one pregnancy complicated by GDM, although increased, the risk of recurrence in a subsequent pregnancy is far from certain, reflecting the variation in insulin resistance in successive

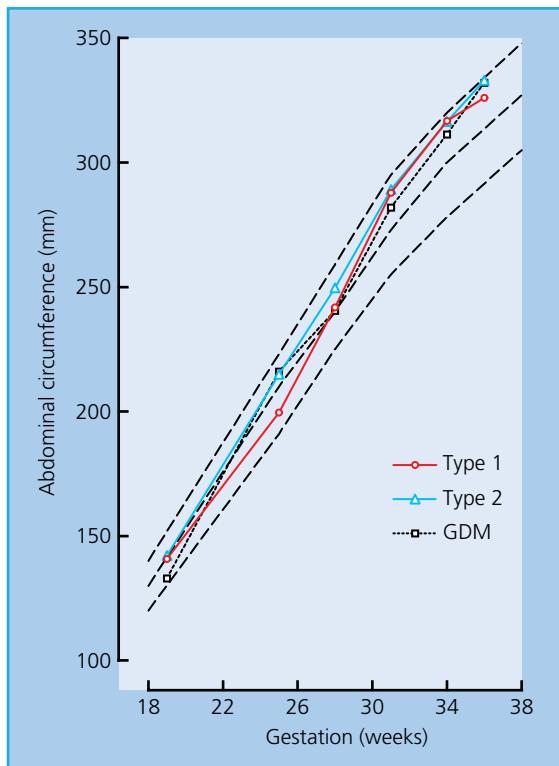

Figure 24.3 Similar rates of increase in fetal abdominal circumference in gestational diabetes (GDM) and pre-gestational diabetes as measured by ultrasound. Source: Reproduced from Lim et al. 2009 [67], with permission from RSM Journals.

pregnancies as the latter is determined by the placenta – tissue that is individual to the fetus. Higher rates have been reported in South Asian and Hispanic populations, as would be expected from the higher background prevalence of type 2 diabetes (52–69%) [68]. The importance of detection and treatment of GDM is reflected by the data shown in Figure 24.3. The rate of intrauterine growth is as rapid in GDM, as it is in type 1 diabetes and type 2 diabetes [67]. Early diagnosis of GDM carries major advantages for mother and child. The risk of developing subsequent diabetes in those with GDM ranges from 2.6% to 70% over periods from 6 weeks to 28 years [69]. The NICE guidelines for diabetes in pregnancy recommend that blood glucose should be tested prior to discharge to rule out persisting hyperglycaemia, then fasting plasma glucose should be performed at 6–13 weeks (or HbA_{1c} after 13 weeks if a fasting plasma glucose is not possible) and an annual HbA_{1c} test for those women with GDM who have a negative postnatal test for diabetes [64]. This will miss a proportion of women with normal fasting plasma glucose and impaired glucose tolerance, but it should be noted that the occurrence of GDM should itself be the trigger to advise vigorous lifestyle change and weight loss in particular.

Screening

It has been estimated from the 2002 US NHANES that one-third of the 13.3 million US adults with diabetes remained undiagnosed [70]. A similar estimate has been made for the UK [71]. Figures based on the Diabetes Prevalence Model by Public Health England estimated that in 2015 there were 3.8 million people aged

16 years and over diagnosed with diabetes in the UK, but that 940 000 had undiagnosed diabetes. Universal screening has not been implemented in the UK, as criteria for cost-effective and clinically effective screening are not met. NICE (2012, updated September 2017) recommends a two-stage strategy to identify people at high risk of type 2 diabetes (and those with undiagnosed type 2 diabetes) whereby a risk assessment is carried out first, and then where necessary a blood test offered to confirm whether type 2 diabetes or pre-diabetes is present [72]. People at risk can be identified using a validated computer-based risk-assessment tool from primary care electronic health records or from validated self-assessment questionnaires for individuals over the age of 40 years, people of South Asian and Chinese descent aged 25–39 years, and any adults with conditions that increase the risk of type 2 diabetes, other than pregnant women. Individuals with high-risk scores should then have fasting plasma glucose or HbA_{1c} tested, which will determine risk of progression to type 2 diabetes or identify possible type 2 diabetes. Fasting plasma glucose ≥ 7.0 mmol/l or HbA_{1c} ≥ 48 mmol/mol (6.5%) indicates the need for a second test to diagnose type 2 diabetes. Those with fasting plasma glucose of 5.5–6.9 mmol/l or HbA_{1c} 42–47 mmol/l (6.0–6.4%) are deemed as having high risk, and the recommendation is for them to be managed as for pre-diabetes with an intensive lifestyle-change programme.

Fasting glucose, two-hour post-challenge glucose, and HbA_{1c} all equally predict the future microvascular complications of diabetes and can be considered diagnostic as well as screening tests [73]. The use of the concept of *impaired fasting glucose* with a cut-off of 5.5 mmol/l offers a simple way of excluding or demonstrating dysglycaemia [74]. Urinalysis for glycosuria has a high specificity (96–100%) but a low sensitivity (16–43%). Testing random blood glucose is specific but insensitive [75].

The population of individuals with early type 2 diabetes who are identified by any screening procedure differs considerably from those who present symptomatically. They are less likely to have established microvascular or macrovascular complications of diabetes. Attitudes to health may differ. The diagnosis will be less welcome, as it does not point the way to relief of symptoms and may not be accepted as important for future health. Following therapeutic advice concerning weight, diet, and physical activity may not be as assiduous as after a symptomatic presentation. For these reasons, a more careful approach to discussing the need for future action is required, with appropriately sensitive follow-up by the diabetes team.

Covid-19 and diabetes

Recently, a novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) that causes coronavirus disease 2019 (Covid-19), has spread rapidly throughout the world in an unprecedented outbreak (Chapter 61). It was first reported in Wuhan, China, in December 2019 and as of 12 July 2023 there had been 767 972 961 globally confirmed cases of Covid-19 reported on the World Health Organization Covid-19 dashboard (<https://covid19.who.int>), including 6 950 655 deaths. The overall mortality of COVID-19 is variable, ranging from 0.7% to 10.8% [76].

Factors such as increasing age, ethnicity, deprivation, and comorbidities are associated with increased Covid-related morbidity and mortality [77]. Diabetes itself has been identified as one of the most common comorbidities associated with Covid-19,

both predisposing to severe illness and onset being precipitated by the illness itself. This is not unexpected, since increases in hospitalization and intensive care unit admission in people with diabetes during the 2010 influenza A (H1N1) pandemic were observed, confirming the susceptibility of people with diabetes due to impaired immune response [78]. People with diabetes have worse clinical outcomes from Covid-19, in particular higher hospitalization rates and a twofold risk of death [79].

Covid-19 contributes to worsening of dysglycaemia in those with diabetes over and above that contributed by stress hyperglycaemia. Several case reports raise the question as to whether SARS-CoV-2 can trigger new-onset diabetes. One series found 29 hospitalized individuals who were not known to have diabetes who developed hyperglycaemia during Covid-19, some of whom had a normal HbA_{1c} on admission [80]. A recent meta-analysis showed a pooled proportion of 14.4% for newly diagnosed diabetes in hospitalized individuals with Covid-19 [81]. Another cohort study, however, found only 4.9% newly diagnosed cases in their hospitalized cohort [82].

Similarly, during the Covid-19 pandemic there has been an apparent increase in new-onset type 1 diabetes in children with evidence of SARS-CoV-2 infection or exposure [83]. This prompted a national survey by the UK Association of Children's Diabetes Clinicians, which found that the proportion of new-onset type 1 diabetes presenting with DKA during the pandemic was higher in 2020 than in previous years, with 20% of units reporting delayed presentations and a significant proportion presenting with severe DKA [84]. Reasons for the delay ranged from fear of acquiring SARS-CoV-2 infection to difficulty in contacting or accessing a medical provider for timely evaluation. This is in contrast to others who found no deviation from the projected numbers of children with newly diagnosed type 1 diabetes [85], but did find an increase in DKA and the severity of DKA episodes in children and adolescents [86].

The interplay between diabetes and Covid-19 is far from clear. Diabetes may contribute to increased disease severity via compromised innate immunity, exaggerated pro-inflammatory cytokine response, and low expression of angiotensin-converting enzyme (ACE-2), and the association with obesity will be additive. Covid-19 itself leads to worsening glycaemia in people with diabetes by a stress hyperglycaemia response, with augmentation of insulin resistance through cytokines as well as

the effects of drugs used in the management of Covid-19 such as corticosteroids, and possible direct virus-mediated β-cell damage [87]. Mechanistic studies suggest that SARS-CoV-2 binds to the ACE-2 receptor proteins expressed in key metabolic organ and tissues including pancreatic β cells, adipose tissue, the small intestine, and the kidneys. This allows the virus to enter human cells and cause pleiotropic alterations of glucose metabolism.

There are still many uncertainties as to the magnitude of new-onset diabetes in Covid-19, whether the glucose perturbations will persist or resolve after the infection, and whether or not Covid-19 increases risk of future diabetes. The severe metabolic stress of the illness would be expected to cause insulin resistance and raise blood glucose levels markedly in those with pre-existing marginal β-cell function. The CovidDiab Registry has been recently launched to track and measure new cases of diabetes among people who have Covid-19 [88], with the hope of shedding more light on these uncertainties and on whether a bi-directional relationship between Covid-19 and diabetes truly exists.

Other presentations

Ants clustering around urine is a classic description of diabetes, although it is not clear how often this constitutes the presenting complaint today. Periodontal disease, especially aggressive periodontitis, is more common in those with diabetes and may occasionally be the presenting complaint (Chapter 56) [89]. Cataracts typically develop 10 years earlier in people with diabetes [90]. Altered taste or excess production of saliva has been reported as a presenting feature of diabetes [91].

Conclusion

The mode of presentation is enormously varied. Especially as the incidence of diabetes is rising in all age groups, both in the UK and worldwide [92], the onus is on healthcare professionals to diagnose the condition effectively. Failure to recognize presenting features of diabetes can be costly for the individual with diabetes and society.

5 Managing the Person with Diabetes

25

The Aims of Diabetes Care

Katharine D. Barnard-Kelly¹ and Richard I.G. Holt^{2,3}

Key points

- People with diabetes are individuals who have a condition that has medical, psychological, personal, and social risk factors and consequences. They are not passive recipients of healthcare and are not defined by their disease state.
- Optimal diabetes management occurs when the multidisciplinary diabetes care team and the person with diabetes actively work together as equal partners to achieve diabetes-related goals.
- Life-threatening diabetes emergencies, such as diabetic ketoacidosis, must be effectively managed, and attention paid to their prevention.
- Acute symptoms of hyperglycaemia need to be addressed by careful pharmacological management and lifestyle modification support.
- Diabetes management is a balance between supporting short-term optimal glycaemic management and quality of life while at the same time

reducing the risk of long-term complications. This is achieved through effective medical treatment of glycaemia, cardiovascular risk factor management, and appropriate psychosocial support and education.

- The time of diagnosis can be traumatic and is a key milestone in the management of diabetes when effective education, support, and treatment are needed. It is important to ensure parity of esteem, by valuing mental health equally with physical health.
- Regular lifelong contact between the person with diabetes and their healthcare team is essential in order to provide person-centred care to support healthy adjustment to, and coping with, the demands of this complex condition that changes throughout a person's life.
- Diabetes-related complications should be managed effectively if and when they present to reduce their morbidity.

Diabetes is a lifelong condition that for the majority is currently incurable. It is associated with premature mortality and morbidity, from an increased prevalence of macrovascular disease and microvascular complications affecting the kidney, nerve, and eye [1,2]. High-quality randomized trials have shown that improving glycaemic levels is associated with a reduction in microvascular complications [3–5], while a multifaceted approach to cardiovascular risk factors will reduce cardiovascular morbidity and mortality [6]. Addressing the psychosocial challenges faced by people with diabetes reduces psychological distress and improves self-management behaviours [7,8]. A holistic approach to supporting the person with diabetes in making choices based on the best evidence available and providing them with autonomy in consultations leads to greater self-care and improved metabolic management [9].

The person living with diabetes will spend the vast majority of their time managing their own diabetes and only an estimated 1% of their time in contact with healthcare professionals. Therefore, it is crucial to provide individuals with appropriate medical and psychosocial support to help them optimally self-manage their diabetes. It is important that the purposes of the consultation or other contacts with the diabetes healthcare team are well defined, with clear aims to make them relevant and useful. To ensure that the individual derives the maximum benefit from the time spent with their diabetes healthcare team, whether this is in a hospital,

primary care, or community setting, the consultation should be collaborative, patient centred, and goal focused. In addition, telemedicine provision of diabetes care, via phone, video-conference, or email contact or through educational sessions outside a traditional clinic setting has proven effective [10].

This chapter provides an overview of the aims and philosophy of diabetes care. Separate aspects of care will be covered in greater detail in subsequent chapters. The aims of diabetes care and management to improve the quality of life of the person with diabetes are fourfold. Life-threatening diabetes emergencies, such as diabetic ketoacidosis or severe hypoglycaemia, should be managed effectively, including preventive measures. The acute manifestations of hyperglycaemia, such as polyuria and polydipsia, need to be addressed. In practice, these occupy only a minority of the work undertaken by diabetes healthcare professionals. Much of the focus of care is therefore directed towards minimizing the long-term complications through screening and working together with the person with diabetes to support improved glycaemic and cardiovascular risk factor management. This provides a challenge for the diabetes team, because people with type 2 diabetes often have no symptoms at the time of care, yet are asked to make lifestyle changes and take medications that may place a considerable burden on them. The fourth aim of care is to avoid iatrogenic side effects, such as hypoglycaemia, and relies on collaborative care planning with the person with diabetes.

St Vincent declaration

During the 1980s, there was a transformation in the widely held perceptions of the roles of people with diabetes and philosophy of care. Instead of their being viewed as passive recipients of healthcare, there was an increasing recognition that people with diabetes are individuals with a condition that has medical, personal, and social consequences. During this time there was an increasing awareness and acceptance of the concept that each person with diabetes should take on part of the responsibility for their diabetes management and act as equal partners with healthcare professionals. In response to this paradigm shift, representatives of government health departments and organizations for people with diabetes from all European countries met with diabetes experts under the auspices of the Regional Offices of the World Health Organization (WHO) and the International Diabetes Federation (IDF) in the hillside town of St Vincent, Italy, on 10–12 October 1989. They unanimously agreed a series of recommendations for diabetes care and urged that action should be taken in all countries throughout Europe to implement them (Box 25.1) [9]. Since that time this philosophy of partnership working between people with diabetes and healthcare professionals has been adopted within individual nations' strategies to improve the quality of diabetes care.

Diabetes care team

The diabetes care team involves a multidisciplinary group of healthcare professionals who are available to support the person with diabetes (Figure 25.1). A key component of diabetes care is to ensure that the individual with diabetes is at the centre of the provision of care. This means that they should be an equal member of the diabetes care team, working together with the healthcare professionals. This relationship should be based on the exchange of information, advice, and education to enable the healthcare team to provide best practice-tailored support for the individual with diabetes so that they feel sufficiently empowered to manage their condition themselves. This approach ensures that the care offered is personalized appropriately for the individual and their circumstances.

The large number of diverse health professionals involved in the diabetes care team means that the roles and responsibilities of all must be clearly presented and agreed. It is often helpful for the person with diabetes if the key members of their diabetes care team are identified, as they will have more contact with some healthcare staff than others.

Most routine type 2 diabetes care takes place in a primary care setting, but some people who have complications or complex medical or psychological needs will require management and support in a specialist setting for some or all of their care [12]. The diabetes physician usually takes overall responsibility for the diabetes medical care, but other specialists may be involved, for example an ophthalmologist may be needed to examine the eyes carefully and treat diabetic retinopathy, if present. Diabetes care is multidisciplinary, involving doctors, nurses, and many allied healthcare professionals whose responsibility is to support the person living with diabetes in the management of their condition. A close collaboration between primary and secondary healthcare professionals and among specialists is needed to ensure that all involved are aware of the issues that are relevant to the individual with diabetes, and that care is integrated and coordinated across the wide range of disciplines

Box 25.1 St Vincent declaration [11]

- Elaborate, initiate, and evaluate comprehensive programmes for detection and control of diabetes and of its complications, with self-care and community support as major components.
- Raise awareness in the population and among healthcare professionals of the present opportunities and the future needs for prevention of the complications of diabetes and of diabetes itself.
- Organize training and teaching in diabetes management and care for people of all ages with diabetes, for their families, friends, and working associates, and for the healthcare team.
- Ensure that care for children with diabetes is provided by individuals and teams specialized both in the management of diabetes and of children, and that families with a child with diabetes get the necessary social, economic, and emotional support.
- Reinforce existing centres of excellence in diabetes care, education, and research.
- Create new centres where the need and potential exist.
- Promote independence, equity, and self-sufficiency for all people with diabetes, children, adolescents, those in the working years of life, and the elderly.
- Remove hindrances to the fullest possible integration of people with diabetes into society.
- Implement effective measures for the prevention of costly complications:
 - Reduce new blindness due to diabetes by one-third or more.
 - Reduce numbers of people entering end-stage renal failure by at least one-third.
 - Reduce by one-half the rate of limb amputations.
 - Cut morbidity and mortality from coronary heart disease by vigorous programmes of risk factor reduction.
 - Achieve pregnancy outcomes in women with diabetes that approximate those of women without diabetes.
- Establish monitoring and control systems using state-of-the-art information technology for quality assurance of diabetes healthcare provision and for laboratory and technical procedures in diabetes diagnosis, treatment, and self-management.
- Promote European and international collaboration in programmes of diabetes research and development through national, regional, and WHO agencies and in active partnership with persons with diabetes and with diabetes organizations.
- Take urgent action in the spirit of the WHO programme 'Health for All', to establish joint machinery between WHO and IDF European Region, to initiate, accelerate, and facilitate the implementation of these recommendations.

involved. Ensuring the person with diabetes remains at the centre of care is likely to facilitate the collaboration.

Given the chronic nature of diabetes, continuity of care is essential. Ideally this should be provided by the same doctors and nurses from visit to visit, but where this is not possible, the healthcare team should have access to previous records so that they are fully aware

Figure 25.1 The multidisciplinary group of healthcare professionals who are available to support the person with diabetes.

of the medical history, background, and lived experience of the person with diabetes. In some developing countries this is particularly challenging, where medical records are often focused around single episodes of acute care of infectious diseases [13].

With the involvement of the person with diabetes in the diabetes team, the individual assumes several responsibilities. The task of implementing the day-to-day management plan of the diabetes lies with the individual; it may sometimes be difficult for healthcare professionals to accept this, particularly if their frame of reference is within an acute medical model of healthcare delivery. It is important to understand that diabetes self-management is challenging and so the diabetes care team should be available to support the person through their experiences with their condition. Diabetes distress, burnout, and impaired psychosocial functioning are all commonly reported by people with diabetes [14]. There have been increasing efforts to standardize psychosocial outcomes alongside biomedical outcomes. The recent US Food and Drug Administration Medical Device Development Tools (MDDT) qualification of the INSPIRE measures demonstrates the rigour now expected of psychosocial assessment in diabetes [15]. In addition, the International Consensus of Health Outcome Measures (ICHOM) produced a standard set of measure outcomes, biomedical and psychosocial, to promote robust assessment thereof across nations globally [16].

Adolescence can be a particularly challenging time, as this period of the person's life coincides with a time of rapid change, transition to adulthood, and increasing independence. Risk taking, experimentation, and increasing responsibility along the path to diabetes self-management by the adolescent are to be expected (Chapter 70).

Improving the outcome of the consultation

The time that a person with diabetes spends with a healthcare professional is limited and should be used as effectively as possible. Clinicians often give conflicting advice, both within the team and from one consultation to the next [9]. Goals are often not followed up, leaving the person with diabetes feeling frustrated. Studies have shown that typically physicians interrupt their patients 18 seconds after the patient starts to describe their problems, approximately half of patients' concerns are not discussed, and in half of consultations the patient and physician disagree on the central problem presented [9]. Such disagreement and inconsistency are associated

with poorer outcomes. Better self-care and metabolic management are achieved through supporting the person with diabetes to make choices based on the best evidence available and providing autonomy in consultations. In the UK, the Department of Health has produced literature entitled 'Questions to ask' (Table 25.1), which provides guidance about the questions a person with diabetes might want to ask during a consultation to maximize the benefits from the visit to their healthcare team [17].

The consultation or educational programme should help the person with diabetes gain a clearer understanding of their condition and the behaviours required for optimal outcomes. This can only be achieved effectively when professionals and people with diabetes are enabled to work together. Taking a holistic approach, such as embodied in the Kaleidoscope model of care [9] (Figure 25.2), can facilitate this collaborative, patient-centred, joint goal-setting process.

The Kaleidoscope model of care presents a novel, holistic, tailored, and individualized approach to healthcare delivery for people with diabetes through an assessment of an individual's current

Table 25.1 Checklist of questions to ask your doctor at your appointment.

Tests, such as blood tests or scans

- What are the tests for?
- How and when will I get the results?
- Who do I contact if I do not get the results?

Before your appointment

- Write down your two or three most important questions.
- List or bring all your medicines and pills – including vitamins and supplements.
- Write down details of your symptoms, including when they started and what makes them better or worse.
- Ask your hospital or surgery for an interpreter or communication support if needed.
- Ask a friend or family member to come with you, if you like.

During your appointment

- Do not be afraid to ask if you do not understand. For example 'Can you say that again? I still do not understand'.
- If you do not understand any words, ask for them to be written down and explained.
- Write things down or ask a family member or friend to take notes.

Before you leave your appointment

Check that:

- You've covered everything on your list.
- You understand, for example 'Can I just check I understood what you said?'
- You know what should happen next – and when. Write it down.

Ask:

- Who to contact if you have any more problems or questions.
- About support groups and where to go for reliable information.
- For copies of letters written about you – you are entitled to see these.

After your appointment, do not forget to

- Write down what you discussed and what happens next. Keep your notes.
- Book any tests that you can and put the dates in your diary.

Ask:

- 'What's happening if I'm not sent my appointment details?'
- 'Can I have the results of any tests?' (If you do not get the results when you expect – ask for them.) Ask what the results mean.

regimen, barriers and motivation, and available support resources. It is flexible and applicable in different health settings, fundamentally promoting the specific needs of the individual with diabetes. These needs are dynamic, taking a different shape at different points in time, while recognizing and adapting to the range of care needed [9].

It is good practice to provide the person with diabetes with copies of any letters written about them [18, 19]. Questions about treatment recommendations should be encouraged and people should be aware of what will happen next, including any requirement for further investigation. Regular review of management plans through joint dialogue, listening, discussion, and decision making between the individual and the healthcare professional, sometimes known as care planning, is the key to enhancing relationships and partnership working [20]. Contact details should be made available to enable the individual with diabetes to seek help if further questions arise.

In 2018 the UK National Health Service (NHS) published its 'Language matters: Language and diabetes' [21] document. This recognizes that the language used by healthcare professionals can have a 'profound impact on how people living with diabetes, and those who care for them, experience their condition and feel about living with it day-to-day'. The document sets out some basic principles for good practice for interactions between healthcare professionals and people living with diabetes. Furthermore, it lays out some common examples of language use and presents suggestions for alternative responses or ways to deal with them. Finally, the document encourages healthcare professionals to engage positively and avoid the use of negative language.

time when they may be least able to do so, perhaps because of shock, denial of, or anger at the diagnosis [22]. Empathy and considerable skill are therefore needed to support the person with diabetes at this time. The diabetes team should perform a medical examination (usually the physician) and work with the individual to develop a programme of care that is individualized and includes treatment-oriented goals. Psychological support should be offered, and ongoing psychosocial assessment of coping, adjustment, and diabetes-related distress should be conducted.

Issues relating to diagnosis

The diagnosis of diabetes is based on the finding of one or more glucose values above internationally agreed values [23, 24] (Chapter 2). Usually a diagnosis has been made prior to referral to the diabetes clinic, but this is not always the case. In the absence of symptoms, individuals require two glucose or glycated haemoglobin ($\text{HbA}_{1\text{c}}$) values above the diagnostic criteria to fulfil the diagnosis of diabetes.

Advice may be required to determine the type of diabetes, as the distinction is not always as clear as may be expected. When a young preschool child develops weight loss, polyuria, polydipsia, and ketoacidosis over a short period of time, the diagnosis is type 1 diabetes, while by contrast if an asymptomatic older overweight individual is found to be hyperglycaemic, the diagnosis is most likely to be type 2 diabetes (Chapter 24). These presentations lie at two ends of a spectrum, and the diagnosis of the type of diabetes may be less clear when the onset occurs in an overweight adult in their 30s who is found to have islet cell antibodies. Diabetes healthcare professionals should also be alert to the possibility of monogenic causes of diabetes (Chapter 20).

Although a precise diagnosis may not be needed from the outset, an early decision should be made about the necessity for insulin therapy (Chapter 24). While there may be clinical features that suggest the type of diabetes, time is often a useful diagnostic tool to determine whether the person with diabetes requires insulin.

Following diagnosis

The period following the diagnosis of diabetes is crucial for the long-term management of diabetes. A huge amount of information and skills need to be assimilated by the person with diabetes at a

Diabetes education

A key component to empower the person with diabetes is the provision of diabetes education [25] (Chapter 26). This information should be offered in a patient-centred manner, as it is retained more effectively when delivered in this way. Education may be provided individually or in a group setting.

It is essential that the person with diabetes understands their diabetes and develops the skills and competencies required to self-manage the condition as well as possible. People with newly diagnosed diabetes should have the chance to speak with a diabetes healthcare professional who can fully explain what diabetes is [26]. This will offer an opportunity to discuss the treatment and goals, as well as providing a practical demonstration of any equipment required to support self-management, for example blood glucose meters or insulin devices. The importance of ketones testing for those with type 1 diabetes should be explained. Where self-monitoring has been advocated, it is essential that the individual knows how to interpret the results and how to act appropriately in response to that information.

A qualified dietitian should provide advice about how to manage the relationships between food, activity, and treatment (Chapter 27). Where necessary, they should explain the links between diabetes and diet and the benefits of a healthy diet, exercise, and optimal diabetes management. As an essential member of an effective clinical care team, a diabetes specialist nurse or practice nurse also has a role in providing dietary advice together with relevant literature [26].

The social effects of diabetes should be discussed, as they may relate to employment, insurance, or driving (Chapter 66). Some countries require individuals with diabetes to inform the appropriate licensing authorities. Advice about diabetes and foot care should also be given (Chapter 53).

Although education is essential following diagnosis, it is important to appreciate that this is a lifelong process that should consider recent advances in medical science and changes in circumstances of the person with diabetes [25]. Education should be available via different modalities that best meet the needs of each individual.

The best measure of effective education is not simply that someone knows more, but rather that they are able to apply the new knowledge to enhance their diabetes self-management. The simple provision of knowledge by itself is often insufficient to influence behavioural change. High demands are placed on the person with diabetes regardless of the type of diabetes, especially when the benefits are not immediate, may only accrue with time, and even then may not be appreciated. The individual with diabetes needs to gain an understanding that improved glycaemic levels can help prevent the long-term complications of diabetes, such as a myocardial infarction or proliferative retinopathy, even though they may have never experienced these conditions.

The diagnosis of diabetes may provoke a grief reaction and the diabetes team needs to support the person with diabetes as they work through this (Box 25.2). Efforts should be made to help the individual adapt to their new reality of living with diabetes and engage in optimal self-management. If this does not happen, they can be left feeling overwhelmed by diabetes or expect that their healthcare team can take control for them. For some it may take a very long time to accept their diabetes and the demands placed on their life. Therefore, emotional and psychological support and techniques need to be available in the long term and should be discussed at every clinic appointment.

People with newly diagnosed diabetes often want to speak with others who have diabetes or who have had similar experiences

Box 25.2 Case study

Dave is 25 years old and recently diagnosed with type 1 diabetes. The diagnosis was made following an acute admission to hospital with diabetic ketoacidosis and insulin therapy was initiated.

Initially appearing to accept the diagnosis, Dave quickly became very angry about his perceived loss of control over his life and the reduction in his quality of life because of the new demands placed by diabetes and its treatment. Feeling guilty about whether he could have prevented it, and despairing about the lifelong condition, Dave found it increasingly difficult to keep up with the daily tasks of self-management, which in turn contributed to his feelings of despair and loss of control.

The healthcare team helped Dave identify some short-term goals for diabetes self-management and signposted social media support online, including on Twitter, as well as a local support group. Dave and his healthcare team worked together on problem-solving techniques to help make some of the diabetes tasks more achievable in his daily routine.

while developing diabetes. Many countries have diabetes-related charities that can provide this support, and it is important that information about what help is available, including local centres or peer support groups, is provided in a timely fashion.

Ongoing clinic visits

The diabetes team needs to work together with the person with diabetes to review the programme of care, including the management goals and targets at each visit [27]. It is important that the individual shares equally in all treatment decisions, as this improves the chances of jointly agreed goals being adopted following the consultation. ‘No decision about me without me’ is central to the NHS philosophy [28]. A family member, friend, or carer should be encouraged to attend the clinic appointment to support the person with diabetes, and to stay abreast of developments in diabetes care [29].

An important goal of management is to prevent the microvascular and macrovascular complications of diabetes without inducing iatrogenic side effects. This involves active management of hyperglycaemia together with a multifaceted approach targeting other cardiovascular risk factors. Ensuring parity of esteem by valuing mental health equally with physical health is crucial at all times. Funding, commissioning, and training should be on a par for both physical and mental health services [30].

Glycaemic management

It is important to enquire about and discuss hyperglycaemic symptoms and problems with medications, including issues relating to injections, hypoglycaemia, and self-monitoring of blood glucose.

Hyperglycaemic symptoms

Symptoms relating to hyperglycaemia usually occur when the blood glucose rises above the renal threshold, leading to an osmotic diuresis. Polyuria, particularly at night, polydipsia, and tiredness may ensue. General malaise may also occur and is not always ascribed to the hyperglycaemia.

Medications

The diabetes care team is responsible for ensuring that the person with diabetes has access to the medication and equipment necessary for diabetes management. In many, but not all, countries this is available for free or at a reduced rate; many people with diabetes may be unaware of this and timely advice may alleviate some of the anxieties about the cost of diabetes.

Oral glucose-lowering drugs

Each of the oral glucose-lowering drugs has its strengths and profile of side effects (Chapter 35) and these should be discussed. Strategies may be devised to maximize the tolerability of diabetes medications. For example, the timing of metformin in relationship to meals, or the use of long-acting preparations, may reduce the risk of gastrointestinal upset. Where treatments are not being tolerated, these should be changed in order to facilitate improved medication taking. Another example is the need to discuss the risks of hypoglycaemia with sulfonylureas.

Insulin

Insulin therapy is complex: it must be given by self-injection or pump and there is considerable variation in the doses, regimens, and devices available to people with diabetes. In addition, the use of continuous glucose monitoring and closed-loop systems by people with type 1 diabetes require discussion on suitability, use, and effectiveness. It is important that during the clinic visit, the individual has an opportunity to discuss injection technique and any difficulties with injection sites, which should be examined at least annually. Information about the appropriate storage of insulin and safe disposal of sharps (needles) is needed.

The commonest side effects of insulin are hypoglycaemia and weight gain (Chapter 31). In addition to these, there are a number of other issues that should be addressed including injection site problems, such as lipohypertrophy, and device and needle problems.

Assessment of glucose levels

Supporting the person with diabetes to achieve optimal glycaemic levels is a vital component of diabetes care. The methods of assessing glucose levels essentially involve short-term measures, such as self-monitoring of blood glucose, and long-term measures, such as HbA_{1c} (Chapter 29). Not all people with diabetes will need to undertake self-monitoring of blood glucose, but where they do it is incumbent on the healthcare professional to discuss with them the findings and how these will affect future management. The HbA_{1c} provides a measure of the longer-term adequacy of glycaemic management and sometimes there may be a discrepancy between this measure and self-monitored blood glucose. It is important to explore the reasons that underlie the differences, which may range from biological issues, such as genetically determined rates of glycation, through inappropriately timed glucose readings to fabricated results. A pristine sheet (with no blood stains from finger-sticks) and the use of a single pen colour may be a clue to the latter. It is important to explore in a non-judgmental way why the individual might engage in such a practice. This could reflect a poor relationship with the healthcare team or potential psychosocial challenges with disease and self-management. The use of computers and the ability to download results may help to observe patterns of hypo- and hyperglycaemia, although it is important to make sure that the meter has not been shared. Increasingly it is possible to use the internet to review glucose remotely.

People with diabetes must be supported in an open and non-judgmental way. Sometimes clinicians can appear to show the opposite, which is unhelpful and counter-productive to joint goal setting and collaborative consultation. Feeling reprimanded or misunderstood can be frustrating and upsetting, and it is understandable why someone would not choose to put themselves through the experience if they did not have to. It is better to build a relationship whereby the person with diabetes feels that the healthcare professional is there to support them and work together to find solutions and overcome barriers to optimal self-management. It must be remembered that the chronic nature of diabetes means there is never, nor will there ever be, a day off self-management. This can be exhausting and feel relentless to those living with the condition. Empathy and understanding go a long way in building positive, enduring therapeutic relationships.

The Diabetes Control and Complications Trial and the UK Prospective Diabetes Study (UKPDS) have clearly established that lower levels of glycaemia are associated with reduced risk of long-term microvascular complications in type 1 diabetes and type 2 diabetes, respectively [3–5]. For this reason, learned societies such as the American Diabetes Association (ADA) and European Association for the Study of Diabetes (EASD) and government bodies such as the National Institute for Health and Care Excellence (NICE) have set tight glycaemic targets to minimize the risk of complications for individuals with diabetes [31–33]. Furthermore, in the UK general practitioners are incentivized financially to achieve tight glycaemic levels for their patients. However, there has been an increasing awareness of the need to individualize targets for the person with diabetes, depending on factors such as life expectancy, duration of diabetes, comorbidity including cardiovascular disease, resources, and availability of support (Figure 25.3).

The natural history of the development of complications is long and, in some situations, may be longer than the life expectancy of the person with diabetes. It would be a poor trade to insist on switching a frail, complication-free 90-year-old person to insulin if they subsequently fell and broke their hip or died as a result of insulin-induced hypoglycaemia. Less melodramatic but still important is the consideration about dietary and lifestyle change in people with low risk of disabling complications: is it really necessary to deny an older person with diabetes a piece of birthday cake if this is one of the few food pleasures in their life? A more sensible approach would be to advise a limit to portion size, rather than insist on severe dietary restriction.

Although there is an appropriate clinical emphasis on glycaemic targets, the results of the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial [35], the Action in Diabetes and Vascular disease: preterAz and diamicron MR Controlled Evaluation (ADVANCE) trial [36], and the Veterans Affairs Diabetes Trial (VA-DT) have led to a note of caution [37]. These trials have shown that tight glycaemic management in people with a longer duration of diabetes did not prolong life. In the case of the ACCORD trial, increased cardiovascular mortality was seen in those receiving intensive glycaemic management [35]. Again, these findings highlight the need for individualized targets.

Despite clinical guidance and the availability of effective treatments, many people with diabetes are unable to achieve the desired glycaemic levels. It is important for the healthcare professional to explore the reasons why this might be the case together with the individual. Advice about adjustment of treatment or further education or psychological support may be needed.

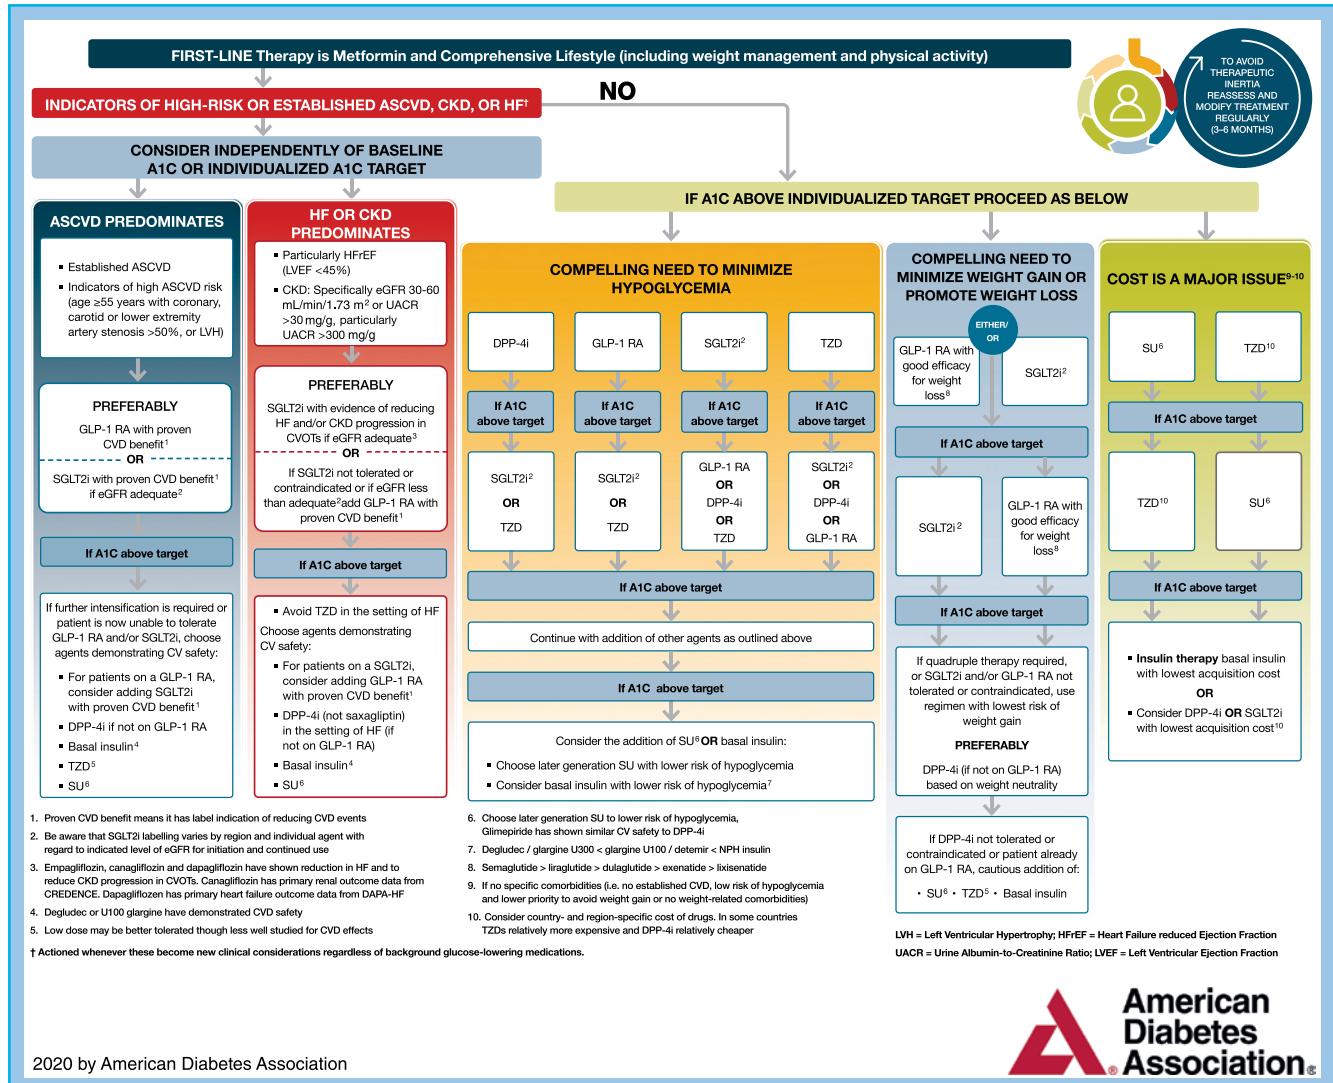

Figure 25.3 European Association for the Study of Diabetes (EASD)/American Diabetes Association (ADA) approach to management of hyperglycaemia. Source: Buse et al. (2020) [34].

A common limiting factor in the ability to achieve optimal glycaemic levels is hypoglycaemia, which is one of the most unpleasant, socially aversive, inconvenient, and feared side effects of diabetes medication (Chapter 40). The frequency and severity of hypoglycaemic episodes should be discussed. An exploration of the underlying causes and advice about prevention are required for the future.

When a person with diabetes is treated with insulin, it is important to ensure that they carry a readily accessible source of fast-acting glucose, such as glucose tablets. Concentrated glucose solution and glucagon should also be made available for use in more severe hypoglycaemia. As these treatments may only be used infrequently, it is worth regularly checking whether they are in date. Furthermore, as they need to be administered by a third party, it is important to ensure that the friends and relatives of the person with diabetes know how to administer them and are confident in doing so before they are needed.

In some instances, the only way of avoiding disabling hypoglycaemia is to accept a higher HbA_{1c}. This recalibration of glycaemic goals should be decided with the individual and a target appropriate for the circumstances should be agreed. As well as the risk of

hypoglycaemia, other factors should be considered when discussing the target, including the overall clinical situation and risk of complications affecting the individual.

Assessment of cardiovascular risk

For many years, the commonest cause of death in people with diabetes was cardiovascular disease and much effort has been expended to develop strategies that will reduce its morbidity and mortality [38].

Cardiovascular risk should be assessed at least once a year for people with diabetes. This should include a history of cardiovascular risk factors, such as family history and smoking, an examination to include weight, waist circumference, and blood pressure, as well as investigations such as a lipid profile. The results of this assessment can be used to calculate cardiovascular risk using the various risk engines available. Some, such as the UKPDS risk engines for coronary heart disease and stroke, were designed specifically for use in people with diabetes and are readily available on the internet [39,40].

Diabetes is a major risk factor for cardiovascular disease [41]. This has influenced prescribing guidelines, which now recommend that specific pharmacological interventions are required to reduce

the incidence of cardiovascular disease in people with diabetes regardless of risk assessment. Large randomized controlled trials have shown the effectiveness of these interventions and are discussed in greater detail in Part 8 [42].

Although physicians may appreciate the close connection between diabetes and cardiovascular disease, many people with diabetes have never been told about this increased risk and the importance of blood pressure and lipid control. Thus, many individuals are not taking appropriate drugs for cardiovascular prevention, or if they are the doses may be inadequate to achieve recommended targets. When working with someone with diabetes, it is important that strategies to reduce cardiovascular disease and the need for preventive drugs are discussed. In addition, the increased vascular damage promoted by smoking in the setting of diabetes may not be appreciated.

The main classes of drugs used are lipid-lowering drugs, predominantly statins, and antihypertensives, particularly drugs acting on the renin–angiotensin system. Antihypertensives are also important in the prevention of microvascular complications, as discussed in the following section. Specific guidance about blood glucose–lowering agents recommends the use of human glucagon-like peptide-1 (GLP-1) receptor agonists and sodium glucose cotransporter 2 (SGLT-2) inhibitors because of the cardiovascular benefits observed in clinical trials of these agents.

While each individual intervention for the various risk factors is important in the prevention of macrovascular disease, the Steno 2 trial has demonstrated that a coordinated approach to the management of cardiovascular risk can be successful [6]. In this study, the clinic setting and protocol-driven approach to overall cardiovascular risk led to significantly improved mortality compared with routine care.

Microvascular complications

With time, most people with diabetes will develop microvascular complications [43]. Many complications will remain asymptomatic until they have catastrophic consequences. The management of microvascular complications involves measures to prevent, detect, and treat. General measures, such as optimal glycaemic and blood pressure management, lead to a reduction in the incidence and progression of microvascular complications, but specific preventive measures are also needed and are discussed next [3–5, 44].

Eyes

Globally diabetic retinopathy remains the commonest cause of blindness in people of working age (Chapter 43). It is almost invariably asymptomatic until there is a catastrophic sight-threatening haemorrhage. For this reason, it is important to screen regularly for retinopathy to allow treatment before haemorrhage and visual loss occur. Traditionally this has been performed by examination of the visual acuity and fundoscopy within the diabetes clinic at least on an annual basis, although longer screening frequencies are being considered. Alternatively, in many countries dilated ophthalmological examinations are regularly performed by a specialist.

The gold standard for screening now, however, is digital retinal photography, which may be undertaken in several different settings. When this is performed outside the traditional diabetes clinic, communication between the screener and diabetes team is essential if other aspects of diabetes care are to take account of the development of retinopathy.

Where retinopathy is detected within the clinic, it is the responsibility of the clinic to ensure that the individual is referred for specialist ophthalmological attention in a timely fashion.

Neuropathy

Distal symmetrical polyneuropathy is the commonest form of neuropathy in diabetes and is addressed in the following section on the diabetic foot. Autonomic neuropathy may affect the person with diabetes in several ways, for example gustatory sweating, postural hypotension, or bloating (Chapter 45). Healthcare professionals should be alert to this possibility if symptoms suggestive of these conditions are raised.

Foot problems

Diabetes is the commonest cause of non-traumatic lower-limb amputation in high-income countries (Chapter 53). Around 10–15% of people with diabetes develop a foot ulcer as a result of the combination of peripheral neuropathy and vascular insufficiency to the foot.

Prevention of ulceration is an important goal and requires educating the person with diabetes so that they are aware of this possibility. It is important to inform people that they should not delay obtaining professional help if problems ensue.

An assessment of the risk of foot ulceration is needed at least annually and more frequently when neuropathy or vascular disease is present. The assessment should include a history of previous ulceration and trauma, as well as an examination of the skin, vascular supply, and sensation. Opportunistic foot screening should also be performed if an individual with diabetes is admitted to hospital.

In people with numbness, close attention to discovering unsuspected foot lesions, including examination of the sole of the foot using a small mirror, must be performed by the individual on a regular basis. This can lead to rapid intervention and prevent an early infection from progressing, potentially averting such devastating consequences as osteomyelitis and gangrene.

Prompt referral to the podiatrist and foot clinic should be arranged by the diabetes clinic if needed.

Kidneys

Diabetic nephropathy is characterized by a progressive increase in urinary albumin excretion that is accompanied by increasing blood pressure and decline in glomerular filtration rate, ultimately culminating in end-stage renal disease (Chapter 44). It is also associated with a marked increase in the rate of cardiovascular disease.

Microalbuminuria, the earliest stage of nephropathy, affects around 50% of people with diabetes after 30 years, while frank proteinuria affects a quarter of people with type 1 diabetes after 25 years. Diabetic nephropathy is a common reason for the initiation of renal replacement therapy. Although it appears that with modern treatments of diabetes the risk of an individual with diabetes developing end-stage renal disease is falling, the absolute numbers requiring renal replacement therapy are increasing in line with the increased prevalence of diabetes worldwide.

Diabetic nephropathy is asymptomatic and so screening is required annually. This is usually achieved by measurement of urinary albumin excretion (UAE). The commonest method is a single urinary albumin-to-creatinine ratio (ACR) measurement, which should be repeated two to three times if abnormal. An estimation of glomerular filtration rate should be obtained annually.

The primary prevention of nephropathy relies on excellent glycaemic management as well as tight blood pressure control. Once nephropathy is present, blood pressure management is the mainstay, as there is little evidence that glycaemic management at this stage slows the rate of progression. The antihypertensive drugs of choice are angiotensin-converting enzyme (ACE) inhibitors

or angiotensin-2 (AT-2) receptor antagonists, as they have specific effects on renal blood flow [45,46]. SGLT-2 inhibitors also reduce the progression of nephropathy, independently to their effect on glucose.

It is important that the person with diabetes understands the need for screening followed by treatment if nephropathy develops. Timely referral to the nephrology team is needed to ensure that the management of renal disease is undertaken promptly in those with abnormal renal function.

Diabetes emergencies

Diabetic ketoacidosis and hyperosmolar hyperglycaemic syndrome

Diabetic ketoacidosis and hyperosmolar hyperglycaemic syndrome are potentially life-threatening emergencies (Chapter 41). The person with diabetes needs to be educated about the risk of these and strategies to prevent them from happening should be discussed. If a person with diabetes has been admitted with diabetic ketoacidosis or hyperosmolar hyperglycaemic syndrome, the opportunity should be taken to explore the reasons why this episode occurred and to identify what might be changed to prevent it from happening in future. The commonest causes of hyperglycaemic emergencies in those with pre-existing diabetes are infections and insulin omission and errors. Bolus calculators are increasingly commonly used; however, it is crucial to regularly check that set parameters remain accurate, including insulin-to-carbohydrate ratio and insulin action time (sometimes called insulin on board, IOB), to ensure that the correct amount of insulin is being advised and delivered. It is particularly important that people with diabetes also understand the ‘sick-day’ rules, where insulin should never be discontinued and indeed doses may need to be increased even when appetite is diminished.

Hypoglycaemia

Hypoglycaemia is a common diabetic emergency affecting most people with type 2 diabetes and ~60% of insulin-treated people with type 2 diabetes (Chapter 40). Hypoglycaemia may have a major adverse effect on quality of life and fear of hypoglycaemia is the most important limiting factor in the achievement of optimal glycaemic levels.

It is important that the person with diabetes is educated about the symptoms of hypoglycaemia and the actions to be taken to prevent and treat it. As noted earlier, friends and family members should be invited to learn about hypoglycaemia and its management in order to intervene when necessary, for example by providing glucagon treatment if the person with diabetes is unconscious. If hypoglycaemia becomes disabling or recurrent, it is important to explore underlying causes (Table 25.2).

Lifestyle issues

Diabetes has social, psychological, and medical consequences and an important aspect of diabetes care is to discuss how diabetes may be affecting social issues such as driving, education, and employment (Chapter 66). The healthcare professional may need to act as an advocate for the person experiencing discrimination. Some aspects of lifestyle also affect diabetes care, such as diet, exercise, smoking, and alcohol. These issues should be discussed sensitively in order help the person with diabetes understand how their lifestyle affects their diabetes and general health. Support should be given to help and encourage the individual to make changes to their

Table 25.2 Causes of hypoglycaemia.

- Excessive insulin administration
 - Person with diabetes, doctor, or pharmacist error
 - Deliberate overdose during a suicide or parasuicide attempt
- Excessive sulfonylurea administration
- Unpredictable insulin absorption
 - Insulin is absorbed more rapidly from the abdomen
 - Lipohypertrophy
- Altered clearance of insulin
 - Decreased insulin clearance in renal failure
- Decreased insulin requirement
 - Missed, small, or delayed meals
 - Alcohol
 - Inhibits hepatic glucose output
 - Vomiting
 - May occur with gastroparesis, a long-term complication of diabetes
 - Exercise
 - Promotes glucose uptake into muscle
 - Increases rate of insulin absorption
- Recurrent hypoglycaemia and unawareness

lifestyle where these are appropriate. Psychological support should be offered where necessary.

Psychological issues

Both the diagnosis of diabetes and the chronicity of the condition can provoke a number of psychological reactions, such as anger and sadness in the individual that may be akin to a bereavement reaction or a chronic sorrow response (Chapter 63). More serious mental health problems, such as depression, are common in people with diabetes and these can impede the person’s ability to achieve optimal glycaemic management [47] (Chapter 65).

It is important for those working in diabetes care to explore with the individual whether they are experiencing psychological problems, as they may be reluctant to raise this in the consultation. While all members of the diabetes team should be able to recognize and address basic psychological problems, an essential team member is a psychologist who can address more complex needs. Despite the importance of psychological issues, this need is frequently unmet because of a lack of trained healthcare professionals.

The Diabetes Attitudes Wishes and Needs (DAWN™) study, a global survey of people with diabetes and healthcare professionals involved in their care, substantiated the association of diabetes with multiple psychological challenges and the close interrelationship between emotional well-being and diabetes outcome [48]. It also pointed to important deficiencies in the emotional care of and support for people with diabetes, which became the basis for the DAWN Call to Action with the goal of implementing person-centred diabetes care.

In 2012, the second global DAWN study (DAWN2™) was conducted to re-evaluate the state of diabetes care, both globally and within each of the 17 participating countries. In the global DAWN2 study, nearly half of the surveyed people with diabetes reported diabetes-related distress, 12% rated their overall quality of life ‘poor’ or ‘very poor’, and approximately 14% had likely depression [49]. Notably, family members were also considerably affected by having an adult with diabetes in their household, with 35% experiencing the care for the person with diabetes as a burden [29]. In 45% of family members, diabetes care had its most negative impact on emotional well-being [29].

Sexual health

Sexual dysfunction

Sexual dysfunction is more common in both men and women with diabetes than in the general population (Chapter 54). This can affect the person's quality of life considerably [50, 51]. Many people are reluctant to discuss this aspect of their lives because of embarrassment, and so it is the responsibility of the healthcare professional to enquire about this. There are now effective treatments for erectile dysfunction and failure to ask about this can deny the person with diabetes the opportunity to receive this treatment.

Pregnancy planning

Starting a family is an important milestone for many and the presence of diabetes can make this decision more difficult for women with diabetes (Chapter 71). Women are often worried about the effects that diabetes will have on their pregnancy and vice versa. The implications for the long-term risk of diabetes in the offspring are also of concern.

Planning for a pregnancy by a woman with diabetes can dramatically improve the outcome, reducing the risk of miscarriage, congenital malformations and macrosomia, with its attendant risks of shoulder dystocia, and neonatal hypoglycaemia [52]. Most oral medications should not be used in pregnancy and the treatment regimen may need to be altered as part of the planning process.

Despite this, many women enter pregnancy without adequate preparation or pre-conception care. It is therefore incumbent on the healthcare professional to discuss pregnancy with all women of child-bearing age, including adolescents, to ascertain their plans regarding pregnancy. The answers are often not black and white; women may not actively be planning to become pregnant, but are sexually active and not using effective contraception. Contraceptive advice is needed and where a pregnancy is being planned, women should be referred to a dedicated pre-conception clinic, as these have been shown to improve the outcomes of diabetic pregnancies.

With an increasing number of women with type 2 diabetes of child-bearing age, it is important that pre-conception advice is not solely focused on those with type 1 diabetes. This is particularly relevant because many women with type 2 diabetes are not seen in specialist centres.

Prompt referral to a joint diabetes antenatal clinic is necessary once a woman becomes pregnant.

Men may also have concerns about embarking on a family because of the increased risks of diabetes in their offspring and these anxieties need to be discussed sensitively.

Inpatient diabetes care

It is estimated that around 10–15% of people in hospital have diabetes (Chapter 39). In many instances the diabetes is coincidental to the admission and the individual remains capable of managing

their own diabetes, often with greater skill than the healthcare professionals around them. Optimal diabetes management remains an important goal, as this improves the rate of recovery and may lead to an earlier discharge.

Admission to hospital is a worrying time, but much of the fear can be alleviated if a full explanation of the treatment in hospital is given along with an opportunity to discuss any particular concerns. Being given the opportunity to discuss the management of diabetes can be reassuring. Where possible, the person with diabetes should be allowed to continue to self-manage their diabetes. The individual should be encouraged to bring in their own insulin supplies where admissions are planned. There should be access to their regular diabetes healthcare team where possible, as the admission may provide an occasion to check techniques and results. Ready access to carbohydrate and appropriate coordination of mealtimes, snacks, and medication should obviate the need for more dramatic treatment of hypoglycaemia.

There will be times when the person with diabetes is unable to manage their diabetes themselves. In these instances, the responsibility will fall entirely on the healthcare team, for example during surgery when the person with diabetes is unconscious and requires intravenous insulin and dextrose.

Following discharge, clear communication with the primary care and hospital diabetes teams is essential so that any changes in management or medication are made known to those involved in the individual's care.

Involving people with diabetes in the planning of healthcare and service development

Involving people with diabetes and their carers in the planning and decision making of local health services enables these to be built around the needs of those who use the service, rather than the needs of the system [53]. An open dialogue is needed, and service users should feel that their views are listened to. This will improve the accountability for and legitimacy of any decisions made and is likely to ameliorate clinical and care outcomes. People with diabetes should be encouraged to express their views and concerns about their services, as better feedback about service provision should help to improve and shape future provision of care.

Conclusion

The aim of diabetes care is to improve the lives of those with diabetes. This can only be achieved through a partnership between the person with diabetes and a multifunctional healthcare team that should be in place to support the person with diabetes.

Education to Empower the Person with Diabetes

Ingrid Willaing¹ and Michael Vallis²

¹ Steno Diabetes Center Copenhagen, Copenhagen, Denmark, and Department of Health Services Research, Institute of Public Health, University of Copenhagen, Copenhagen, Denmark

² Department of Family Medicine, Dalhousie University, Halifax, NS, Canada

Key points

- Diabetes education and psychosocial support are critical elements of care for all people with diabetes and their family members.
- Being able to self-manage diabetes requires substantial knowledge, motivation, and behavioural competencies on the part of people with diabetes and their family members.
- Diabetes education needs to be implemented in a sufficiently flexible manner to be incorporated into multiple settings, not just formal and structured diabetes education.
- People with diabetes must be placed at the centre at all times in diabetes education. Active involvement in their own healthcare must be prioritized over educator-dominated involvement.
- Diabetes education programmes are more effective if they are based on participant- and empowerment-oriented principles and principles of adult learning.
- Group-based diabetes education has a positive effect on clinical outcomes, health behaviours, and psychosocial outcomes, including glycated

- haemoglobin (HbA_{1c}), fasting blood glucose concentration, diabetes knowledge, self-management, empowerment, and self-efficacy.
- The provision of appropriate training of diabetes educators, including the management of psychosocial issues, cannot be overestimated.
- Group processes and active participation during diabetes education appear to be more important for improving coping skills than the didactic content of the programme.
- People with diabetes should be supported to work specifically and realistically with setting goals and to think about potential obstacles and facilitators to achieving them.
- Family-based diabetes education interventions seem to be a potentially important supplement to enhance diabetes management in everyday life.
- Evaluation of diabetes education should focus on understanding how, for whom, and under what conditions specific programmes will work.
- The main limiting factor of diabetes education is that it almost always does not include ongoing care and education.

The foundation of diabetes self-management education and support

There is broad consensus in the global diabetes community that diabetes education and psychosocial support are critical elements of care for all people with diabetes and their family members [1]. Yet questions remain about the extent to which diabetes education effectively enhances self-management or addresses the psychosocial aspects of living with diabetes. The purpose of this chapter is to support enhanced competency in the delivery of self-management education and psychosocial support by clearly specifying the values, attitudes, and competencies that promote self-management.

Many issues that impair the efforts of diabetes educators in promoting self-management are grounded in communication challenges [2]. Educators unwittingly restrict participation from people with diabetes through time constraints, pre-planned topics, and persuasive recommendations [3] that operate counter to the evidence that goals generated by people with diabetes produce better

outcomes than goals generated by healthcare professionals [4]. It makes sense that a person will be more committed to pursuing their own goals than goals that are *given* to them by another person. A health technology assessment of education programmes concluded that those for people with diabetes are more effective if they are based on participant- and empowerment-oriented principles and principles of adult learning [5]. The best outcomes of patient education seem to be produced with an empowerment approach, which is problem based, and individually and culturally tailored to address psychosocial, behavioural, and clinical issues relevant to people's needs and readiness to learn [6]. In reality, educators are responsible for translating abstract concepts and theories into concrete programmes tailored to the needs of different individuals with diabetes [7].

Diabetes education and support has the potential to empower people with diabetes to live well with diabetes. For the individuals with diabetes and their family, this means the freedom to live as they want while feeling healthy and being safe. For people with diabetes and their healthcare team, this also means achieving

desirable clinical outcomes such as glycaemic, blood pressure, and cholesterol targets [8–10].

Diabetes self-management education and support (DSMES) is an ongoing process to provide the individual with the knowledge, skills, and confidence to self-manage [11, 12]. DSMES is intended to support informed decision making, problem solving, health behaviour change, and active collaboration with a healthcare team. The process of DSMES must be based on the needs, goals, and life experiences of the person with diabetes. As such, it is less about teaching and more about collaborating.

Modalities of education

There are many evidence-based curricula available for diabetes education. The UK National Institute for Health and Care Excellence (NICE) defines structured diabetes patient education as ‘A planned and graded programme that is comprehensive in scope, flexible in content, responsive to an individual’s clinical and psychological needs, and adaptable to his or her educational and cultural background’ [13]. In its review of the evidence, NICE identifies principles of good practice, including the following [14]:

- It is evidence based and suits the needs of the person.
- It has specific aims and learning objectives and supports the person and their family members and carers in developing attitudes, beliefs, knowledge, and skills to self-manage diabetes.
- It has a structured curriculum that is theory driven, evidence based, and resource effective, has supporting materials, and is written down.
- It is delivered by trained educators, who have an understanding of educational theory appropriate to the age and needs of the person, and who are trained and competent to deliver the principles and content of the programme.
- It is quality assured, and reviewed by trained, competent, independent assessors who measure it against criteria that ensure consistency.
- The outcomes are audited regularly.

There are many programmes and methods available for diabetes education and support, with more or less evidence of effect (e.g. [15–17]). There is evidence for the effect of one-on-one education as well as group education [18]. Group-based education can be cost-effective and equally or more satisfying to recipients [6, 19, 20]. Group-based education including peer support has the advantage of observational learning and modelling [21, 22], which may be at least as important for improving coping skills as the didactic content of the programme [23, 24].

Individual differences and contextual factors are critical to success in diabetes education. Support is likely to be especially beneficial in relation to specific events in life such as being diagnosed in adulthood [9, 25], starting to use diabetes technology, a wish to participate in extreme physical activity such as a marathon [26], the Covid-19 pandemic [27, 28], or other new situations in the lifespan generating specific needs [29, 30]. Given that at least half of people with diabetes do not participate in formal diabetes education services [31], DSMES needs to be adapted to settings beyond formal diabetes education services such as primary or specialty care, community settings, and public health [32]. DSMES is based on three main building blocks: values, tools, and competencies. This chapter is structured around these three areas, which will be described in more detail in what follows.

Values, competencies, and tools

Diabetes is managed on a daily basis by the person with diabetes in the context of their sociocultural environment [33, 34]. It is critical to accept that diabetes is not a goal sought by the individual: no one chooses to have diabetes. It is an unwanted intrusion into a person’s life that is a major source of threat and burden. The implication of this is that it can be expected that the person with diabetes would want to minimize the intrusiveness of the disease in their life. The irony is that self-management requires significant vigilance and effortful health behaviours, which increase psychological intrusion. Successful self-management support can help the individual to psychologically reframe diabetes self-management from an intrusive burden, which impairs quality of life, to a chosen strategy that enhances quality of life; that is, as empowerment. In this way, DSMES is inseparable from managing the emotional and psychosocial aspects of living with diabetes. DSMES must facilitate this fundamental psychological reframing, which is an internal process of the person with diabetes and not controlled but supported by the healthcare team.

Accepting that diabetes is a self-managed disease that no one chooses to have and that requires considerable, continuous, and arduous self-care behaviours places the educator in the proper context. The power in the relationship does not belong to the educator, but to the individual. Thus, tools and procedures should not be prioritized over the person with diabetes and the healthcare professional relationship. Rather, tools should be used to empower the person with diabetes and enhance the collaboration between the person with diabetes and the healthcare team. Diabetes self-management occurs outside of the clinical encounter where the individual is in charge of their choices. To make the most of DSMES, the educator needs to implement an evidence-based care plan. However, this plan should not prioritize tools and procedures over the use of the patient–healthcare professional relationship to empower the person with diabetes to *choose* to follow recommended procedures and tools. As such, the foundation of DSMES is more value based than tool based. This is illustrated in Figure 26.1, where values are the bedrock that define the competencies needed to facilitate self-management.

The value of DSMES includes respecting the *autonomy* of the individual (their questions are most important to address, and their decisions carry the greatest weight) by *collaborating* (being person

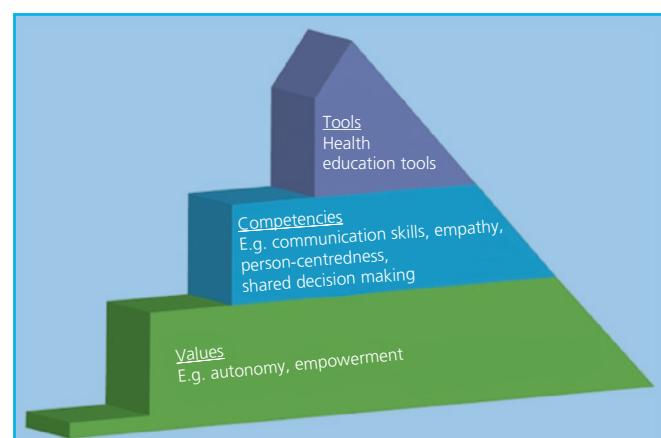

Figure 26.1 Values, competencies, and tools in diabetes education and support.
Source: Hansen et al. 2018 [35].

centred and using shared decision making) to achieve *empowerment*. Healthcare professional competencies and the use of relevant tools should be perceived as a stepwise execution of these values. In fact, value-based education and support by competent educators may obviate the need for tools. A meta-analysis of motivational interviewing discovered that manual-based implementations were less effective than implementations that were not manual based, but instead based on the 'spirit of motivational interviewing' [36].

Organizing the activities of the educator around the concepts of person-centredness, collaboration (shared decision making), and empowerment represents a major shift towards placing the relationship in front of education [34, 37]. It is unacceptable for a diabetes healthcare professional to say 'I did not have time to address the psychosocial aspects of diabetes'. Many diabetes educators are more comfortable with providing recommendations and teaching management skills than with addressing the psychosocial context of a person's life [38, 39]. This raises a stressful situation for the educator; that is, issues unrelated to diabetes may be overriding priorities for the person with diabetes, limiting the goals and expectations of the educator at any moment in time. Educators experience numerous barriers regarding the facilitation of person-centred and participant-involving education [39, 40], despite the evidence in favour of these experiences [41]. Thus, DSMES should be standardized by function, not by content [39, 40, 42]. Traditional education focuses on input (what healthcare professionals present to the patient). We are claiming that output is more important (what is important for the person with diabetes to do or to hear about).

The role of the healthcare professional: how do we guide people with diabetes to self-management behaviours?

Person-centred DSMES is intended to empower people with diabetes to engage in the challenging behaviours associated with managing glycaemic, lipid, and blood pressure levels and prevention of complications. For many individuals, this means becoming motivated and skilled to engage and sustain behaviours that are challenging to maintain. For healthcare professionals, this requires shifting from being an educator to being a collaborator first and an educator second [2, 39, 40, 43]. Preechasuk et al. reported a broad survey of diabetes educators, doctors, and administrators in Thailand regarding diabetes self-management education [44]. Only 30% of educators reported that self-management education was effective, with obstacles to care including time, behaviour change skills for the healthcare professional, and perceived lack of interest and motivation for the person with diabetes. Clearly, universal uptake of DSMES is lacking. Based on the values of autonomy, collaboration, and empowerment, the competencies of the diabetes educator are in the ability to establish a change-based relationship with the person with diabetes. As such, it is the roles that the educator takes in the relationship that define DSMES competencies. Effective change-based relationships will promote behaviour change interventions that can be supported by tools.

The fundamental relationship dynamic that will promote DSMES involves the educator basing their relationship on dialogue and participation.

Dialogue, as a way of conducting diabetes education [45, 46], differs from the traditional one-way didactic model: the monologue. Didactic education can successfully convey information, but it is

less successful in supporting individuals with diabetes to take responsibility for self-management [5]. Much diabetes education does not engage the person with diabetes [47]. Behaviour change theory indicates that educators should elicit commitment, identify challenges, set goals, increase self-efficacy, and address barriers to change, and the main way to do this is through dialogue [48, 49]. It is useful to take the position that behaviour change is hard, and sustained behaviour change is even harder. Once behavioural habits become entrenched, much behaviour is cued by the environment, as well as natural preferences. For example, a 55-year-old man with type 2 diabetes who has never liked exercise and dislikes the idea of medication and being labelled as ill (preferences), and who has developed unhealthy eating and drinking habits as part of a stable and supportive friendship circle (cued environment), is unlikely to change behaviour as a result of listening to lectures on the benefits of healthy eating, taking medication as prescribed, and physical activity.

Participation likewise implies a shift in perspective from a disease- and expert-centred approach towards the needs of the person with diabetes. Effective and meaningful diabetes education requires that people with diabetes are actively involved and that teaching is tailored to their needs and preferences [45, 50, 51]. One way of conceptualizing this is as in a journey. The educator might make the first step, in the form of a recommendation or educational intervention, but then needs to see if the individual is able to follow that step. Traditional education involves the educator conveying huge amounts of information, effectively leaving the person with diabetes far behind as more and more knowledge and recommendations are conveyed. Evidence on the value of the teach-back method (having the individual summarize their learning throughout the encounter and not moving on till the person with diabetes has understood the message) in chronic disease management supports this notion of participation [52]. A useful concept here is *talk time*: monitoring who is talking more in an encounter ensures that the person with diabetes has enough time to express themselves fully [53, 54].

Educator knowledge, attitudes, wishes, and needs must take second place to the decisional processes of the person with diabetes. Consider the same 55-year-old man with diabetes who dislikes exercise, has never been physically active, and has many individual, social, and financial barriers to increasing activity. What are the conditions under which this person will choose to do all the work necessary to add a disliked behaviour to his routine? Overcoming the personal barriers to change is less likely to arise from teaching and telling than it would from effective understanding and supportive negotiation of health behaviour choices (participation through dialogue). In this example, the educator could communicate understanding and respect of the challenges to the recommended behaviour, and explicitly acknowledge that the person is in charge of the decision, while seeking permission to discuss ways to overcome barriers, be they informational, motivational, emotional, relational, or practical. The AADE7 Self-Care Behaviors framework [55] recommends orienting services around the behaviours of healthy eating, being active, glucose monitoring, medication taking, problem solving, reducing risk, and healthy coping. However, many educators will need to change their approach in order for self-management support to be implemented effectively. Involvement through dialogue requires the person–healthcare professional relationship to be one in which the patient feels comfortable sharing their truth without judgement by the healthcare professional. The majority of people with chronic illness avoid telling their clinician

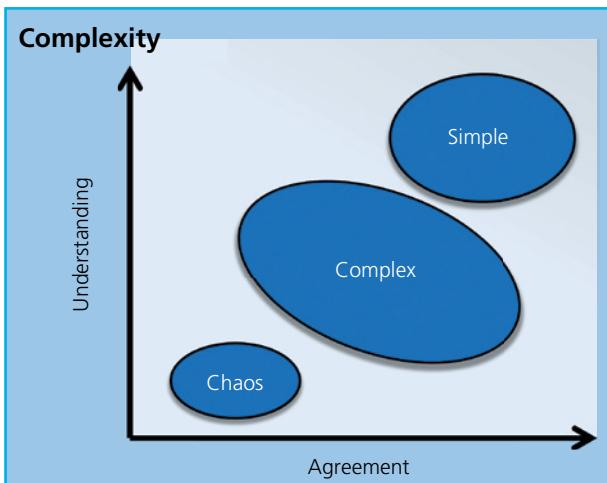

Figure 26.2 Complexity, understanding, and agreement.

important information and non-disclosure is based primarily on fear of judgement by healthcare professionals [56].

Many educators have developed the belief that their professional role is to provide the person with diabetes with the knowledge and skills they believe are needed to perform the recommended behaviours. They are the expert and it is their responsibility to educate. This relationship dynamic has been described as the 'expert clinician with the uninformed help-seeker' and can be understood through an appreciation of complexity (Figure 26.2) [57]. Some constructs, functions, or domains are simple, some are complex, and some are chaotic. This distinction can be understood by considering the degree of understanding and the degree of agreement regarding a phenomenon [57].

When the degree of understanding about a phenomenon is high and the degree of agreement on how to address the phenomenon is high, this is an indication of a simple system and a situation where reductionist protocols are effective. Since most medical professions base their training on the scientific method that emphasizes reductionism (determining the diagnosis) and determinism (understanding the mechanism of action), it naturally follows that this is a default relationship position an educator takes. However, not all systems are simple. When the degree of understanding and the degree of agreement are low, this is called a chaotic system; there is no precise guidance available. In this situation, gathering and organizing information to gain understanding is most effective (pattern recognition or phenotyping). When degrees of understanding and agreement are partial, this is called a complex system. Behaviour, including diabetes self-management behaviour, can be considered to be at least complex. As such, appropriate interventions are not so much guided by procedure but by principle. Different procedures may be equally appropriate if they have similar impacts on the principle. For example, if self-efficacy is the principle that predicts sustained behaviour, then any procedure recommended by an educator that increases self-efficacy is acceptable.

Effective self-management support shifts the professional role from method (what one does) to principle (the guiding rationale for what one does). Given that self-management necessarily places the responsibility on the person with diabetes, it becomes necessary to respect the choices made by the person. If the educator focuses on the principle, then they can negotiate the method without threatening personal choice.

Reflecting on the dominance of the scientific method in healthcare, it is no surprise that educators often do most of the talking in

clinical encounters, that they make frequent recommendations in the form of statements, and that they commonly interrupt individuals with diabetes if they stray from the agenda of the educator [58]. These relational dynamics reflect the educator as expert, where professional competency is based on conducting an assessment to make a diagnosis, determining a treatment intervention based on evidence, and evaluating how well the person responds to the intervention. This professional competency model of diagnose, determine treatment, and measure outcomes works well if the outcomes being achieved are under the direct control of the clinician. When outcomes are not determined by the competency of the clinician but by the behavioural choices made by the person with diabetes outside of the clinician encounter, these competency standards no longer apply. Dialogue and participation explicitly reframe this dynamic from *teach and tell* (educate and recommend) to a shared interaction. Figure 26.3 shows how competency can be reframed using the concepts of dialogue and participation. The left-hand panel in Figure 26.3 shows the traditional model where outcomes, which are based on the clinician's expertise, follow from the diagnosis, treatment, and focus on outcomes [38]. In simple biomedical contexts, this is fine. In behavioural and sociocultural contexts, the task of diagnosing can be replaced with the task of describing. It is not the clinician's job to tell the person what their problem is, but it is the clinician's job to understand the patient's behaviour. For instance, medication taking or vaccinations can be understood by examining the person's beliefs regarding perceived need for treatment and perceived concerns about treatment. Once behaviour is understood, it is the job of the clinician to help the person with diabetes appreciate the predicted outcome of their current behavioural choices. Rather than judging the outcomes of the person's efforts, the clinician must link important (to the person) outcomes to the choices made and encourage different choices consistent with recommendations. So, using dialogue to engage the person in a participatory approach can improve self-management via the skills of description, prediction, and choice – not diagnosis, treatment determination, and outcome judgement (Figure 26.3).

Working with dialogue and participation

Dialogue and participation enable the educator to shift from the expert (*teach and tell*) to collaboration (collaboration and empowerment). In doing so educators manage different roles and the shifting between roles; the juggling is, however, challenging [59]. Juggling is the ability to master switching between different roles to meet the needs of the individual or group and to evoke readiness to change [46]. Some well-recognized juggler attributes are:

- *Humility* – the ability to be approachable without projecting one's self and beliefs onto the group.
- *Flexibility* – openness to try new process approaches, willingness to change, or stretch outside one's boundaries in the facilitator role.
- *Professionalism* – being ready to deal professionally with feelings in the group [60].

The roles that are juggled include the embracer, the facilitator, the translator, and the initiator [46, 61].

The *embracer* role is based on empathy [62, 63], which encompasses the desire and ability to understand people with diabetes on their own terms [62]. Morse et al. [64] propose a descriptive model of clinical empathy with affective, moral, cognitive, and behavioural dimensions. Norfolk et al. [62] propose a model about the empathic

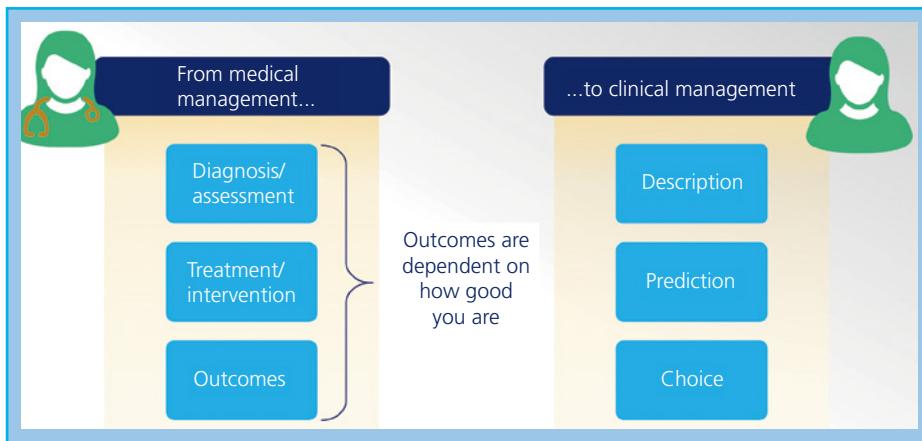

Figure 26.3 Are behavioural interventions doomed to fail? Source: Vallis 2018 [38].

journey towards therapeutic rapport in consultations focusing on the doctor's behaviour, motivation, and required skills. The factors mentioned in these studies are important competencies for educators' ability to act in the embracer role.

The *facilitator* role is rarely described in the literature. Notable exceptions are guidelines for facilitating patient empowerment programmes [65] and a study about speech practices facilitating patient participation in health counselling, in which concrete facilitation skills are suggested [3]. However, other professional fields, such as business and organization, provide more extensive literature on facilitation [60, 66].

The *translator* role, in which the educator translates medical concepts into relevant and understandable information, implies a change of the typical health educator roles. In traditional medical and disease-specific patient education, educators give information and advice, handle acute situations, and perform problem solving [63]. Following patient demands for a more active role in healthcare, the Ottawa Charter emphasized the need to view the individual as a *whole person* [67]. As translators, healthcare professionals recognize that they are experts in medical knowledge and that individuals with diabetes are experts on their lives [68].

The *initiator* role closely links to principles of motivational interviewing [69] and empowerment interventions [70]. The initiator faces the challenge of avoiding confrontation or authority traps such as *knowing best*. In general, facilitation and participatory methods are rarely part of the healthcare professional curriculum [63], which may explain the challenges experienced when delivering participatory, group-based diabetes education.

The tool in Figure 26.4 to self-assess professional skills in facilitating group-based diabetes education seems useful and stimulating, and is suggested as an excellent starting point to promote more person-centred communication between individuals with diabetes and healthcare professionals [71]. It is easier for healthcare professionals to embrace the roles of translator and embracer than those of facilitator and initiator [72].

develop competency in eliciting behaviour change. One of the learnings from behavioural sciences is the importance of theory-driven interventions. Behavioural theories explain why people engage in certain behaviours and provide a guide to promote behaviour change. By contrast, the use of tools, without theory, might be misguided. Theory can guide the selection of which tool is useful in a given situation. For instance, the literature supports regular weighing as a way of maintaining a healthy weight. However, regular weighing may be negative for one person and positive for another. If a person feels disappointed and shameful when the weight on the scale is not what was hoped for, regular weighing may be demotivating rather than motivating.

At the centre, the person with diabetes is an individual who will make specific behavioural choices (person as decision maker). A dominant theoretical model describing how people make behavioural choices is the Self-Regulation Model, also referred to as the Health Belief Model [73]. There are five dimensions of illness beliefs:

- Consequences (e.g. perceived seriousness)
- Personal control
- Treatment control
- Timeline
- Emotional representation.

Understanding these beliefs can be a valuable guide to the diabetes educator for supporting the person with diabetes. Consider the person who perceives the consequences of their diagnosis as minor (low seriousness) or someone who does not believe that treatment will reduce complications, perhaps based on a family history of early, devastating complications (low treatment control), or consider the person who reports overwhelmingly distressing emotions following diagnosis. Understanding these common-sense beliefs will guide the educator to potential solutions. A variant of the Health Belief Model, which is a useful screen for potential lack of medication taking, is needs and concerns analysis [74]. Consider a recommendation by a professional to start medication or insulin. Asking the person with diabetes the extent to which they need the medication and the extent to which they have concerns about medication can be accomplished quickly and frames potential adherence challenges. High perceived need and low perceived concern would favour acceptance; high perceived need and high perceived concern suggest ambivalence; low perceived need and low perceived concern suggest indifference; while low perceived need and high perceived concern suggest scepticism. The Health Belief Model can be useful in supporting the acceptance of the diagnosis of diabetes. Supportive counselling can be helpful in empowering the person to come to view diabetes as serious but manageable, in which needs and concerns are addressed and balanced.

A framework to guide selection of education methods

Juggling the roles of embracer, facilitator, translator, and initiator using dialogue and participation defines many of the competencies needed for effective DSMES. In addition, the educator is required to

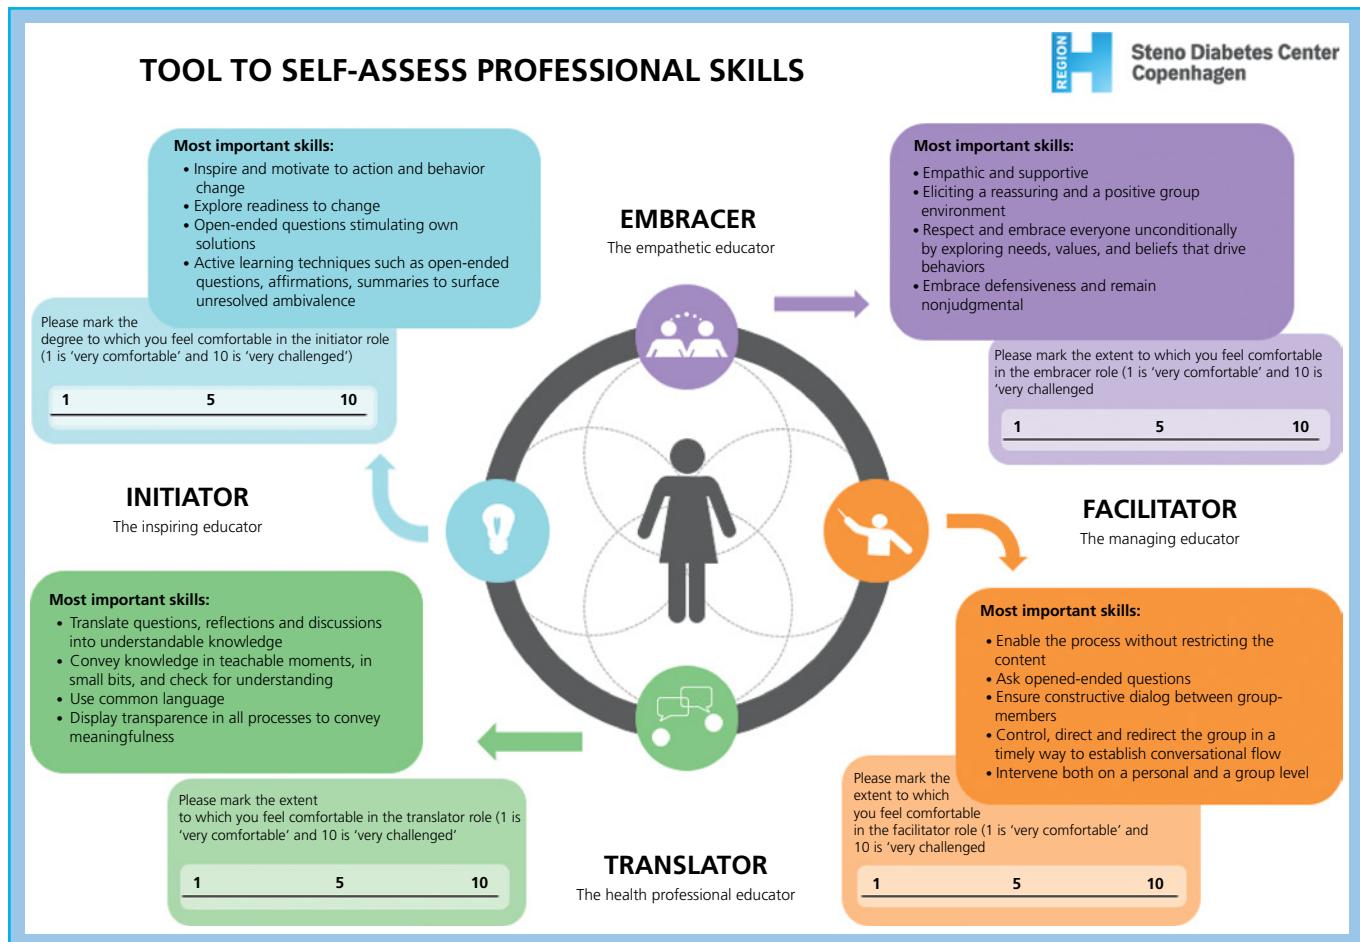

Figure 26.4 Self-assessment tool to develop skills of a person-centred approach in diabetes education and support. Source: Stenov et al. 2017 [71].

Additional theoretical models explaining the drivers of health behaviour have shown great promise in supporting acceptance of disease, acceptance of treatment, and health behaviour change. Prominent among them are social cognitive theory [75], the theory of planned behaviour [76], self-determination theory [77], and the trans-theoretical model [78]. These perspectives help to explain what determines a person's behaviour and can help the educator identify important motivational constructs that are associated with change (Table 26.1).

Perhaps most important are the principles that guide the educator on how to counsel a person with diabetes to help them develop the motivation to change. Here the principles of patient-centredness [79], empowerment [80], and motivational interviewing [81] provide specific knowledge and pathways to guide people towards change. Table 26.2 illustrates the tasks required of people with diabetes and healthcare professionals, and links these guiding principles with theory and constructs that can be brought into the clinical exchange.

Supporting the behaviour change process

Guiding the person towards sustained behaviour change can be understood as using the relationship between the person with diabetes and the healthcare professional to establish four tasks through dialogue and participation [84,85]:

- *Establishing a change-based relationship.* This is an explicit shift away from the expert teach-and-tell role to one of collaboration and empowerment. It is achieved by recognizing the dangers of a teach-and-tell approach and, using motivational communication, establishes empathy, non-judgmental curiosity, as well as an appreciation of the role of ambivalence. The relationship between the person with diabetes and the healthcare professional achieves common ground regarding the bond alliance, the task alliance, and the goal alliance.
- *Identification of a specific behaviour to change and determining the readiness of the person with diabetes to change that behaviour.* Not being ready to do the work of change is common and readiness is state based, not trait based. This allows one to avoid becoming preoccupied with changing a behaviour that the person is not ready to work on by finding a behaviour that the person is ready to change. Working with those who are ambivalent about change or not ready to change is a fertile area for behaviour change counselling, and virtually the entire content of this chapter speaks to how professionals can support change.
- *Using behaviour modification interventions to promote successful behaviour change.* Numerous behaviour change tools can be implemented when a person is ready to do the work of change.
- *Addressing the psychosocial determinants of behaviour.* Those relational, environmental, and structural issues that make change hard can be addressed. Importantly, with regard to scope of practice, addressing these issues can be successful if the healthcare

Part 5 Managing the Person with Diabetes

Table 26.1 Behaviour change theories in diabetes education.

Theory	Description	Key elements	Application to diabetes education
Social cognitive theory	Specifies determinants of health behaviour, mechanisms through which they work, and ways to translate this knowledge into health practices	Knowledge, perceived self-efficacy, outcome expectations, perceived facilitators, social and structural impediments	Diabetes education should address the determinants of people's health behaviour. The educator can acquire different roles in the education to facilitate this
Self-determination theory	Motivation is either intrinsic or extrinsic and is driven by the needs for competence, autonomy, and relatedness	Assess intrinsic versus extrinsic motivations (doing it for self or for the healthcare team), as well as the impact of self-management on autonomy and connection to others	Diabetes education should promote intrinsic motivation by supporting a person's competence in a way that does not impair connectedness to important others
Theory of planned behaviour	Proposes that the intention to engage in a specific behaviour depends on attitude towards the behaviour, subjective norms regarding the behaviour, and perceived behavioural control	Attitude, subjective norms, perceived behavioural control, intention	Diabetes education should explore attitudes, norms, and perceived behavioural control among individuals to assess their intention to change behaviour
Trans-theoretical model of change/stages of change model	Outlines behaviour change through five stages from a situation where individuals are not aware of a risk to a situation where they are changing their behaviour and fighting relapse	Pre-contemplation, contemplation, preparation, action, maintenance	Diabetes education should guide and support people with diabetes in the process of behaviour change. This includes exploring patient perceptions about importance, confidence, and readiness with regard to behaviour change

Table 26.2 Counselling principles to facilitate self-management motivation.

	Guiding principle	Theoretical model	Example constructs
Person with diabetes	Health beliefs	Self-regulation model [82]	Perceived consequences, personal control, treatment control, timeline, and emotional impact
	Motivation	Social cognitive theory [75] Theory of planned behaviour [76] Trans-theoretical model [78]	Self-efficacy, perceived social norms, readiness to change/intentions
	Emotion	Diabetes distress scale [83]	Emotional burden, regimen-related distress, physician-related distress, interpersonal distress
Person with diabetes—educator relationship	Patient-centredness	Patient-centred clinical method [79]	Understand the whole person, explore the person's illness experience, find common ground, and cultivate the relationship to overcome barriers
	Motivational communication	Motivational interviewing [69]	Non-judgmental curiosity, effective use of questioning and listening, working with ambivalence, and supporting self-efficacy
	Empowerment	Person empowerment [43]	Appreciating the process of respecting the autonomy of the person with diabetes

professional adopts the principles of identify, educate, recommend, and support. When a psychosocial issue of relevance is encountered (identify), there is great value in having a healthcare professional assist the person in understanding how the issue affects self-management (educate), increase awareness of how to manage the

issue (recommend), and then support the person with diabetes in their efforts to actualize these recommendations.

Recently, a great deal of work has been devoted to integrating the vast array of theories of behaviour change into an overarching model. West et al. examined behaviour change theories, which

included 128 theoretical constructs related to behaviour change, and integrated them into a single framework, called the Theoretical Domains Framework (TDF) [86]. This framework can guide both the development of behaviour change interventions and their implementation. The TDF is made more elegant by its integration into a simplified behaviour change model called COM-B. In this model *Behaviour* is seen to be the result of *Capability*, *Opportunity*, and *Motivation*. The 128 theoretical constructs related to behaviour change interventions were reduced to 14 domains, which were then integrated in the COM-B perspective [86].

This model has great potential in diabetes education and support. For instance, the healthcare professional and the person with diabetes collaboratively identify a *behaviour* they would like to change. The professional can then assess the factors that might be associated with success in changing this behaviour using this framework. The result of this assessment can identify resources (strengths that the person with diabetes presents that support change) as well as areas for intervention.

Capability involves both psychological and physical components. Physical capability is the skill in the behaviour, where psychological capability involves knowledge, psychological skill, memory, attention, and decision processes as well as behavioural regulation skills. *Opportunity* includes social influence factors as well as environmental context and resources. This comprehensive model has been helpful both from the perspective of designing an intervention as well as guiding the behaviour change counselling within any given interventions. Finally, *motivation* can involve reflective as well as automatic aspects. Reflective motivation results from intentions, goals, beliefs about capabilities, beliefs about consequences, social role and identity, and optimism (six domains). Automatic motivation results from reinforcement, emotion, optimism, and social role and identity (two new domains, two domains overlapping with reflective motivation). Professional counselling to enhance motivation can utilize these constructs as interventions.

Empowerment through language and the flourishing mindset

Several medical journals, national health services, diabetes organizations, as well as academics and professional groups have, during the last decade, advocated for an improvement in the language used in diabetes. As an example, Diabetes Australia and researchers in diabetes psychology provide the following recommendations [87]: ‘On average, people with diabetes experience greater emotional distress than those without diabetes. One source of distress can be the language used to refer to diabetes, its management and the person with diabetes. The way verbal and written language is used reflects and shapes people’s thoughts, beliefs and behaviours. Language has the power to persuade, change or reinforce beliefs and stereotypes – for better or worse. Words do more than reflect people’s reality: they create reality and affect how people view the world and their diabetes.’

An example from the *New England Journal of Medicine* shows how language can be used to anchor the importance of the patient first. Michael Berry and Susan Edgeman-Levitin suggest a substitution of ‘What is the matter with you?’ with ‘What matters to you?’ [88]. This shows a movement away from psychopathology (*what is the matter with you?*) to quality of life (*what matters to you?*).

A useful way of framing the juggling of self-management support roles in DSMES has origins within positive psychology and is

Table 26.3 Comparison of coping and flourishing treatment strategies.

Treatment characteristics	Coping mindset	Flourishing mindset
Approach	Cope and repair	Design and build on what is already working
Goal	Come up to ‘normal’	Go beyond ‘normal’ and flourish physically and psychologically
Direction	Avoid what you don’t want	Move towards what you do want
Focus	The disease, what is going wrong, and corrective actions	The patient in a personal life context, what is going well, and building on successes
Healthcare provider–patient relationship	The healthcare provider is the expert and decides, tells, and explains what the patient should do	The healthcare provider and the patient are both experts who leverage each other’s strengths to co-design a way forward
View of diabetes and impact on one’s life	A burden that one must fight/battle/overcome and that makes life smaller/limiting	Bestows benefits, integrates into one’s life, and makes life bigger/offers possibilities

Source: Modified from Greenberg and Bertsch 2013 [90].

described by the American psychologist Martin Seligman as the concepts of learned helplessness and flourishing [89]. Riva Greenberg, an American diabetes activist, has been the leading front person of developing a mindset called the *flourishing mindset*. This mindset builds on positive experiences by focusing on health rather than illness [90]. The operationalization happens by supporting people in finding their innate resilience, particularly through open dialogues aiming to identify what people do well in everyday life and then how to build on that, as opposed to focusing on illness and corrections of behaviour. This can create a relationship of trust, connection, and support between healthcare professionals and people with diabetes, which is the bedrock from which, engaged and encouraged, people can move forward (Table 26.3 and Box 26.1).

Outcomes must mirror biomedical as well as behavioural and emotional challenges

One of the most challenging aspects of diabetes education is that diabetes is both a biomedical disease and a behavioural, social and emotional challenge [48, 90, 91]. For positive diabetes outcomes to be realized, the person with diabetes must engage in intentional, effortful, and sustained behaviours. However, the importance of outcomes to the educator (e.g. $\text{HbA}_{1c} < 7.0\%$, 53 mmol/mol) cannot supersede the importance of outcomes for the person with diabetes (e.g. living life as normally as possible) and things go well only when the two are in synchrony. Thus, the essential outcomes should include biomedical as well as psychosocial outcomes [92].

There is an association between psychosocial problems and poor diabetes outcomes such as risk of hypoglycaemia and frequent omission of prescribed medicine [93, 94]. At the same time, poor diabetes outcomes can cause psychosocial problems, such as

Box 26.1 Tips for working from a flourishing mindset

- Begin each session by asking ‘What’s improved since we last met?’ This encourages the patient to reflect on successes, thereby guiding the visit in a positive direction.
- Ask the patient to share a challenge or difficult life event and describe the steps they took to overcome it. Listen for strengths that were used, provide congratulations, and ask, ‘How can you use these strengths to help improve your diabetes management?’
- When looking at a patient’s logbook or discussing proposed nutrition interventions, focus on what they are doing well, such as blood glucose numbers that are in range or the two vegetables a week they do eat. Ask ‘How did you do this?’ and ‘What can you do to make this happen more often?’
- Provide patients with suggested areas where improvement is needed and ask them to identify areas of focus and goal setting. Patients are more likely to be successful when they feel ownership for the goal. Discuss ideas for improvement and encourage the patient to implement one or two of them. Even if the selected approach(es) is(are) not successful initially, the patient is more likely to engage in alternative approaches and future recommendations by the healthcare provider if given the opportunity to choose.
- Be present, attentive, and mindful in your visit with a patient. Show genuine curiosity and interest. As is often quoted in medicine, ‘Patients don’t care how much you know until they know how much you care.’

Source: Modified from Greenberg and Bertsch 2013 [90].

It is also useful for the diabetes educator to be mindful of how diabetes fits into the social world of an individual. The idea of diabetes-specific as well as general social support is important here [100, 101]. People with diabetes can benefit from having sensitive discussions with their diabetes educator about the presence or absence of support from others regarding diabetes self-management. The potential of engaging peers in supporting diabetes outcomes should also be noted [102].

Diabetes self-management education and support in the social context

The second Diabetes, Attitudes, Wishes and Needs (DAWN2) study included a survey of 2057 adult family members of adults with diabetes. According to this study, supporting a relative with diabetes was perceived as a considerable burden by 35% of family members. The study also revealed that 40% of family members experienced high levels of distress related to concerns about their relative with diabetes, and 61% stated they were very worried about hypoglycaemia in their family member with diabetes [103, 104].

People with diabetes generally engage in self-management of their diabetes within a family setting and family members play a role in many everyday tasks such as meal preparation, often providing moral, emotional, and practical support. Thus, struggles with self-management and blood glucose levels, poor well-being, and psychological distress are relevant not only to the individual adult with diabetes. To the contrary, these problems affect – and are affected by – the entire family. Unfortunately, most education programmes exclusively target individuals with diabetes [105–108]. Furthermore, research targeting the interface between adults with chronic disease and their families is relatively scarce and family factors have until recently been virtually ignored in relation to adults with diabetes. A recent study shows how professional support may contribute to the creation of a shared illness identity and a reduction of diabetes-related conflicts within the family as well as enhanced support of self-management [109]. Another study shows that maintaining resilient, good-quality intimate relationships optimizes physical and psychological outcomes for people with diabetes [110]. The vast majority of psychoeducational interventions in type 1 diabetes focus exclusively on people with diabetes, with only a few offering support for family members [95]. However, the importance of partner support is increasingly recognized and its enhancement has become one of the main goals of current psychoeducational interventions in diabetes [111, 112]. The family provides the frame for the potential effects of culture, race, and ethnicity on disease outcomes, and we need to improve our understanding of family influences on diabetes management and ways to engage family members through family-tailored education and support [113].

Appreciation of culture is also essential when considering the context of the person with diabetes. Cultural factors such as self-efficacy, levels of health literacy, and effects of stigma impair accessibility and acceptability to diabetes education [114]. Ethnic minority groups are specifically vulnerable [115, 116]. To reduce the *literacy burden* of ethnic minorities and enhance support for self-management, the cultural context needs to be included to make diabetes education more accessible for all people with diabetes [117, 118].

fear of hypoglycaemia, diabetes distress, and functional or occupational interference. Depressive phenomena are common in those with diabetes, particularly diabetes distress. Diabetes distress is distinct from and more prevalent than depression among adults with diabetes [95, 96]. Further, compared to depression, diabetes distress is independently and more strongly associated with suboptimal diabetes self-management and hyperglycaemia [96]. People with diabetes distress may be incorrectly diagnosed as having depression and thus experience an ineffective approach to treatment [97]. A recently published paper by Fisher et al. emphasizes that emotional distress is best considered as a *continuous psychological characteristic*, rather than a distinct *comorbid clinical condition* [98]. In this way, diabetes distress is distinct from mental health disorders and thus is a characteristic to be considered in diabetes education.

While it can be stressful for diabetes educators without a background in psychology to address psychosocial issues within their scope of practice, it can be helpful to know that the ability to communicate one’s distress (i.e. to be heard) is often experienced as beneficial in and of itself. If the educator takes the position that they are not the expert and that it is not their responsibility to fix the potential problems, then supportive communication can be easier. For instance, it would not be inappropriate for a professional to declare, ‘I’d be interested in hearing about what you are going through and possibly make any recommendations that I think might be helpful.’ Research indicates a positive association between the presence of physician empathy and better diabetes outcomes [99].

The final step: using health education tools to promote and support change and self-management

Using cultural probes and design thinking [119] is a promising method in diabetes education. Design thinking is a research method deriving from the design world [120] as well as ethnographic studies [121, 122]. Methods include, for example, the use of postcards with questions concerning participants' attitudes to their lives, maps where participants can highlight areas of importance to their lives, and cameras with instructions asking participants to take photos of important objects. Visual methods similar to cultural probes such as photos, videos, and drawings are often used for data collection [123, 124]. The use of cultural probes in diabetes education is a promising method of translating the theoretical concepts of person-centredness and active involvement into practice to support both educators and people with diabetes. One of the early examples of the use of probes was the Conversation Maps tool, which successfully facilitates interactive dialogue among people with diabetes through relationship building, trust, and confidence as well as the sharing of personal stories and experiences [125]. Further examples are the British Diabetes Education and Self Management for Ongoing and Newly Diagnosed (DESMOND) programme [15] and the Danish NExt EDUcation (NEED), Empowerment, Motivation and Medical Adherence (EMMA), and Involvement in families with Type 2 diabetes (PIFT) programmes [126, 127] (Box 26.2).

Evaluation of diabetes education

Given the potential positive role that DSMES can have on people living with diabetes and their family, perhaps the most important indicator in the evaluation of diabetes education is the availability of and access to diabetes education. Biological outcome measures have for a long time dominated the evaluation of diabetes education, which is unsurprising as they make up essential outcomes in diabetes. In reviews and meta-analyses of diabetes education, the most used outcome measures can be divided into four categories: biological, behavioural, knowledge, and psychosocial outcomes. Most attention has been paid to biological outcomes, particularly HbA_{1c}, and knowledge-based outcomes. Less attention has been placed on behavioural outcomes and least on psychosocial outcomes [131].

An interesting and useful perspective, which is consistent with the complexity of diabetes education, is to examine the mechanisms by which an education programme works [132, 133]. If an education programme is found to be effective, how do we know what to replicate and what to change when we implement the programme somewhere else? Why do some programmes work in one place for one group of participants and not for another? Focusing on mechanisms of effects is complicated, as the education process typically involves multiple interacting components. It is thus difficult to identify the precise mechanisms leading to effects of the various components [134, 135]. Further, outcomes depend on the competencies of educators and the preconditions and motivation of participants as well as organizational conditions, all of which may be difficult to capture in a randomized controlled trial [135]. In response to this, theory-driven forms of evaluation have gained attention, as they can generate knowledge about the effectiveness of an education programme as well as knowledge about the underlying mechanisms of effects [136, 137].

Box 26.2 Examples of dialogue tools to be implemented to facilitate diabetes self-management education and support

The family mirror

The Family Mirror tool (Figure 26.5) aims to allow each member of a family with diabetes to visualize how they experience the effect of diabetes on their everyday life [128]. Each family member makes a figure of themselves and/or another family member, with the goal of being able to look at diabetes and family life from different perspectives. Further, the aspect of sharing the lived experiences of having diabetes in the family allows for all voices of the family to be heard, as well as the creation of transparency and dialogue on the challenging aspects of living with diabetes in the family's everyday life.

Steps in using the Family Mirror:

- The purpose of the Family Mirror is described.
- Each participant collects a stack of cards and a figure representing themselves and sits across from their relatives.
- The participants make a figure of themselves.
- The participants make a new figure of their relative with the help of the cards.
- The figures are presented within the family. The participants explain which cards they have chosen and why.
- The families share reflections and experience.

Balance cards

Balance cards [126, 129] comprise 27 cards with pictures and quotes (Figure 26.6). The aim of the exercise is to assist participants in talking about the imbalances, challenges, and possibilities they experience in their daily lives with diabetes. The exercise can make it easier for participants to express difficult topics and facilitates dialogue among participants about everyday life with diabetes.

My day

The My Day tool [130] aims to establish a good relationship between the person with diabetes and the educator (Figure 26.7). The educator gains insight into the everyday life of the person with diabetes guided by their focus and needs. This includes valuable information about physical activity, medication taking, social relations, etc.

The person with diabetes is encouraged to discuss their everyday life and challenges, particularly when completing the statement 'It is difficult for me to live with diabetes when...'. A shared understanding is achieved between the educator and the person with diabetes about the challenges involved in living with a chronic illness for specifically this person. This insight allows the educator to acknowledge the difficulties the person with diabetes is going through by including these dynamics in their relationship.

Theory-driven evaluation comprises 'an explicit theory or model of how the program causes the intended or observed outcomes and an evaluation that is at least partly guided by this model' [137]. Thus, a core element of theory-driven forms of evaluation is the development and use of theory in the evaluation process. The theory, often referred to as programme theory, specifies relationships between intervention actions and intended outcomes [136].

An education programme is an incarnated theory of change: a theory about how to change problematic conditions or behaviour.

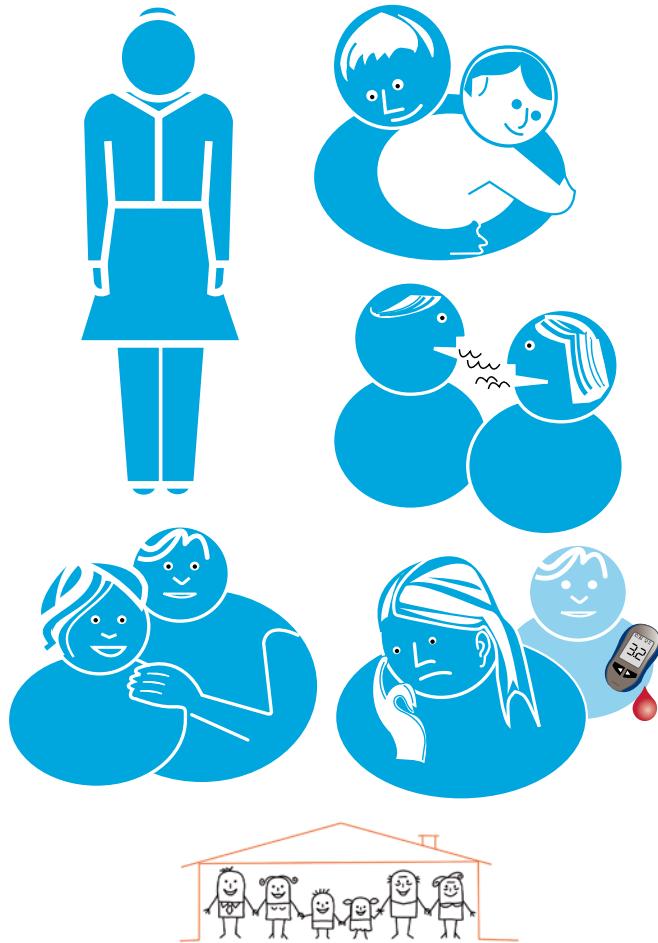

Figure 26.5 The family mirror.

Figure 26.6 Balance cards.

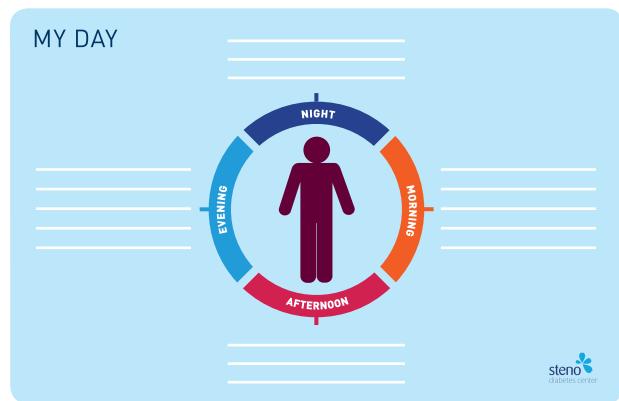

Figure 26.7 My day.

However, this theory is often unrecognized or poorly articulated, perhaps since a programme is an active open system that:

- Is apt to change over time as the programme unfolds.
- Works through the ideas and intentions of those implicated.
- Works differently among different subgroups.

Pawson and Tilley [138] describe the realistic evaluation approach, which focuses on three key concepts for understanding how, for whom, and under what conditions programmes will work: *most effective outcomes*, *mechanisms* through which outcomes occur, and *contexts* where the outcomes potentially will be replicable. Mechanisms refer to the process of how people interpret and act on the intervention to produce outcomes. Mechanisms are not assumed to be fixed, but are contingent on contexts. Thus, the programme theory can be expressed as context–mechanism–outcome configurations (C–M–O configurations). The evaluation implies the development of a theory about how outcomes, mechanisms, and contexts operate and use of this theory to direct empirical work. The evaluation focuses on exploring whether the theory can explain the observational data [138]. In a recent review regarding use of realistic evaluation, the use of C–M–O configurations was found to provide clarity in complex evaluation environments and rich information about what type of interventions work for whom in what context [139].

Table 26.4 shows a programme theory. If a person with diabetes is recruited to the programme and completes it, and if the programme takes a specific educational approach, then the person will attain improved knowledge and skills related to the management of diabetes and increased autonomy and quality of life. Working with programme theory, ideally a second level of data collection and analysis is needed in order to evaluate whether (i) the theory is right but not properly implemented; (ii) the theory should be refined; or (iii) the theory is wrong. Table 26.5 gives the key points in programme theory.

Conclusion

The provision of DSMES based on evidence, values and theories, skills, and tools (Figure 26.1) [35] is a challenging task; however, the evidence base of the beneficial effects of this approach is rapidly increasing. Self-management education is considered a complex intervention [140] with many different components, actors, and settings, leading to challenges in identifying the most effective components. Therefore, it is difficult to assess the effect of a single tool or method, or whether specific combinations of tools and methods or

Table 26.4 Programme theory.

Context	Mechanisms	Outcomes
The specific diabetes education programme or concept is applied: • Involvement, dialogue • Integrates cognitive, emotional, and bodily elements • Facilitates exchange of experience The educator has the skills to juggle, facilitate, and motivate, and is empathic	The participants reflect on their experiences and feelings and share them with other participants and the educator Educator talk ratio <40% on average The participants feel involved in the education process and experience that their individual needs are met	The participants increase their knowledge and confidence in relation to diabetes self-management The participants increase their well-being The participants engage in health-promoting behaviour The participants improve as regards articulated outcomes of the programme

Table 26.5 Key points in programme theory.

- Realistic evaluation is about theory testing and refinement
- Realistic evaluation develops and tests context–mechanism–outcome (C–M–O) configurations (hypotheses) empirically
- Realistic evaluation applies any approaches, tools, and methods that are appropriate to test a programme theory
- Realistic evaluation is potentially time-consuming as there is no independent criteria for closure

the quality or quantity makes interventions effective [141]. However, the Health Foundation in the UK identified effective elements of the implementation of 11 programmes of self-management support and shared decision making in chronic disease, including diabetes [141].

Figure 26.8 summarizes the points made in this chapter. A limiting factor of diabetes education is that it almost always does not include ongoing education and support. Once people with diabetes complete an education programme in its entirety, they are not provided with a component of ongoing support to allow tailoring of the education to their continued diabetes care needs. The ‘once’ education becomes education for life and therefore conclusive, without any opportunity for an information refresher or support mechanism that may be needed to adjust to changes in the perceived needs and preferences of people with diabetes. The lifelong process of diabetes self-management requires continued adjustments in knowledge, skills, motivation, and support. DSMES should be a lifelong process, starting at the point of diagnosis and remaining as an essential component of diabetes care [142].

Dietary Management of Diabetes

Nicola Guess

Department of Primary Care Health Sciences, University of Oxford, Oxford, UK

Key points

- Weight loss is a primary mediator of diabetes risk reduction and management of type 2 diabetes in those who have overweight or obesity.
- Calorie content and maintenance of the diet are more important than macronutrient content for successful weight loss maintenance.
- The type and quality of dietary fat and carbohydrate are more important than amounts of these macronutrients for prevention and management of diabetes and its complications.
- Various dietary patterns are effective for weight loss, and for diabetes and cardiovascular risk reduction, and clinicians should consider individual preferences.
- Matching carbohydrate to insulin dose, either as part of multiple daily insulin or continuous subcutaneous insulin regimen, is the most effective approach for the management of glycaemia in type 1 diabetes.
- Women with diabetes planning to become pregnant should take 5 mg of folic acid per day to prevent neural tube defects.
- Calorie restriction to lose weight should not currently be recommended during pregnancy, but limiting weight gain can improve pregnancy outcomes.
- Low-glycaemic index foods may help manage blood glucose concentrations during pregnancy.

Diet plays an important role in the effective management of type 1 diabetes and type 2 diabetes and is fundamental to the prevention of type 2 diabetes. The aim of nutritional management of diabetes is to optimize glycaemic and blood pressure management, correct any lipid abnormalities, and, in doing so, reduce the risk of long-term complications [1–3]. Dietary advice must be evidence based and individualized, taking into account personal and cultural preferences, and ensuring the diet is appropriate and compatible with the person's lifestyle, existing treatment regimen, other comorbidities, and willingness to change [1–3].
