Individuals with diabetes are up to four times more likely to develop cardiovascular disease [4,5], with an elevated risk also seen in impaired glucose tolerance [5] compared to individuals with normoglycaemia. Therefore, evidence-based nutritional recommendations for individuals with diabetes are based on the glucose management of the diabetes, reducing the risk of developing cardiovascular disease and the complications of diabetes [1–3]. The strength of evidence for the different nutritional recommendations for both management of diabetes and prevention of cardiovascular disease is graded according to the type and quality of published studies as well as statements from expert committees [2]. The gold standard for evidence-based guidelines is meta-analyses of large, well-controlled trials with long follow-up periods that include fatal or non-fatal clinical endpoints. However, this information is often not available and instead surrogate endpoints, such as glycaemia, body composition, lipoprotein profile, blood pressure, insulin sensitivity, and renal function, are used to determine the potential of dietary modification to influence glycaemic levels and risk of acute and chronic complications of diabetes [1,2].

There are many confounding factors within long-term dietary trials in diabetes, which limit the precision of such trials to establish effectiveness. These include but are not limited to differences in weight loss [2], medication withdrawal [6], and the composition and intensity of the control diet [7]. Adherence to a dietary trial protocol tends to lapse over time, which often means that intended differences in the dietary composition of intervention and control arms diminish in long-term trials [8]. While short-term trials can often achieve better adherence to a dietary intervention [9], the external validity of these trials to understand the long-term effect of diet on chronic disease management is poor. Each of these factors should be considered when interpreting findings from meta-analyses of nutritional interventions.

While nutritional science illuminates the underlying mechanisms of diet on disease risk, in practice nutrients are consumed as foods and as part of dietary patterns. Therefore, throughout this chapter, while reference will be made to the impact of individual macro- and micronutrients on clinical outcomes, it is important to consider how these nutrients form part of an overall healthful dietary pattern for diabetes prevention and management. Tables 27.1 and 27.2 summarize such dietary approaches.

Energy balance and body weight

Weight management is now understood to be the primary strategy for prevention of type 2 diabetes and for glycaemic management in people with type 2 diabetes who have overweight or obesity [1,2]. Weight gain is associated with an increased incidence of type 2 diabetes [10],

Table 27.1 The association of particular dietary components with risk or management of type 2 diabetes, and their inclusion or exclusion in established dietary patterns or guidelines.

Dietary components	Mediterranean	DASH	Diabetes UK	NICE	Effect on diabetes management/risk
Fruit	×	×	×	×	Dietary fibre associated with reduction of risk
Vegetables	×	×	×	×	Dietary fibre associated with reduction of risk
Nuts/seeds	×	×	×	×	↑ PUFA/MUFA to SFA ratio associated with reduction in FPG, HbA _{1c} , and insulin resistance Insoluble fibres associated with reduction in risk of diabetes Magnesium associated with reduction in risk of diabetes
Pulses	×	×	×	×	Soluble fibres reduce post-prandial glucose in randomized controlled trials. Low GI is associated with reduction of risk, and reduces HbA _{1c} by 5 mmol/mol (0.5%)
Fish and seafood	×		×	×	No known effects of omega-3 on diabetes management or risk
Increased white to red meat ratio			×	×	↑ PUFA/MUFA to SFA ratio associated with reduction in FPG, HbA _{1c} , and insulin resistance
Wholegrains/ cereal fibre	×	×	×	×	Insoluble fibres associated with reduction in risk of diabetes Magnesium associated with reduction of risk of diabetes
Low glycaemic index			×	×	Associated with reduction of risk, and reduces HbA _{1c} by 5 mmol/mol (0.5%)
Olive oil	×				↑ PUFA/MUFA to SFA ratio associated with reduction in FPG, HbA _{1c} , and insulin resistance

while weight loss reduces insulin resistance and improves glucose handling in people with and without diabetes [11]. A series of large-scale, lifestyle-based randomized controlled trials [12, 13] have conclusively shown that a 5–7% weight loss in people at risk of diabetes reduces risk by up to 66% (Figure 27.1). While these programmes also included other components such as increasing fibre, decreasing total and saturated fat, and increasing physical activity, weight loss was the primary driver of the reduction in risk [14]. A trial testing the independent effect of dietary fibre on type 2 diabetes development did not find that it significantly reduced the risk of type 2 diabetes [15]. Interestingly,

there also appears to be a legacy effect of weight loss on diabetes prevention, such that even three years after the intervention stopped, there was still a 48% risk reduction in the intervention group [16].

Each of the large-scale type 2 diabetes prevention trials tested a similar dietary pattern: low fat, with some of the trials specifying low saturated fat and/or high fibre. One recent multinational trial compared a high- versus low-protein diet and did not find that the protein content influenced the risk of type 2 diabetes [17]. However, prior to randomization to the high- or low-protein groups, all participants had undergone an intensive weight loss intervention and

lost about ~10kg over eight weeks. This type of intervention “reboots” the pancreatic β cells and normalizes blood glucose concentrations in type 2 diabetes [18], and likely would have done the same in people with pre-diabetes. Therefore, at the present time, it is unknown whether the addition (or reduction) of specific nutrients or food groups within a weight loss intervention could optimize type 2 diabetes prevention programmes.

Remission of type 2 diabetes

Remission of type 2 diabetes refers to the normalization of blood glucose concentrations in the absence of anti-diabetes medications, although there is currently no consensus on the exact

definition. While numerous short-term studies have shown that marked caloric restriction can normalize the underlying pathophysiology and hyperglycaemia of type 2 diabetes [19], until recently it was not known how enduring this *normalization* could be. The DiRECT trial (Diabetes Remission Clinical Trial) published in 2017 showed that remission of type 2 diabetes can be long-lasting, but is dependent on both the achievement and maintenance of substantial weight loss, in the order of 10–15 kg [18, 20].

Remission appears to be contingent on the return of the first-phase insulin response [21]. The first-phase insulin response declines along the pathway of type 2 diabetes; it is reduced in newly diagnosed type 2 diabetes and nearly absent in type 2 diabetes of long duration [22]. It appears that return of the first-phase insulin

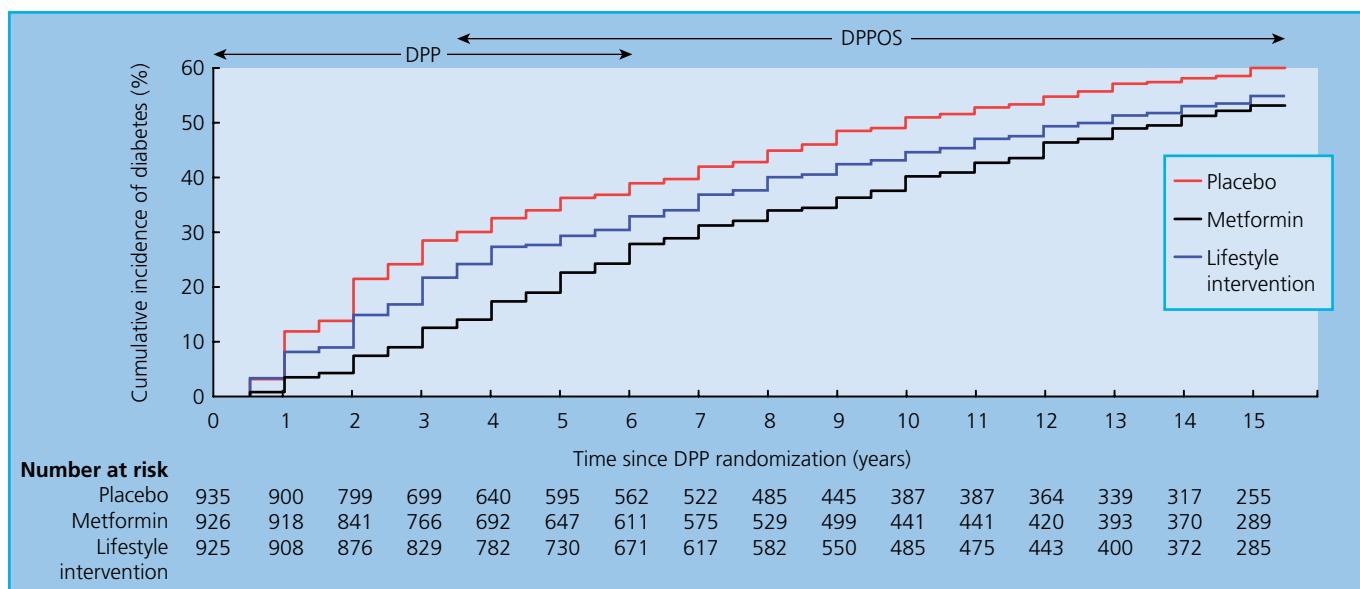

Figure 27.1 Reduction in the incidence of diabetes in the US Diabetes Prevention Program (DPP). This figure shows the data from the DPP itself and data from the follow-on Diabetes Prevention Program Outcomes Study (DPPOS), which followed the same individuals up to 15 years. response can occur in type 2 diabetes of short duration (within approximately 4–6 years of diagnosis), but is much less likely in type 2 diabetes of long duration [21].

As an emerging area of research, there are many unknowns surrounding remission of type 2 diabetes, including whether it can occur with more modest weight loss; and whether other dietary strategies, particularly low carbohydrate, could increase the rate of remission and prevent relapse to type 2 diabetes. Currently available data suggest that ketogenic or high-protein, low-carbohydrate diets could help achieve remission, potentially via mechanisms independent of weight loss [23, 24] but longer-term and/or controlled studies are needed to confirm this.

Weight loss also reduces important cardiovascular risk factors, including circulating triglycerides and blood pressure [2]. A systematic review of studies with at least two years' follow-up showed that intentional weight loss in people with type 2 diabetes reduces their mortality risk by 25%, with a higher risk reduction with greater weight loss [25]. The LookAHEAD (Action for Health in Diabetes) study found that an intensive lifestyle for primary prevention of cardiovascular disease did not significantly reduce cardiovascular disease-related morbidity or mortality after nearly 10 years of follow-up [26]. However, this may reflect the limitations of dietary improvements in long-term mortality in people treated aggressively with antihypertensive and lipid medications [27], and does not discount the role of weight loss and dietary change in improving quality of life [27], reducing intensification of medical treatment of diabetes and cardiovascular disease, and greater physical functioning [26, 27]. Reductions of 5–10% are effective at reducing cardiovascular risk factors and are achievable and feasible, although greater weight loss may reduce risk further [28].

Weight management has also been considered for people with type 1 diabetes, as the prevalence of overweight and obesity is increasing in type 1 diabetes [29] and the co-presentation of insulin resistance is associated with hyperglycaemia [30]. However, there is little evidence that body weight or weight loss influences glycaemic

levels in people with type 1 diabetes [29]. Furthermore, in both type 1 and type 2 diabetes, caution should be applied to intentional versus unintentional weight loss, as unintended weight loss in people with diabetes may also be an indication of suboptimal medical management or omission or inadequate dosing of medications leading to hyperglycaemia [31].

Therefore, national [32–34] and international guidelines [5] recommend initial weight loss of 5–10% in those with overweight or obesity for the purposes of type 2 diabetes management and prevention of type 2 diabetes and cardiovascular disease.

Currently there is no consensus on the optimal diet to achieve and maintain the recommended weight loss [1]; however, the overall energy content of the diet is more important than macronutrient composition [2, 35, 36]. Effective strategies for which there is evidence in people with diabetes include low-carbohydrate [37], low-glycaemic index (GI) [38], low-fat [28], or very low-calorie diets [39], and meal replacement [40]. There has been particular interest in low-carbohydrate diets, which appear to be most effective at promoting weight loss over the short term, and may also have beneficial effects on glycaemia independent of body weight [41, 42] and greater withdrawal of type 2 diabetes medications [42]. While there is little evidence for superiority over the long term [43, 44], practitioners should be open to this approach and individual preference. The primary factor in achieving and maintaining weight loss remains long-term maintenance of the diet, and the best approach is therefore one that fits with a person's lifestyle, habits, and goals [1, 2].

Carbohydrate and diabetes

The relationship between carbohydrate intake and glycaemia in type 2 diabetes is not straightforward and currently there is no definitive evidence that carbohydrate reduction *per se* durably lowers

glycaemia. However, carbohydrate intake remains the primary determinant of glycaemic levels in people with type 1 diabetes [1].

Quantity

There is no evidence for a specific quantity of carbohydrate in the diet for the management of type 2 diabetes [1]. The trial evidence is severely limited by varying amounts of carbohydrate being prescribed in the low-carbohydrate arm, the actual carbohydrate amount and type being consumed throughout the trial, whether or not anti-diabetes medications were taken or withdrawn during the trial, the protein content of the dietary arm, and differences in weight loss achieved. Physiological studies [41] and short-term trials [24] indicate that the ketones produced on a very low-carbohydrate (ketogenic) diet could help lower blood glucose independent of weight loss, perhaps by reducing hepatic glucose output [45]. Trial evidence [46, 47] shows that nutritional ketosis is an effective option for the management of type 2 diabetes, but whether it is superior to other approaches requires better controlled trials.

There are no randomized controlled trials investigating ecaloric carbohydrate restriction and risk of diabetes, but epidemiological data suggest there is no relationship between total carbohydrate intake and risk of type 2 diabetes [48]. Based on the currently available evidence, the quality and source of carbohydrate are more important than total amount for the prevention of type 2 diabetes.

In contrast, carbohydrate counting forms the basis of the management of type 1 diabetes, where recommended carbohydrate intake should take account of energy requirements, blood glucose concentrations, and insulin dosing [49, 50]. Carbohydrate counting is a meal planning approach that involves matching 10 g or 15 g carbohydrate portions to a particular bolus insulin dose [49], and is based on the premise that carbohydrate is the primary driver of post-prandial glucose concentrations [51]. As a concept, carbohydrate counting has been around since the 1920s, but has been widely employed since its use in the Diabetes Control and Complications Trial [52]. It is now the dietary strategy of choice in type 1 diabetes. Approaches to carbohydrate counting can vary immensely between country, region, institution, and individual practitioner, but may include the following:

- Carbohydrate awareness.
- Basic carbohydrate counting and label reading.
- Development of the person's skills in monitoring and recording blood glucose levels in relation to food intake, medications, and physical activity.
- Sophisticated matching of carbohydrate to insulin dose. This may include the use of wizard bolus meters or apps to aid in the estimation of carbohydrate intake and insulin requirement.

These techniques should enable the person with type 1 diabetes to add or subtract short- or rapid-acting insulin at meals and snacks to manage and correct blood glucose levels [49, 53]. The heterogeneity in these approaches must be taken into account when interpreting the evidence for carbohydrate counting [54].

Adjustment of insulin to carbohydrate intake

In people with type 1 diabetes treated with multiple daily insulin or continuous subcutaneous insulin infusions, carbohydrate counting with insulin dose adjustment is an effective approach to lower glycated haemoglobin (HbA_{1c}), reduce the occurrence of hypoglycaemic episodes, and improve quality of life and other clinical markers such as body mass index (BMI) and waist circumference [3, 53, 55, 56]. However, there is a need for good-quality education, and appropriate clinical support is necessary to ensure

accurate and consistent insulin dose adjustments [3, 57]. Inaccuracy in carbohydrate counting or dose adjustment is common, and is associated with poorer clinical outcomes [58]. Care must be taken to ensure that carbohydrate counting and dietary advice are not detrimental to an individual's weight management goal. Additional snacks are not automatically required and should be tailored to the individual's needs. Referral to a structured education programme of proven benefit is recommended, such as the DAFNE (Dose Adjustment For Normal Eating) programme, ideally 6–12 months after diagnosis [3]. In individuals with fixed or biphasic insulin regimens, consistency in carbohydrate intake is recommended and is associated with reductions in HbA_{1c} [3, 59, 60].

A small number of recent studies have suggested that the fat and protein content of the meal should also be taken into account when planning an insulin regimen [61, 62]. However, any potential physiological benefits of these approaches need to be balanced with the complexity and burden for the person with diabetes.

Carbohydrate in the treatment of mild to moderate hypoglycaemia

Mild or moderate hypoglycaemia is a common occurrence with insulin treatment in both type 1 diabetes and type 2 diabetes. Glucose is the most effective treatment and should be given immediately [3]. National and international guidelines recommend 15–20 g should be given straight away (Box 27.1), followed by another 15 g if blood glucose does not rise by 4 mmol/l after 15 minutes [49]. A follow-up carbohydrate snack (15–20 g) may be necessary to reduce the risk of further hypoglycaemia, particularly in circumstances where blood glucose is likely to continue to decrease, such as following alcohol consumption or physical activity [49].

Carbohydrate quality

Dietary carbohydrates represent a heterogeneous group of compounds, which include glucose, cellulose, fructose, lactose, starch, resistant starch, sucrose, oligosaccharides, and lignin. The diverse effects of these different structures [63] on diabetes and metabolic risk factors are too numerous to expand on in this chapter, but these factors emphasize the limitations of such terms as a high- or low-carbohydrate diet. Nevertheless, the *quality* of these different carbohydrates can be imperfectly but usefully captured by use of the glycaemic index.

The GI is an indication of the glucose-raising potential of the carbohydrate, and is defined by the incremental area under the blood glucose curve (iAUC) as a percentage of each person's average iAUC for a standard food, usually 50 g glucose or white bread [64]. The glycaemic load, which is the product of the dietary GI and total dietary carbohydrate, may also be used to express the overall quality of carbohydrate in the diet [65].

In people with type 2 diabetes, a Cochrane review of randomized controlled trials suggests adoption of a low-GI diet can lead to

Box 27.1 Foods containing 15–20 g of fast-acting carbohydrate

- Small glass of sugary (non-diet) drink
- At least three glucose tablets
- Five sweets, e.g. jelly babies
- Small carton of pure fruit juice
- Glucose gel

HbA_{1c} reductions of 5 mmol/mol (0.5%) [65]. While data from epidemiological studies suggest low-GI diets are associated with a lower BMI [66], randomized controlled trials have demonstrated a reduction in HbA_{1c} independent of changes in body weight [67,68]. Low-GI diets are associated with a lower risk of type 2 diabetes [69], but there are no controlled trials examining the effect of the GI on type 2 diabetes incidence as a primary outcome.

The evidence of effectiveness of low-GI diets in management of glycaemia of type 1 diabetes is unclear [2] and the latest National Institute for Health and Care Excellence (NICE) guidelines do not recommend their use in people with type 1 diabetes [3].

Low-GI diets may also reduce cardiovascular disease risk by lowering triglyceride and low-density lipoprotein (LDL) cholesterol levels [70]. However, current guidelines do not make specific recommendations regarding GI and cardiovascular disease risk.

Dietary fibre

The indigestible nature of dietary fibres renders them low or non-glycaemic [63,71]. However, dietary fibres themselves and foods high in fibre appear to influence glucose homeostasis beyond their GI [72,73]. Increasing dietary fibre by approximately 18 g/d up to a total intake of 50 g/d leads to a reduction in fasting plasma glucose of 0.7–0.9 mmol/l [72,74] and in HbA_{1c} of 4 mmol/mol (0.3%) [72]. However, according to the American Diabetes Association, there is insufficient evidence to recommend people with diabetes consume fibre in amounts exceeding the current recommended daily allowances (RDA) [75]. Furthermore, the majority of people in Western populations do not meet the minimum recommendations, and targeting this should be a dietary priority.

Dietary fibre is inversely associated with diabetes risk in cohort studies [76]. In the Finnish Diabetes Prevention Study, participants were advised to consume 15 g/1000 kcal of fibre [13], which appeared to reduce diabetes risk, an effect partly independent of its effects on body weight [77]. Current guidelines for diabetes prevention recommend increasing fibre intake to reduce diabetes risk [2].

Epidemiological data support a protective role of dietary fibre against cardiovascular disease, with the data most consistent for wholegrains [78]. There are currently insufficient data from randomized controlled trials, and current guidelines do not make specific recommendations for the role of fibre in cardiovascular disease risk.

Dietary mono- and disaccharides

Sucrose

Despite controversy about the role of sugar in diabetes management, moderate intake of sucrose (10–15% total energy) or other added sugars can be included in the diet of people with diabetes without worsening glycaemic levels or insulin sensitivity [2,60,79–81]; however, care must be taken not to exceed energy requirements [2,60,82]. In a randomized controlled trial, there was no difference in insulin resistance after six weeks of 25% versus 10% of energy from sucrose in healthy people [79]. In contrast, 11 per day of a sucrose-containing beverage increases hepatic lipid deposition compared to isocaloric quantities of milk, water, or aspartame-sweetened beverages [83]. There is no definitive evidence that sucrose *per se* influences cardiovascular disease risk, but the totality of the evidence supports limiting or avoidance of sucrose as a prudent dietary strategy [84]. In summary, recommendations for sucrose intake for people with or at risk of diabetes are based on those for the general population, namely limiting the consumption of energy-dense, nutrient-depleted sucrose.

Fructose

Fructose is a low-GI monosaccharide and isocaloric exchange of fructose for other carbohydrate improves glycaemic levels in people with type 2 diabetes over the short term, even when consumed up to 160 g/day [85]. However, the metabolism of fructose leads to processes detrimental to human metabolism, including increased *de novo* lipogenesis, higher ectopic lipid accumulation, and elevated triglycerides and uric acid, leading to non-alcoholic fatty liver disease and increased cardiovascular risk [86]. While there is a need to identify the optimal quantity of fructose that improves glycaemia without deleterious cardiometabolic effects [87], a variety of fruits and vegetables are to be encouraged as part of an overall dietary pattern [2] (Tables 27.1 and 27.2).

Non-nutritive sweeteners

The non-nutritive sweeteners approved for use in the UK and Europe include aspartame, saccharin, acesulfame potassium, cyclamate, and sucralose [88]. The increased sweetness of these compounds means they are consumed in minuscule amounts in the diet, and recommendations for people at risk of or with diabetes are the same as the general population [89]. These sweeteners do not contribute to energy intake or influence glucose levels [89]. Other sweeteners commonly used are sugar alcohols. While they are moderately glycaemic, sugar alcohols are consumed in such minor amounts that their consumption does not require alterations in insulin adjustment [2].

Dietary fat

The role of dietary fat in diabetes management has been of interest for decades following observations in the 1950s that dietary fat can modify insulin signalling [90] and the association between saturated fat and cardiovascular disease [2,91]. However, there appears to be little association between total fat in the diet and risk of diabetes [90]. Although diabetes prevention programmes have limited total fat [12,13], weight reduction *per se* and not macronutrient composition of the diet was the primary driver of risk reduction [14]. Similarly, there is no consensus on percent calories from fat in relation to diabetes management [2,90]. Instead, the types and sources of fat consumed and total quality of the diet appear to be more important.

Saturated fat

Replacement of saturated fat (SFA) with polyunsaturated fat (PUFA) is associated with a reduction in diabetes risk in multiple cohort studies [90,92]. The evidence is stronger for replacement with PUFAs than monounsaturated fatty acids (MUFAs), but this may reflect the close association of MUFAs with SFAs in Western diets and the availability of biomarkers for PUFA intake in prospective studies [90]. Data from randomized controlled trials do not consistently demonstrate a detrimental effect of SFA on insulin sensitivity [93–95], but methodological differences in these studies, such as sample size, duration, and the macronutrient that replaces SFA, may explain these inconsistencies.

The proposed relationship between SFA and cardiovascular disease largely arose based on early population studies [96]. However, several updated meta-analyses have questioned the conclusion that simply reducing SFA intake will necessarily reduce cardiovascular disease prevalence [97,98]. Instead, replacing the macronutrient

appears to be important: replacement of SFA with refined but not high-quality carbohydrate or unsaturated fat has been linked to worsening of atherosclerotic risk factors including elevated triglycerides, reduced high-density lipoprotein (HDL) cholesterol, and increased concentrations of small, dense LDL particles [97–101], emphasizing the need to consider the quality of the diet as a whole.

Similarly, recent studies have also drawn attention to the heterogeneous nature of dietary fat classes, with short-chain, long-chain, and odd-chain SFAs associated with diabetes risk reduction, and medium-chain SFAs associated with increased risk [102, 103]. Odd-chain fatty acids are predominantly found in dairy products, but whether or not these fatty acids have beneficial effects *per se* or whether these associations reflect other nutrient components found in dairy is currently unclear.

Similarly, SFAs come from a variety of food sources, including red and processed meats, dairy products, nuts, and oils, and a prudent approach is therefore to promote foods associated with healthful dietary patterns such as nuts, seeds, oils, low-fat dairy, fish, and fruit and vegetables, and to limit red (particularly processed) meat and butter (Tables 27.1 and 27.2).

In summary, current guidelines recommend limiting saturated fat to 7% of energy intake, but careful consideration should be given to the replacing macronutrient and overall dietary pattern (Tables 27.1 and 27.2).

Polyunsaturated fat

The most abundant PUFA in the diet is linoleic acid, which is inversely associated with diabetes incidence and cardiovascular disease in prospective cohort studies [90, 92]. The use of long-chain PUFAs as biomarkers for intake strengthens the subjective nature of cohort studies, which typically rely on self-reported dietary intake [90, 104]. Clinical trials evaluating the effect of PUFAs on insulin sensitivity or surrogate markers for diabetes risk have not been consistent [105–107]. The short duration of some of these studies may be important, as PUFAs are believed to act partly via altering membrane fluidity, which may take up to three months [90].

Replacement of saturated fat with PUFAs reduces cardiovascular disease risk, and surrogate risk markers [97–101, 108, 109], and sources of PUFAs such as nuts, seeds, and vegetable oils should be encouraged as part of a healthy diet (Tables 27.1 and 27.2).

Omega-3 fatty acids

There is little evidence from observational and experimental studies that omega-3 fats improve glycaemia in healthy individuals and people with type 2 diabetes [110, 111] or reduce the risk of developing diabetes [107], and high doses of fish oil impair glucose homeostasis [110]. In contrast, the cardioprotective effects of omega-3 fats, such as reducing serum triglycerides and modifying platelet aggregation and thrombogenicity [112], have led to recommendations to include oily fish twice a week to reduce cardiovascular disease [2, 33, 113]. Importantly, *more* is not better, and previous support for omega-3 supplementation for prevention of cardiovascular disease in people with diabetes was withdrawn by NICE [33].

Monounsaturated fat

Recent evidence from the PREDIMED (Prevención con Dieta Mediterránea) and earlier KANWU (Kuopio, Aarhus, Naples, Wollongong and Uppsala) trials suggests MUFAs may improve insulin sensitivity and reduce diabetes risk independent of energy restriction, particularly where MUFAs replace SFAs [93, 114].

There is also good evidence from randomized controlled trials that diets high in MUFAs can reduce glucose concentrations in people with type 2 diabetes [115–117], and can be used to replace carbohydrate without detrimental effects [2, 118]. There are few studies that have specifically examined the effect of MUFAs on glycaemic levels in individuals with type 1 diabetes, and there is insufficient evidence to make firm recommendations.

Replacing SFAs with MUFAs can reduce risk of cardiovascular disease [119, 120], and controlled trials demonstrate that high-MUFA diets can increase HDL cholesterol, lower blood pressure, and improve other surrogate markers of cardiovascular disease risk [98, 105, 108, 121, 122].

MUFA is a significant component of a Mediterranean diet [123], and it is important to consider the confounding effects on clinical risk factors of other aspects of this dietary pattern, including fish, fruits and vegetables, and moderate alcohol. For example, in the PREDIMED trial, extra-virgin olive oil had a greater effect on cardiovascular disease risk reduction than olive oil, despite identical proportions of MUFA, indicating that nutritive and non-nutritive components are also important [124]. Therefore, while MUFAs appear to have independent effects on glucose homeostasis and cardiovascular disease risk, greater risk reduction is likely achieved by following a diet rich in wholegrains, fruit, vegetables, fish, and limited saturated fat [2, 123, 124].

Trans fats

Trans fats occur naturally in foods such as milk or other dairy products as a byproduct of rumination or are produced industrially (partially hydrogenated vegetable oils). There is little evidence that total trans fat in the diet influences glucose homeostasis [125]; however, prospective studies using the dairy fat transpalmitoleic acid as a biomarker have shown that this naturally occurring trans fat is inversely related to diabetes risk [126]. However, it is unclear whether the fat *per se* has beneficial effects on glucose homeostasis, or whether the erstwhile nutrients of dairy mediate this risk reduction. Naturally occurring trans fats are found in minute amounts in dairy foods, whereas industrially produced trans fat can contribute up to 4 g a day in US diets [127].

There is compelling evidence from clinical and epidemiological studies that industrially produced trans fats have a deleterious effect on cardiovascular disease risk [127–129], and national and international guidelines have recommended their reduction or complete elimination in the diet [2, 127, 130].

In practice, these observations support and inform recommendations for a healthy dietary pattern (Table 27.2), with dairy products forming part of approaches, such as the well-researched Dietary Approaches to Stop Hypertension (DASH) diet, and minimizing foods high in hydrogenated vegetable oil, which typically include biscuits, cakes, and other sweet, high-fat goods.

Dietary cholesterol

There is little evidence that dietary cholesterol increases diabetes risk [131]. Instead, recommendations to limit cholesterol intake come from some clinical studies, which have demonstrated that dietary cholesterol can raise LDL cholesterol [132]. This contention has been a subject of considerable debate for many years. A recent meta-analysis of prospective studies examining whether dietary cholesterol ultimately influences risk of cardiovascular disease was inconclusive [133] and the American Heart Association/American

College of Cardiology have raised concerns about the heterogeneity of the data available [127]. However, given the potential impact of dietary cholesterol on LDL cholesterol, the possible increased absorption of dietary cholesterol in people with diabetes [134], and the elevated risk of cardiovascular disease in people with diabetes, any changes to current guidelines to limit dietary cholesterol to 200–300 mg/d are premature [135].

Protein

Given the primary role of weight loss in the prevention and management of type 2 diabetes and prevention of cardiovascular disease, numerous studies have evaluated the effect of higher protein intakes on satiety and weight management in amounts of up to 40% energy from protein [136–139]. However, the concomitant changes in the amount and quality of carbohydrate and fat in these studies make it difficult to draw any firm conclusions. Guidelines therefore reiterate that the most effective weight loss diet is one that takes into account an individual's preferences, beliefs, cultural values, and practical considerations [1, 2, 140].

Protein is also a macronutrient of interest due to its capacity to increase insulin secretion acutely [141]. However, a high protein intake could induce insulin resistance [142], and therefore the long-term effect of high protein on glycaemia [143] or type 2 diabetes risk may be a trade-off between its effect on promoting prandial insulin release while potentially reducing insulin sensitivity [144]. Suggestions that dietary protein may be modestly linked to increased risk of diabetes [145] may reflect sources of protein such as red or processed meats; dietary patterns that provide vegetable sources of protein alongside low-fat meat represent a prudent approach (Table 27.1).

Increasing the protein content of the diet lowers liver fat [146, 147], independent of weight loss. The provision of amino acids protects against hepatic triglyceride deposition under experimental obesogenic conditions [148, 149]. Given the association between liver fat and type 2 diabetes, high-protein diets might therefore be expected to offer protection against the development of type 2 diabetes.

High-protein diets may also have a role to play in managing hypertension. Observational studies [150] and trials in which carbohydrate is replaced with protein [151, 152] indicate that diets high in plant-based protein in particular may help in managing this cardiovascular disease risk factor.

People with diabetes are at higher risk of renal disease, and caution should be employed when recommending changes to protein intake in individuals with chronic kidney disease. In people with stage 3–5 chronic kidney disease not requiring dialysis, a restricted protein intake of 0.6–0.8 g/kg of body weight/d has been recommended by expert panels [153]. Persons with chronic kidney disease on dialysis require 1.0–1.2 g/kg of body weight/d [153].

Micronutrients

Several micronutrients have been specifically linked to diabetes risk in cohort studies; however, very few randomized controlled trials have confirmed these associations. Such micronutrients include magnesium [154], vitamin D [155], calcium [156], and chro-

mium [157]. Similarly, epidemiological trials and *in vitro* data have suggested that antioxidant vitamins and folate (vitamins A, C, E, and beta-carotene) could play a role in modifying cardiovascular disease risk. However, well-designed randomized controlled trials to confirm these associations are lacking [158], and NICE does not recommend such supplementation [159].

Therefore, current guidelines recommend regular consumption of a variety of vegetables, fresh fruit, legumes, dairy products, vegetable oils, nuts, wholegrain breads, and oily fish to ensure that recommended vitamin and mineral requirements are met [1] (Tables 27.1 and 27.2). This message should be reinforced alongside clarification that there is no proven benefit of vitamin or mineral supplements for management of diabetes.

Salt or sodium

Reduced sodium intake can lower blood pressure, and sodium intake should be limited across the population, including individuals at higher risk of cardiovascular disease [160, 161]. A reduction in mean salt intake of 3 g/d for adults (to achieve a target of 6 g/d) would lead to around 14–20 000 fewer deaths per year from cardiovascular disease [162]. Dietary patterns, such as the DASH diet, that are low in sodium and high in potassium, magnesium, and calcium form an effective approach to control hypertension and are appropriate in people with diabetes (Table 27.2).

Sterols and stanols

Plant sterols and stanols have no known effect on glucose homeostasis, but reduce LDL and total cholesterol in people with and without diabetes [163]. Dietary guidelines have recommended 2–3 g/d of fortified foods to lower LDL and total cholesterol irrespective of whether the individual is taking statins [2], but they are not included in the updated NICE guidelines for lipid modification in the prevention of cardiovascular disease in people with diabetes.

Alcohol

In cross-sectional and prospective studies, a modest alcohol intake is associated with a reduced risk of diabetes and cardiovascular disease, while excessive (>30–60 g/d) and chronic intakes appear to raise blood pressure, increase plasma triglycerides, and heighten the risk of cardiovascular disease [164, 165].

In people with diet-treated diabetes, alcohol consumed with carbohydrate may raise glucose levels, but does not appear to affect glucose or insulin concentrations when consumed alone [140]. However, in people treated with insulin or insulin secretagogues, alcohol increases the risk of hypoglycaemia [2, 140]. The risk increases with the quantity of alcohol consumed and may remain elevated the following day [166]. Therefore, in these people, alcohol should be consumed with food.

Finally, alcohol is a source of energy and is associated with increases in BMI and greater waist-to-hip ratio [167]. Therefore, recommendations for prevention and management of diabetes are the same as those for the general population: 2–3 units/d in women;

3–4 units/d in men [2]. One alcohol unit is measured as 10 ml or 8 g of pure alcohol. This equals one 25 ml single measure of whisky (alcohol by volume [ABV] 40%), or a third of a pint of beer (ABV 5–6%), or half a standard (175 ml) glass of red wine (ABV 12%). The new UK Department of Health guidelines recommended only 14 units per week for both men and women [168].

Diet in special circumstances

Diet in pregnancy

Diabetes increases the risk of adverse pregnancy outcomes, and the risk increases with the duration of diabetes (Chapter 71) [169]. Maintenance of HbA_{1c} towards the target of 48 mmol/mol (6.5%) is likely to reduce the risk of congenital malformations, but may be associated with increased episodes of hypoglycaemia. Excess weight gain is associated with worse glycaemic levels [140, 170]. Therefore, women with a BMI of 27 kg/m² should be provided with advice and support to attain a healthy weight prior to pregnancy [170]; however, weight reduction should not be attempted during pregnancy [171]. In the UK there are no specific guidelines on weight gain during pregnancy, though NICE emphasizes that energy needs do not change in the first six months of pregnancy and increase by a modest degree (approximately 200 kcal/d) in the last three months. The Institute of Medicine has more defined guidelines for weight gain over each trimester, which range from 11 to 20 lb (5–9 kg) for mothers who have obesity at conception to 28–40 lb (13–18 kg) for underweight mothers [172]. There is little evidence to support particular dietary approaches during pregnancy. However, a low-GI diet may modestly improve glycaemia [2, 173].

Folic acid requirements increase to 5 mg/d for women with diabetes, as risk of neural tube defects is increased [168]. Folic acid should be taken up to 12 weeks' gestation to prevent neural tube defects. However, in practice, 50% of pregnancies in the UK are unplanned, in which case folic acid supplementation should be commenced immediately [168].

Diet in children with diabetes

Management of type 1 diabetes and type 2 diabetes in children does not differ substantively from that in adults [140, 174, 175]. Children and their families (or carers) should receive education that covers insulin therapy and dosage adjustment; blood glucose monitoring; detecting and managing hypoglycaemia, hyperglycaemia, and ketosis; and the effects of diet, physical activity, and intercurrent illness on blood glucose levels. Additionally, age and maturity, emotional well-being, and life goals should be considered in an individualized approach. As energy requirements change with age, growth rates have to be monitored and the evaluation of a meal plan should be rechecked at least once a year [176].

As in all healthy children, energy and nutrient intakes should be adequate to ensure optimal growth and development. Good nutrition may also contribute to maintaining normal serum lipid values and meeting blood pressure goals. Meal plans must be individualized to accommodate food preferences and the eating pattern of the family [176].

Exercise and insulin-treated diabetes

Physical activity and exercise have numerous benefits for people with diabetes, including improved glucose levels, lower blood pressure, reduced requirements for medications, and lower cardiovascular risk (Chapter 28) [1–3]. However, risk of hypoglycaemia increases with exercise intensity and duration in insulin-treated diabetes, and careful management of glucose is critical [1–3, 177]. Referral to a specialist diabetes dietitian is recommended to advise on optimal management of different modalities, duration, and intensity of exercise [3]. However, general recommendations for insulin-treated diabetes are to adjust insulin dosing for planned exercise, and to provide additional dietary carbohydrate for unplanned exercise [2, 50, 177]. In practice, for the majority of people who engage in moderate physical activity, additional carbohydrate requirements increase only modestly, and an additional 10–15 g/h should be sufficient to maintain blood glucose levels [50].

For more serious exercisers and athletes, the amount of carbohydrate required will be based on the individual, with sufficient carbohydrate prior to exercise in order to maintain glucose levels during the exercise, and replenishment of glycogen stores in the post-exercise period to enhance performance and prevent hypoglycaemia during the next exercise bout, particularly for those who exercise daily [175, 178]. The complexity, both physiological and psychological, of managing glycaemia during exercise has been acknowledged, and individuals with type 1 diabetes may benefit from specialist support [179].

Many exercisers, particularly young men engaged in weight training, have specific questions about protein intake. There is little evidence that excessive protein intake increases muscle growth or mass in most casual exercisers; but for weight lifters or endurance athletes, the American College of Sports Medicine recommends 1.4–1.7 g/kg/d [180, 181]. In general, most athletes or weight-training men will meet this protein requirement through diet alone. For individuals who do not consume sufficient protein, shakes supplemented with proteins such as whey can be consumed. However, careful monitoring of blood glucose is advised, as whey and other proteins lower glucose levels in people with and without diabetes [147, 182]. Although no studies have been carried out in people with type 1 diabetes, whey could theoretically increase the risk of post-exercise hypoglycaemia. In practice, most shakes of this type will contain additional carbohydrate, which may counteract any glucose-lowering effect.

Key points

- In people with type 1 diabetes, exercise improves fitness and strength, reduces cardiovascular risk factors, and improves well-being.
- While regular exercise has not conclusively been found to improve glycaemia in type 1 diabetes, it is associated with decreased long-term morbidity and mortality in this population.
- Managing type 1 diabetes in the context of exercise can be complicated by both hypoglycaemia and hyperglycaemia during and after exercise.
- It is recommended that individuals with type 1 diabetes adjust their insulin dose and carbohydrate consumption prior to, during, and/or after exercise to accommodate the type, intensity, and duration of exercise performed.
- Structured, supervised diet and exercise interventions can reduce the risk of developing type 2 diabetes by ~60% in individuals with impaired glucose tolerance.
- Regular exercise improves fitness and strength, reduces cardiovascular risk factors, and improves glycated haemoglobin (HbA_{1c}), and is associated with decreased long-term morbidity and mortality in people with type 2 diabetes.
- People with type 2 diabetes should combine aerobic and resistance exercises for ≥ 150 min/wk to maximize the effect of exercise on glucose levels.
- While regular exercise has not conclusively been found to prevent gestational diabetes, there is emerging evidence that it can improve glycaemia in women with gestational diabetes.

Defining exercise, type of exercise, and intensity

Physical activity, exercise, and physical fitness are terms that describe different concepts. However, they are often confused with one another, and the terms are sometimes used interchangeably. Physical activity is defined as any bodily movements that involve muscle contraction to produce energy expenditures above the basal level. Exercise is a type of physical activity, which is planned, structured, and repetitive, with the objective of improving or maintaining physical fitness [1]. Physical fitness is generally accepted as the ability to carry out daily tasks without undue fatigue. Physical fitness comprises various elements, including health-related and skill-related components.

Physical activity is measured in metabolic equivalent (MET) units that estimate the oxygen consumption of an activity. One MET is equivalent to oxygen consumption of $3.5 \text{ ml O}_2/\text{kg/min}$ in a resting seated adult. Moderate physical activity, which includes leisure cycling, swimming, walking, and general house cleaning, is equivalent to 3–6 METs. Vigorous physical activity is activities equivalent to >6 METs, such as running, rope jumping, and sit-ups.

Physical fitness refers to the circulatory and respiratory systems' ability to supply oxygen during sustained exercise. The intensity of an exercise is typically measured as a percentage of maximal oxygen consumption ($\text{VO}_{2\text{max}}$). Moderate activity is when the body utilizes

40–60% of $\text{VO}_{2\text{max}}$, whereas high-intensity activity reaches 80–90% $\text{VO}_{2\text{max}}$. The volume of exercise is usually measured by the duration of the activity.

Exercise can be categorized into aerobic, anaerobic and resistance training. There are few data to support that one type of exercise is superior to another in terms of general health benefits [2]. However, an exercise that is enjoyable and suitable to the individual is likely to be performed regularly and maintained for a longer period.

Aerobic exercise engages large muscle groups with repetitive and continuous movements for ≥ 10 minutes to produce improved oxygen utilization with the aim of improving cardiovascular and respiratory fitness. Examples include walking, cycling, and jogging.

Anaerobic exercise comprises short, but high-intensity, bursts of physical activity that rely on rapid release of energy produced via glycolysis, rather than being dependent on oxygen consumption. This exercise builds lean muscles, improves muscle and bone strength, and enhances sports performance.

Resistance training enhances muscle strength by working muscles against a resistance load or weight. By altering the combination of weight load and frequency of repetition, this exercise improves muscle endurance and strength as well as increasing the lean muscle mass and metabolic rate.

Aerobic, anaerobic, and resistance training exercises can be used alone or in combination to achieve the desired effect of improving cardiorespiratory fitness, muscle strength, and endurance, as well

as achieving weight loss and its maintenance. The type, intensity, and volume of exercise should be tailored to individual needs to allow maximal adherence and long-term health benefits. Although the benefits greatly outweigh the risks, there are restrictions to exercise for people with certain medical conditions in terms of the type and intensity of physical activity. Gradual increases in exercise intensity and volume are generally advisable, but especially in those who are ordinarily sedentary at the start of an exercise programme.

Type 1 diabetes and exercise

Prevention of type 1 diabetes

Many people view type 1 diabetes as affecting young, otherwise healthy individuals. This together with the disease's autoimmune pathogenesis mean that regular exercise is not typically thought to prevent type 1 diabetes. Evidence is now emerging, however, that exercise may be one of the modifiable factors that interact with genetic predisposition to determine if and when type 1 diabetes develops [3].

Figure 28.1 shows the possible mechanism by which exercise could improve or maintain β -cell mass. Physical activity induces elevations in circulating levels of growth hormone (GH), insulin-like growth factor I (IGF-I), glucagon-like peptide 1 (GLP-1), interleukin 6 (IL-6), and IL-1 receptor agonist (IL-1 RA), all of which increase proliferation of β cells [4–8]. By reducing fat and visceral fat mass, exercise reduces pro-inflammatory adipokines, such as leptin and tumour necrosis factor α (TNF- α), and increases anti-inflammatory adipokines, such as adiponectin, which may help to reduce β -cell death [9]. Exercise may reduce the destructive immune response to the β cell by reducing the Toll-like receptors (TLRs) on monocytes and macrophage immune cells [10]. Finally, exercise improves insulin sensitivity, which in turn helps to normalize plasma glucose [11] and serum lipids [12], which may cause β -cell death when chronically elevated.

In animal models of diabetes, exercise protects the β cell from oxidative stress [13]. In healthy individuals [14], those at risk of type 2 diabetes [15], and people with type 2 diabetes, regular exercise improves β -cell function [16]. However, no human studies have examined whether exercise can delay or prevent individuals at risk from type 1 diabetes from developing the disease. However, the fact that exercise improves insulin resistance, which predicts progression to type 1 diabetes [17], coupled with findings from a cross-sectional study that reported that increased physical activity was associated with better glucose levels, lower insulin needs, and higher C-peptide levels at the onset of type 1 diabetes [18], suggests that more human research is needed in this area.

Treatment of type 1 diabetes

Although the evidence for benefit is less than for type 2 diabetes, there is sufficient to suggest that exercise should be encouraged in people with type 1 diabetes. Figure 28.2 summarizes the benefits that people with type 1 diabetes can expect from exercise.

Physical fitness, cardiovascular disease, and mortality

Although there are only a few small studies of fitness in people with type 1 diabetes, young adults (12–44 years old) with type 1 diabetes are less fit than matched individuals without diabetes, despite similar levels of physical activity [20–24]. Abnormalities in cardiac muscle and autonomic nerve function [25], reduction in skeletal muscle size and power [26], as well as an altered cardiac metabolism that favours non-esterified fatty acids (NEFA) over glucose as a fuel source [27], may contribute to this. Supervised physical activity programmes, however, improve fitness in people with type 1 diabetes [28–30], with increases in $VO_{2\max}$ of up to 27% [22, 30–34].

No large randomized controlled trials (RCTs) have examined whether regular physical activity reduces cardiovascular disease or mortality in type 1 diabetes. A large retrospective study, the Pittsburgh Insulin-Dependent Diabetes Mellitus (IDDM) Morbidity and Mortality study, suggests that regular physical activity may be of benefit. This study demonstrated that in men with

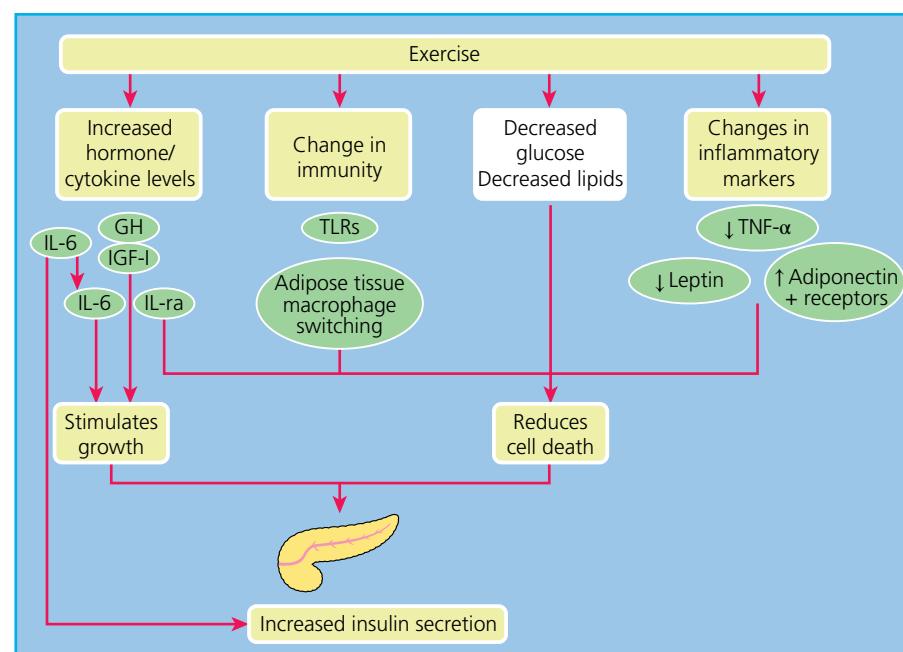

Figure 28.1 Potential mechanisms through which exercise could improve β -cell mass and/or function. GH, growth hormone; GLP-1, glucagon-like peptide 1; IGF-I, insulin-like growth factor I; IL-1 RA, interleukin 1 receptor agonist; IL-6, interleukin 6; TLR, Toll-like receptors; TNF- α , tumour necrosis factor α . type 1 diabetes of 25 years' duration, those who had participated in team sports during high school were three times less likely to report macrovascular disease and had mortality rates three times lower than those who did not participate [35]. This pattern was not seen in women, but their participation in team sports was lower (24% reported participation versus 39% in men). The level of physical activity in adulthood (measured using a validated questionnaire) also predicted mortality at six years [20]. Sedentary men were three times more likely to die than active men, and a similar (but again non-significant) effect was seen in women. In the Finnish Diabetic Nephropathy (FinnDiane) study, a prospective and observational study of 2369 individuals with type 1 diabetes who were followed up for a mean of 11.4 ± 3.5 years, exercise was associated with a lower risk of premature all-cause and cardiovascular mortality in both men and women with type 1 diabetes. This study also demonstrated that physical activity is associated with a lower risk of mortality in those with type 1 diabetes and chronic kidney disease [36].

Glycaemic levels and insulin requirements

The effect of physical activity on glycaemia in people with type 1 diabetes is unclear, with some studies showing benefit but the majority showing no benefit. Table 28.1 lists the intervention studies where the controls have type 1 diabetes and Table 28.2 lists other studies.

The intervention studies have tended to use supervised exercise programmes of short duration (1–3 months), have involved small numbers of participants (all but one had fewer than 60), and predominantly involved adolescents or young adults. There have been several meta-analyses of the effect of exercise on glycated haemo-

globin (HbA_{1c}) in type 1 diabetes. Kennedy et al. only included studies in which there was a non-intervention group of participants with type 1 diabetes [80]. They found no glycaemic benefit of exercise in people with type 1 diabetes. However, subanalyses suggested that exercise may confer glycaemic benefit in the young, and when undertaken for longer periods. They also stated that exercise can be carried out by people with type 1 diabetes without significant risk of hypoglycaemia. This is important because some studies have reported that hypoglycaemia is a barrier to exercise in those with type 1 diabetes [81,82].

Tonoli et al. [83] used less stringent criteria, including trials with no control groups, but excluded some of the studies used in the Kennedy analysis. Exercise overall resulted in a small but statistically significant reduction in HbA_{1c} (0.3%; 3 mmol/mol). When exercise was analysed by type, aerobic exercise reduced HbA_{1c} by 0.2% (2 mmol/mol), strength training did not lower HbA_{1c} , and combined aerobic exercise and strength training showed a statistically significant reduction in HbA_{1c} of –1.6% (17 mmol/mol).

In the meta-analysis by Wu et al. [84], studies were included if they were RCTs, quasi-experimental trials, and crossover trials and the exercise intervention comprised supervised or unsupervised aerobic, resistance, or combined physical activity for ≥ 4 weeks. The study identified 21 studies that met these criteria and had HbA_{1c} before and after the intervention, with 7 having adult participants and 17 children and adolescents. Overall HbA_{1c} fell by 0.45% (5 mmol/mol) in the exercise group compared to control. When broken down by age, children and adolescents saw a fall of 0.6% (6 mmol/mol), but no effect was seen in adults. Subgroup analysis showed that combined exercise was the only form of exercise that

All studies quoted have included people with type 1 diabetes in the intervention group, but the control group has either not been present or has included people without diabetes. The studies are listed in chronological order according to physical activity effect on HbA_{1c}.

BMI, body mass index; NA, not available.

significantly lowered HbA_{1c} (-0.71% ; 8 mmol/mol). It also suggested that people needed to exercise more than three times a week and for longer than 12 weeks to see an effect on HbA_{1c}.

Studies in people with type 1 diabetes that have examined the effect of exercise on plasma glucose have not shown a consistent benefit on fasting glucose [28, 33, 69, 70]. However, these studies have shown, as seen with healthy individuals [50], that blood glucose decreases (without hypoglycaemia) around the time of exercise [37, 71]. The lack of glycaemic benefit as assessed by HbA_{1c} may result from rebound hyperglycaemia immediately following exercise, and better management of this may be beneficial.

Two main factors may account for the poor effect of exercise on HbA_{1c}. Many individuals with type 1 diabetes consume energy when physical active, either as a fuel source or to manage hypoglycaemia, and this may counteract any glucose-lowering effect of physical activity [50]. Similarly, people with type 1 diabetes who exercise regularly reduce their daily insulin dosages by 6–15% [28, 29, 48]. While this may be required to manage hypoglycaemia, these reductions may mask improvements in HbA_{1c}.

Vascular risk factors other than glucose

People with type 1 diabetes commonly have hypertension and dyslipidaemia that are associated with increased risk of vascular disease [85]. Most studies suggest that physical activity in people with type 1 diabetes improves lipid profile [22, 28, 30, 31, 33, 59]. These studies were of short duration (generally ≤ 4 months) and showed similar benefits to those seen in individuals without diabetes. High-density lipoprotein (HDL) cholesterol increased by 8–30%, while low-density lipoprotein (LDL) cholesterol and triglycerides decreased by 8–14% and 13–15%, respectively. Exercise also reduces apolipoprotein B, which is pro-atherogenic and is associated with premature mortality in type 1 diabetes [86], and increases the anti-atherogenic apolipoprotein A-I [28]. These benefits are independent of changes in glycaemia and weight and most pronounced in those with an adverse lipid profile.

Only four studies have examined the effect of physical activity on blood pressure in type 1 diabetes. All four studied young adults and used similar supervised exercise programmes. Two showed no benefits in systolic or diastolic blood pressure [31, 33] and two showed a 2–3% reduction in blood pressure [51, 59]. Three studies were small: 26, 14, and 20 participants, respectively [31, 33, 59]. The remaining study was larger and included 196 participants and was one of the studies to show a benefit [51].

People with type 1 diabetes have clear evidence of endothelial dysfunction and this is worse if microalbuminuria is present [21]. Regular exercise can reverse endothelial dysfunction [87] and improve vascular function, but this improvement is not as great as that seen in individuals without diabetes [31, 88]. Improved vascular function is also seen in vascular beds not supplying exercising muscles, suggesting that this is a global rather than local benefit of exercise. Benefits only persist while people are exercising regularly and cease soon after regular activity is stopped.

Although less insulin resistant than those with type 2 diabetes, people with type 1 diabetes are more insulin resistant than matched individuals without diabetes [21, 30]. This insulin resistance can be improved by up to 23% by both resistance and endurance exercises [29–31, 66].

The beneficial effects of physical activity on insulin resistance, as well as on lipid levels and endothelial function, suggest that physical activity should reduce vascular complications in type 1 diabetes.

Microvascular complications

Increased physical activity is associated with fewer diabetes-related complications in individuals with type 1 diabetes [89]. In the Pittsburgh IDDM Morbidity and Mortality study [90], in men but not women activity levels were inversely associated with the risk of nephropathy and neuropathy, but not retinopathy. However, a retrospective analysis of baseline physical activity in the Diabetes Control and Complication (DCCT) trial found that rates of development or progression of diabetic retinopathy, nephropathy, and neuropathy were unaltered by physical activity after a mean follow-up of 6.5 years [91].

Other studies have shown an inverse association between physical activity and the severity of several complications in type 1 diabetes [89, 92]. A follow-up study involving 1945 individuals with type 1 diabetes reported that those involved in either little leisure-time physical activity or low-intensity activity were more likely to have impaired renal function and more proteinuria as well as greater rates of retinopathy and cardiovascular disease when compared to their more frequently and more vigorously active counterparts [89]. Balducci et al. randomized 78 people (21 with type 1 diabetes and 57 with type 2 diabetes) without signs and symptoms of peripheral diabetic neuropathy to either supervised exercise or a control group [92]. The percentage of people with diabetes who developed motor and sensory neuropathy during the four-year study was significantly higher in the control than the exercise group, 17.0% vs 0.0% and 29.8% vs 6.4%, respectively. Thus, long-term aerobic exercise training seems to prevent the onset or modify the natural history of diabetes neuropathy [92].

More recently, a cross-sectional multicentre study of 18028 people with type 1 diabetes reported that frequencies of retinopathy and microalbuminuria were lower in active compared with inactive people [93]. However, due to the cross-sectional design, no causality can be inferred. It remains unclear whether the presence of comorbidities affected people's ability to exercise or whether being physically active decreased the risk of developing these complications.

β -cell function

Type 1 diabetes is a chronic inflammatory autoimmune disease characterized by destruction of insulin-producing β cells and subsequent insulin deficiency [94]. This loss of β cells is gradual and at the time of diagnosis of type 1 diabetes significant β -cell function remains [95]. While it is generally assumed that the remaining β cells are completely destroyed soon after diagnosis, studies now indicate that these cells can persist for many years [96].

The preservation of these remaining β cells has important clinical benefits. A meal-stimulated C-peptide value of $>200 \text{ pmol/l}$ is associated with improved glucose levels for the first four years after diagnosis, a reduced risk of developing retinopathy and nephropathy, and a $>50\%$ reduction in hypoglycaemia rates [97]. Thus, interventions that have the potential to preserve β -cell function are worth striving for.

In diabetes animal models [13], healthy individuals [14], and people with type 2 diabetes, physical activity preserves β -cell function [15]. In a two-year prospective study of 125 children diagnosed with type 1 diabetes, those who were physically active had higher rates of partial remission compared to the inactive group [98]. Similarly, in a case-controlled study of adults recently diagnosed with type 1 diabetes, the honeymoon period was more than five times longer in men undertaking high levels of physical exercise, compared with age-, sex-, and body mass index (BMI)-matched sedentary controls [99]. In a pilot RCT of adults with newly diagnosed type 1 diabetes, β -cell

function, corrected for improved insulin sensitivity, was preserved by exercise [43]. A large RCT is needed to confirm these findings.

Bone density

People with type 1 diabetes have reduced bone mineral density and osteoporosis and increased risk of fracture [100]. A systematic review identified two RCTs and twelve observational (ten cross-sectional and two longitudinal) studies that had reported associations between physical activity and skeletal outcomes [101]. The two RCTs reported a beneficial effect of physical activity interventions on bone accrual in children. Results of the observational studies were mixed, with four finding a positive association with a measure of activity and a skeletal outcome and eight finding no effect. No studies have examined whether physical activity reduces fracture risk in people with type 1 diabetes.

Cancer

Whether people with type 1 diabetes are at increased risk of cancer is unknown [102]. Physical activity appears to protect the general population from cancer and improve outcomes in those who develop cancer (surgical outcome, side effects of chemotherapy, subsequent prevention of recurrence). Again, this has not been examined in type 1 diabetes.

Well-being

People with type 1 diabetes are two to three times more likely to have depression than the general population [85]. In young adults, physical activity is associated with significantly greater satisfaction with life and well-being [74], but these associations were not found in the one study that examined this in children [81].

Type 2 diabetes and exercise

Prevention of type 2 diabetes

Prospective observational studies

The earliest evidence that indicated that exercise might play a role in prevention of diabetes came from large prospective cohort studies. In these studies, higher levels of physical activity and/or cardiorespiratory fitness were consistently associated with reduced risk of developing type 2 diabetes [103–115]. After adjustment for confounding variables, the most active participants had a 25–60% lower risk of subsequent diabetes compared to those who were most sedentary. This reduction was seen regardless of the presence or absence of additional diabetes risk factors such as hypertension, parental history of diabetes, and obesity. In addition, similar magnitudes of risk reduction were seen with walking compared to more vigorous activity, when total energy expenditures were similar [111].

Non-randomized studies

The first large study to assess the effectiveness of lifestyle modification in preventing and treating diabetes was the Malmö study [116]. In this non-randomized study, 41 participants with type 2 diabetes and 181 with impaired glucose tolerance accepted enrolment into a 6–12-month intervention in which they were given advice to reduce energy intake and increase physical activity. The control group comprised 114 healthy individuals and 79 with impaired glucose tolerance who declined the intervention. At six-year follow-up, 10.6% of those with impaired glucose tolerance in the intervention

group had progressed to type 2 diabetes, compared with 28.6% in the control group, a risk reduction of 63% [16]. Over 12 years, mortality among the controls was 14.0 per 1000 person-years, but only 6.5 per 1000 person-years in the intervention group [117]. This seminal study led on to several RCTs that have assessed the effect of lifestyle programmes in preventing type 2 diabetes.

Randomized studies

Table 28.3 summarizes the RCTs that have assessed whether lifestyle can prevent type 2 diabetes.

The China Da Qing Diabetes Prevention Outcome Study included 577 participants with impaired glucose tolerance who were randomized by centre into four arms – diet only, exercise only, diet and exercise, or control – and followed for six years [118]. The cumulative incidence of type 2 diabetes was 68% in controls, but only 44%, 41%, and 46% in the diet, exercise, and diet and exercise groups, respectively. The long-term follow-up is even more encouraging and indicates that the benefits from these lifestyle interventions continue for many years after completing *active treatment*; the so-called *legacy effect*. After 20 years' follow-up, 14 years after leaving the study, those in the interventional groups had 43% lower incidence and spent on average 3.6 fewer years with diabetes compared to the control group [119].

In the Finnish Diabetes Prevention Study, 522 people with impaired glucose tolerance were randomized to an exercise and diet intervention or control [120]. The intervention was intense and included individualized exercise plans, thrice-weekly supervised facility-based aerobic and resistance exercise, and seven one-hour meetings with a dietitian focusing on weight reduction, reduced fat intake, and reduced total caloric intake. Participants in the control group had one meeting per year. At four years, 22% of the control group and only 10% of the intervention group had developed diabetes, a 58% risk reduction. Again, a legacy effect was seen, with participants in the intervention arm having a 43% lower risk of developing diabetes three years after leaving the study [121].

In the American Diabetes Prevention Program [122], 3234 men and women with impaired glucose tolerance were randomly assigned to placebo, metformin, or a lifestyle-modification programme. Again, the lifestyle intervention was intense, with the participants provided with 16 lessons in the first 24 weeks. These lessons were delivered individually and covered diet, exercise, and behaviour modification. A minimum of two supervised exercise sessions per week and at least monthly contact with the study personnel were maintained thereafter. Cumulative incidences of type 2 diabetes were 11.0/100 person-years in the placebo group, 7.8 per 100 person-years in the metformin group, and only 4.8 per 100 person-years in the intensive lifestyle group. The risk of type 2 diabetes was 58% lower in the lifestyle group than in the placebo group, and 39% lower than in the metformin group [123].

The India Diabetes study randomized 421 men and 110 women with impaired glucose tolerance (mean age 45.9 ± 5.7 years, BMI $25.8 \pm 3.5 \text{ kg/m}^2$) into four groups [125]. Group 1 was the control, Group 2 was given advice on lifestyle modification, Group 3 was treated with metformin, and Group 4 was given lifestyle modification plus metformin. The lifestyle advice was less intense than that given in the American and Finnish prevention studies. Participants in the lifestyle-modification group were asked to increase their activity to 30 minutes per day; if they were already achieving this goal, they were asked to maintain this level of activity. Exercise was not supervised. Diet modification was advised for each participant

Table 28.3 Controlled studies that have examined the prevention of type 2 diabetes.

Name	Number of participants	Design of study	Study participants	Detail of intervention	Duration	Outcome
Malmo Study [116, 117]	222	Non-RCT	C: 114 healthy and 79 individuals with IGT; LSM: 41 individuals with type 2 diabetes and 181 individuals with IGT	Individuals were given advice to reduce energy intake and increase physical activity. Intervention lasted for 0.5–1 yr	6 yr	Progression to type 2 diabetes: 10.6% vs 28.6% for LSM vs C group. A 63% risk reduction for the development of type 2 diabetes. Over 12 years, mortality was 14 vs. 6.5 per 1000 person-years in the C and LSM groups, respectively
China Da Qing Diabetes Prevention Outcome Study [118, 119]	577	RCT	Individuals with IGT randomized into four arms, D, E, D + E, or C	D: received prescribed diet, advice on healthy eating and caloric reduction; E: taught exercise with increased exercise intensity; D + E: include both diet and exercise instructions as D and E groups. All intervention groups received regular counselling sessions	6 yr, and follow-up at 20 yr	Cumulative incidence of type 2 diabetes was 44%, 41%, 46%, 68% in D, E, D + E, C groups, respectively. Legacy effect: D, E, and D + E groups had 43% lower incidence and spent average 3.6 fewer yr with type 2 diabetes compared to C group
Finish Diabetes Prevention Study [120, 121]	522	RCT	Individuals with IGT randomized into two arms: LSM and C	LSM: individualized exercise plans, thrice-weekly supervised facility-based aerobic and resistance exercise, and seven 1 h meetings with a dietitian focusing on weight reduction, reduced fat intake, and reduced total caloric intake	4 yr and follow-up at 7 yr	Development of type 2 diabetes 10% in LSM compared to C group. Risk reduction 58%. Legacy effect: 43% lower risk in intervention arm
American Diabetes Prevention Program [122, 123]	3234	RCT	Individuals with IGT randomized into three arms: placebo, MET, or an LSM programme	LSM included intense 16 lessons in first 24 wk, delivered 1 to 1 and covering diet, exercise, and behaviour modification. A minimum of two supervised exercise sessions per week and at least monthly contact with the study personnel were maintained thereafter	Average 2.8 yr	Cumulative incidences of type 2 diabetes were 11, 7.8, and 4.8 per 100 person-years in the placebo, metformin, and lifestyle groups respectively
Prevention of type 2 diabetes by lifestyle intervention: a Japanese trial in IGT males [124]	458	RCT	Men with IGT randomized into two arms in ratio 4:1: control (356) and LSM (102)	Control: if $BMI \geq 24 \text{ kg/m}^2$ advised to have 5–10% smaller meals, increase physical activity, and lose weight. If $BMI < 24 \text{ kg/m}^2$ told to avoid gaining weight. Seen every 6 months. LSM: $BMI \geq 22 \text{ kg/m}^2$ advised how to lose weight and increase weight. If $BMI < 22 \text{ kg/m}^2$ advice how to maintain weight by diet and exercise. Seen every 4 mo	4 yr	Cumulative 4 yr incidence of diabetes 9.3% in control group, versus 3.0% in LSM group, and reduction in risk of diabetes 67.4% ($p < 0.001$)

(continued)

Table 28.3 (Continued)

Name	Number of participants	Design of study	Study participants	Detail of intervention	Duration	Outcome
Indian Diabetes study [125]	531	RCT	Individuals with IGT randomized into four arms: C, LSM, MET, and LSM plus MET	LSM: asked to increase or maintain their activity to 30 min per day. Non-supervised exercise. Diet modification included reduction in total calories, refined carbohydrates, and fats, avoidance of sugar, and inclusion of fibre-rich foods. Individuals with LSM were contacted monthly by telephone and seen 6-monthly during the study	2.5yr	3 yr cumulative incidences of diabetes were 55.0%, 39.3%, 40.5%, and 39.5% in control, LSM, MET, and LSM + MET, respectively. Relative risk reduction 28.5% with LSM, 26.4% with MET, and 28.2% with LSM + MET compared with control group
European Diabetes Prevention RCT [126]	102	RCT	Individuals with IGT over age of 40 and BMI 25 kg/m ² randomized into two arms, LSM and C	C: standard diet and exercise advice. LSM: individual motivational interviewing aimed at weight reduction, increase in physical activity, fibre and carbohydrate intake, and reduction of fat intake	Mean follow-up of 3.1 yr	Absolute incidence of type 2 diabetes 32.7 per 1000 person-years LSE and 67.1 C. Incidence of diabetes reduced by 55% in LSM compared with C
Two-year-supervised resistance training prevented diabetes incidence in people with prediabetes [127]	137	RCT	Individuals with IGT randomized into four arms: C, AT, RT, or AT + RT	Control: continue activity as normal. AT: 60 min 3 times/wk. RT: 60 min all major muscles 3 times/wk. Combined: 30 min AT + 30 min RT 3 times/wk	2yr	Incidence of diabetes adjusted by sex and age significantly decreased by 74% (combined), 65% (AT), and 72% (RT) compared with control group

AT, aerobic training; BMI, body mass index; C, control; D, diet; E, exercise; IGT, impaired glucose tolerance; LSM, lifestyle modification; MET, metformin; RCT, randomized controlled trial; RT, resistance training.

and included reduction in total calories, refined carbohydrates, and fats; avoidance of sugar; and inclusion of fibre-rich foods. To support the lifestyle modification, people were contacted monthly by telephone and seen six-monthly during the study. The median follow-up period was 30 months, and the three-year cumulative incidences of diabetes were 55.0%, 39.3%, 40.5%, and 39.5% in Groups 1–4, respectively. The relative risk reduction was 28.5% with lifestyle modification, 26.4% with metformin, and 28.2% with combine lifestyle modification and metformin compared with the control group.

In these prevention studies, weight loss seems to be the main factor in reducing diabetes incidence. In the US Diabetes Prevention Program, among those in the intervention arm for every kilogram in weight loss a 16% reduction in diabetes was seen, when adjustment for changes in diet and lifestyle were made [128]. Results from a meta-analysis also suggest that the effectiveness of these lifestyles programmes may be greater in those who are more overweight.

Weight loss, however, does not explain all the intervention effects. In the Indian Diabetes Prevention Programme, a 28.5% reduction in diabetes incidence was achieved without weight loss or reduction in waist circumference [125]. In the exercise intervention arm of the Da Qing study, a 46% reduction in diabetes incidence was achieved without weight loss [118]. These factors

suggest that some aspects of diet as well as physical activity, not necessarily related to weight loss, may be involved in mediating the beneficial effect of lifestyle modification in the prevention of type 2 diabetes.

A recent study has examined the effect of exercise alone on preventing type 2 diabetes in people with impaired glucose tolerance [127]. In this study 137 people with impaired glucose tolerance were randomized into four groups. Group 1 was the control and continued normal activity. Group 2 did 60 minutes of aerobic exercise (dance) three times per week, Group 3 did 60 minutes of resistance training three times a week, and Group 4 did combined aerobic and resistance training for 60 minutes three times per week. After 24 months the incidence of diabetes was 69%, 22%, 26%, and 22% in Groups 1–4, respectively. The relative risk reduction was 72% with aerobic exercise, 65% with resistance training, and 74% with combined exercise compared with the control group.

Treatment of type 2 diabetes

There is very clear evidence that exercise alone has profound benefits in people with established type 2 diabetes. Figure 28.2 summarizes the benefits that people with type 2 diabetes can expect to see with exercise.

Physical fitness, cardiovascular disease, and mortality

People with type 2 diabetes have a significantly lower $\text{VO}_{2\text{max}}$ than healthy age-, BMI-, and activity-matched participants without diabetes [129]. Meta-analysis of nine RCTs involving 266 people with type 2 diabetes, comparing exercise and control, shows that regular exercise, at least 50% of $\text{VO}_{2\text{Max}}$, improved overall $\text{VO}_{2\text{Max}}$ by 11.8% in the exercise group versus a reduction of 1% in the control group. Additionally, higher-intensity exercise produces even larger improvements in cardiorespiratory fitness [130].

Observational studies have shown that increased physical activity improves cardiorespiratory fitness and lowers mortality rate in participants without diabetes [131,132], while prospective studies in people with diabetes report that even walking for two hours a week is associated with less cardiovascular mortality; however, the effect is greater with three to four hours of walking a week [133]. No RCT has assessed the effect of improved physical fitness on mortality in type 2 diabetes.

Glycaemic management

Supervised exercise training

Structured exercise training is normally defined as an intervention in which people engage in a planned, individualized, and supervised exercise programme. The most recent meta-analysis that examined the effect of structured exercise training on $\text{HbA}_{1\text{c}}$ in type 2 diabetes reported in 2011 [134] (Figure 28.3). This included 23 RCTs with 1533 participants. Studies had to be RCTs of ≥ 12 weeks' duration and had a control group of people with type 2 diabetes. Overall, structured exercise reduced $\text{HbA}_{1\text{c}}$ by 0.7% (7 mmol/mol) compared to control participants. When dividing the studies into exercise type, 18 studies with 848 people demonstrated that structured aerobic exercise training reduced $\text{HbA}_{1\text{c}}$ by 0.7% (7 mmol/mol), 4 studies with 261 people showed that structured resistance exercise training reduced $\text{HbA}_{1\text{c}}$ by 0.6% (6 mmol/mol), and 7 studies with 404 people demonstrated

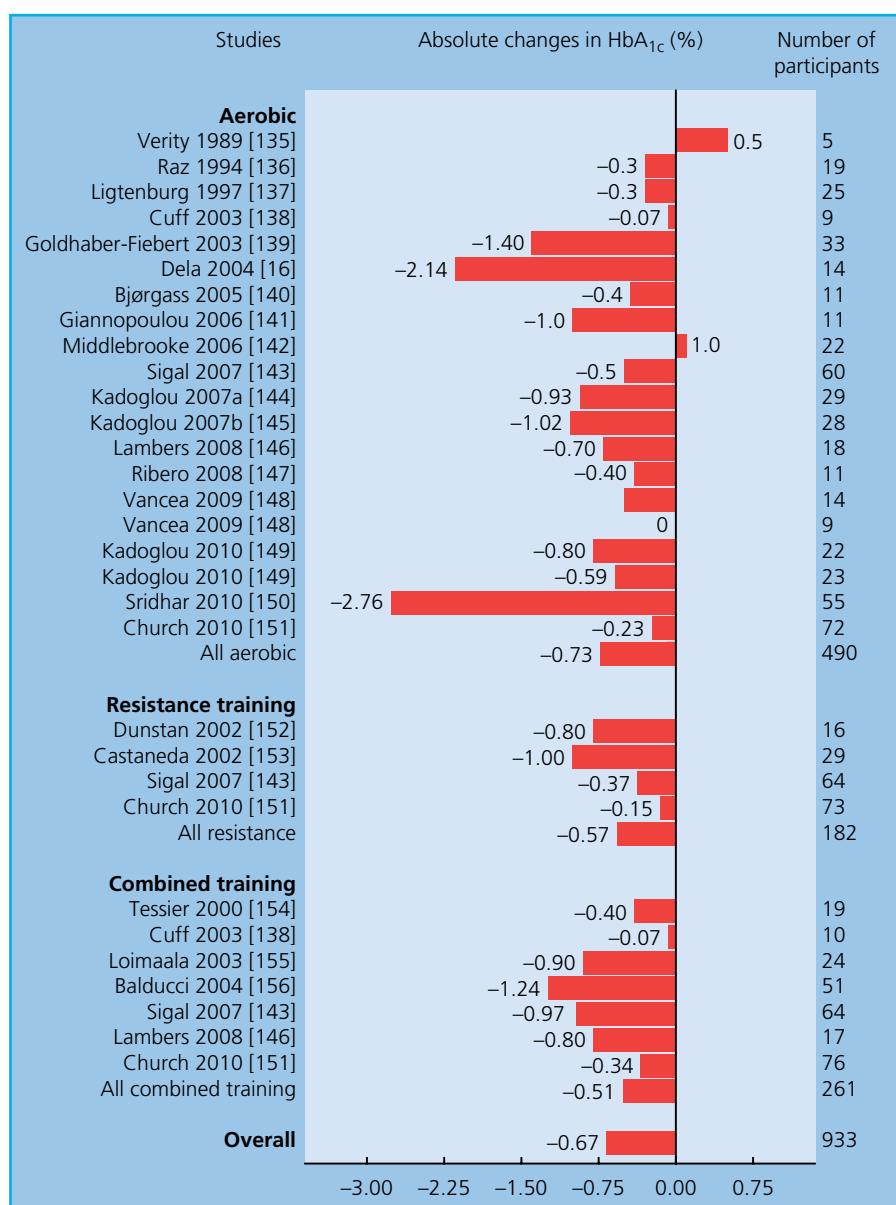

Figure 28.3 Absolute changes in glycated haemoglobin ($\text{HbA}_{1\text{c}}$) of individual studies of structured exercise training versus no intervention. Number of participants in each exercise regimen is shown in the box in white. Source: Adapted from Umpierre et al. 2011 [134].

that the combined aerobic and resistance exercise reduced HbA_{1c} by 0.5% (5 mmol/mol). This meta-analysis also showed that structured exercise duration of ≥150 minutes per week was associated with greater benefit than structured exercise duration of ≤150 minutes (0.9% vs 0.4%; 9 mmol/mol vs 4 mmol/mol reduction, respectively).

Using a meta-regression analysis, Umpierre et al. assessed the association between intensity and volume of supervised exercise training (aerobic, resistance, or combined) and HbA_{1c} changes in type 2 diabetes [157]. Higher baseline HbA_{1c} was associated with greater HbA_{1c} reduction with training. For supervised aerobic training and combined aerobic/resistance training, higher volume of exercise was associated with greater HbA_{1c} reduction. For example, each set of aerobic exercise added within the exercise week produced a 0.4% (4 mmol/mol) HbA_{1c} reduction. No exercise variables were found to be possible candidates to explain the effects of supervised resistance training.

A meta-analysis of RCTs that compared supervised resistant exercise with aerobic exercise in people with type 2 diabetes sought to clarify whether there was an optimum type of exercise for treating type 2 diabetes [158, 159]. The 12 included studies of 626 participants were RCTs of ≥8 weeks' duration that compared supervised resistant exercise with supervised aerobic exercise. Although there was a greater reduction of HbA_{1c} with supervised aerobic exercise compared to supervised resistant exercise, the difference was only 0.2% (2 mmol/mol) and not clinically significant.

Two RCTs have compared the three commonly used types of supervised exercise for treating type 2 diabetes, namely aerobic, resistance training, or a combination [143, 151] (Figure 28.4). In the Diabetes Aerobic and Resistance Exercise (DARE) trial [143], 251 previously sedentary individuals with type 2 diabetes were randomized into four arms: aerobic exercise training, resistance exercise training, combined aerobic and resistance exercise training, or a non-exercising control group. Compared to the control group, HbA_{1c} decreased significantly in the aerobic group by 0.5% (5 mmol/mol) and the resistance group by 0.4% (4 mmol/mol). In the combined exercise group, HbA_{1c} fell by an additional 0.5% (5 mmol/mol) compared with the aerobic group and 0.6% (6 mmol/mol) compared with the resistance group. In people with HbA_{1c} ≤7.5% (48 mmol/mol), HbA_{1c} only decreased significantly in the combined exercise training group.

Church et al. [151] randomized 262 sedentary people with type 2 diabetes to four groups: aerobic exercise training, resistance exercise training, combined aerobic and resistance exercise training, or a non-exercising control group. Compared with the control group, neither the resistance nor aerobic training produced a significant change in HbA_{1c}. For the combination training exercise group, a fall in HbA_{1c} of 0.3% (3 mmol/mol) was seen compared to the control group.

High-intensity interval training (HIIT) is the newest form of exercise to be tried in the management of type 2 diabetes, as it takes less time to perform and can produce similar physiological effects to longer duration of standard exercises. Recently a meta-analysis of ten small studies that aimed to quantify the effects of HIIT on markers of glucose regulation with control conditions or continuous training has reported [158]. Compared with control conditions, in people with type 2 diabetes HIIT did not produce a significant reduction in HbA_{1c}, but was superior to continuous training with a 0.37% (4 mmol/mol) HbA_{1c} reduction.

Physical activity advice

Although structured exercise training may be available to some people with type 2 diabetes, physical activity advice may be more feasible. Physical activity advice is normally defined as formal instructions to exercise regularly with or without an individualized exercise prescription. The most recent meta-analysis that assessed the effect of physical advice on HbA_{1c} in people with type 2 diabetes reported in 2011 [134] (Figure 28.5). This included 24 studies with 7025 participants. Overall physical activity advice produces a 0.4% (4 mmol/mol) decrease in HbA_{1c} compared to control. When the studies were broken down to those that included dietary advice, it was seen that physical activity advice in combination with dietary advice (12 studies, 6313 people) was associated with a 0.6% HbA_{1c} reduction (6 mmol/mol) compared with control, but physical activity advice alone (14 studies, 712 people) was not associated with HbA_{1c} changes.

Structured exercise training versus physical activity advice

The Italian Diabetes and Exercise Study [184] compared structured exercise training to physical activity advice. In the study, 606 individuals with type 2 diabetes were randomized to a full year of either physical activity advice alone, or supervised facility-based combined aerobic and resistance exercise training twice weekly plus physical activity advice. HbA_{1c} fell to a greater extent in the

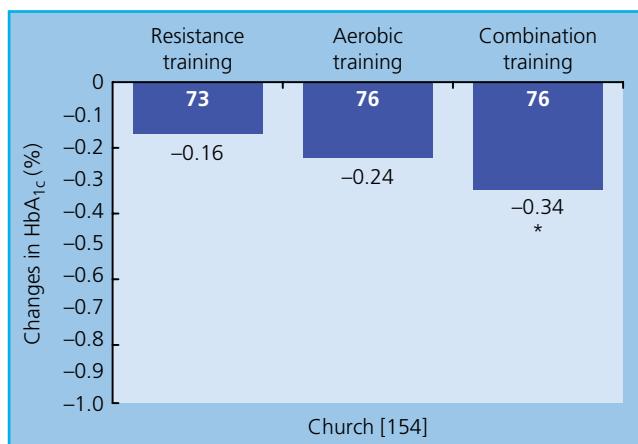

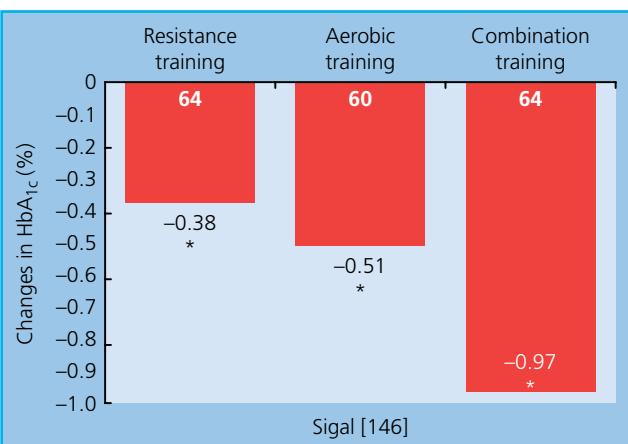

Figure 28.4 Reduction in glycated haemoglobin (HbA_{1c}) seen with different exercise regimens compared to control group in two studies, Church [150] and Sigal [143]. Number of participants in each exercise regimen is shown in the box in white. A star denotes significant improvement compared to control group.

supervised exercise group (0.4%; 4 mmol/mol) than the advice group (0.1%; 1 mmol/mol). This study suggests that supervised exercise programmes are more effective than physical activity advice.

Vascular risk factors other than glucose

In healthy people, aerobic and resistance training lower both systolic and diastolic blood pressure, whereas combined training only lowers diastolic blood pressure [185]. In 2014 Figueira et al. conducted a meta-analysis to assess the effect of physical activity advice alone or structured exercise training on blood pressure in type 2 diabetes [186]. They identified 30 RCTs (2217 participants) of structured exercise training and 21 RCTs (7323 participants) of physical activity advice alone. Overall, structured exercise reduced systolic blood pressure by 4 mmHg and diastolic blood pressure by 2 mmHg compared to controls. Greater reductions in blood pressure were seen when exercise duration was ≥ 150 minutes and when the intensity of the exercise was higher. When exercise training was broken down into exercise type, compared to control, aerobic exercise training reduced systolic blood pressure by 5 mmHg and diastolic blood pressure by 2 mmHg, and resistant exercise training reduced systolic blood pressure by 4 mmHg and diastolic blood pressure by 3 mmHg. Combined exercise training was not associated with a reduction in blood pressure. Physical activity advice

alone produced a 3 mmHg reduction in systolic blood pressure and a 1 mmHg reduction in diastolic blood pressure.

Several studies have examined the effect of aerobic and combined aerobic and resistance supervised exercise on lipids in type 2 diabetes. In a meta-analysis, both reduced triglycerides by 0.3 mmol/l but had no effect on HDL cholesterol or LDL cholesterol [187]. Only one study has assessed the effect of resistance training and found no effect on total cholesterol, HDL cholesterol, LDL cholesterol, or triglycerides [176].

People with type 2 diabetes have impaired endothelial function [188, 189], which is a powerful and independent predictor of long-term cardiovascular events [190, 191]. Only a few small studies have assessed the effect of exercise on endothelium function in type 2 diabetes, but a meta-analysis of 5 studies including 217 participants reported that supervised exercise improved endothelium function [191].

Insulin resistance is one of the hallmarks of type 2 diabetes and is involved in the pathogenesis of hypertension and cardiovascular disease. Both aerobic and resistance training improve insulin resistance in type 2 diabetes [138]. Although in healthy individuals resistance exercise has a greater effect on insulin sensitivity than aerobic exercise, there is insufficient evidence to confirm whether this is the case in type 2 diabetes [192].

Microvascular complications

The fact that exercise improves HbA_{1c} and blood pressure, the two key risk factors in the development of diabetic microvascular complications, suggests that regular exercise should protect against microvascular complications. Few studies have examined whether this is the case. Impaired exercise capacity is associated with diabetic nephropathy and retinopathy [193]. In retrospective and prospective cohort studies, regular physical activity was associated with reduced progression and development of diabetic kidney disease [194, 195]. In the Look Ahead study, people randomized to the intervention arm (diet, exercise, and weight loss) were less likely to develop retinopathy or neuropathy [196]. In contrast, in the Japan Diabetes Complications Study in which 2033 participants were randomized to a lifestyle intervention (diet and exercise) or usual care, there was no difference in incident retinopathy or nephropathy between groups at eight years' follow-up [197]. No RCTs have examined the effect of exercise alone on microvascular risk in people with type 2 diabetes.

β-cell function

In the UK Prospective Diabetes Study, progressive decline of β-cell function was associated with worsening of glycaemic levels in people with type 2 diabetes, irrespective of treatment strategy [198]. Thus, maintenance of β-cell function is important to meet glucose targets in people with type 2 diabetes. Several studies have shown that aerobic exercise of varying intensity improves insulin secretion in type 2 diabetes [199–202].

Bone mineral density

People with type 2 diabetes are at increased risk of fractures despite normal, or even increased, bone mineral density [203]. This increase in fracture risk may be due to altered bone architecture or an increased risk of falling due to neuropathy. No studies has assessed the effect of physical activity on bone mineral density or fracture risk in type 2 diabetes.

Cancer

Type 2 diabetes is associated with an increased risk of developing cancer [203]. In the general population regular physical activity reduces cancer risk and improves outcomes in those who develop it. Again, no studies have examined whether this holds true for people with type 2 diabetes.

Well-being

People with type 2 diabetes have a higher chance of developing depression [204, 205]. They also have a poorer quality of life [206] and a higher prevalence of general anxiety disorder (14%) than the general population [207]. The effects of exercise training on quality of life, symptoms of depression and anxiety, and emotional well-being in type 2 diabetes were reviewed in 2014 [208], with two further studies since then [215, 225]. A summary of all studies is shown in Table 28.4. No form of exercise improved quality of life and emotional well-being, while depressive symptoms were only improved by resistant training and anxiety symptoms were only improved by aerobic training.

Table 28.4 Effect of exercise on well-being.

		Number of studies	Length of interventions (wk)	Number of participants	Results
Quality of life	Aerobic	5	8, 16, 16 and 52, 12 and 12	18, 50, 44, 29, 38	4 found no effect [146, 208–211] and 1 found effect on physical health and sleep subscales but not other subscales [212]
	Resistance	5	16, 16, 12 and 26, 16 and 12	58, 48, 110, 37, 30	3 found no difference [213–215], 1 found a significant effect [216], and 1 found effects on general health subscale [170] but no effect on other subscales
	Combined	11	24, 52, 16 and 52, 12 and 26, 8, 12, 26, 12, 16, 16	84, 606, 64, 109, 36, 77, 43, 28, 38, 29	6 found no effect [146, 154, 167, 210, 213, 217]. 4 found improvement across all measures of quality of life [218–221]. Remaining 1 found improvement in emotional role, mental health, and vitality, but not for other subscales [222]
Well-being	Aerobic	3	6, 8, 8	58, 40, 20	2 showed improvement [223, 224] and 1 no improvement [225]
	Resistance	2	8, 12 and 26	20, 110	One showed improvement [225], the other did not [213]
	Combined	1	12 and 26	109	No effect [213]
Depression	Aerobic	2	6 and 8	78, 58	Both showed no effect [223, 226]
	Resistance	1	16	58	Improved [216]
	Combined	1	8	36	No effect [222]
Anxiety	Aerobic	1	6	58	Reduced anxiety [223]
	Resistance	—			
	Combined	—			

Physical activity and gestational diabetes

Prevention of gestational diabetes

Gestational diabetes (GDM) is a condition in which women without a previous diagnosis of diabetes develop glucose intolerance during pregnancy (Chapter 71) [227]. The prevalence of GDM ranges from 1% to 14% depending on the diagnostic criteria used and the population being studied [228]. It is associated with adverse maternal and fetal outcomes; women with GDM have an increased risk of developing GDM in subsequent pregnancies and type 2 diabetes. Offspring of mothers with GDM are at high risk of macrosomia [229] and as adults are more likely to develop obesity [230] and type 2 diabetes [231]. Preventing GDM is therefore a clinical priority.

Several prospective studies have shown that low physical activity is associated with the development of GDM. In the largest of these studies, including 21 765 women, Zhang et al. found that when comparing the highest with the lowest quintiles of vigorous activity there was a relative risk reduction of 0.77 [232]. Among women who did not engage in vigorous activities, women who briskly walked ≥ 30 minutes or climbed ≥ 15 flights of stairs daily also had a lower risk of GDM [232].

Two recent systematic reviews have examined whether prenatal physical activity prevents GDM. Sanabria-Martinez et al. reviewed RCTs of sedentary healthy women or those with low levels of physical activity (exercising <20 minutes on <3 days per week) with uncomplicated and singleton pregnancies [233]. In their review, 13 RCTs with 2873 pregnant women met the inclusion criteria, of which only 3 reported ethnicity and involved white women. Exercise reduced the risk of GDM by 31%, with this increasing to 36% if started early in pregnancy. Davenport et al. identified 46 RCTs with 14 923 pregnant women and found that prenatal exercise was associated with 24% lower odds of developing GDM compared with no exercise [234]. Both reviews felt that larger, better-quality studies were needed to confirm or refute these findings.

Treatment of gestational diabetes

Regular exercise during pregnancy is associated with many benefits, including improved cardiorespiratory fitness, less low back pain, reduced urinary incontinence, reduced depressive symptoms [235], and less weight gain in pregnancy [236]. Although diet and exercise are recommended as the first step in managing GDM, there is debate about whether there is clear evidence about the effectiveness of exercise. A 2006 Cochrane review concluded that 'there is insufficient evidence to recommend, or advise against, diabetic pregnant women to enrol in exercise programs. Further trials, with larger sample size, involving women with gestational diabetes, and possibly type 1 and 2 diabetes, are needed to evaluate this intervention' [237]. A systematic review identified seven studies that examined the effect of exercise in managing GDM [238]. Five studies found improvements in glycaemic levels and/or a limitation in insulin use [239–243], but two reported no effect [244,245].

Exercise advice for people with type 1 diabetes or type 2 diabetes

Exercise guidelines

The American Diabetes Association has published recommendations and guidelines for exercise in individuals with diabetes [246]. These and other guidelines are summarized in Table 28.5.

Table 28.5 Exercise guidelines for adults and children with type 1 diabetes and type 2 diabetes and pregnant women with diabetes.

Categories	Physical activity recommendations
Adults with type 1 diabetes and type 2 diabetes	At least 150 min/wk of moderate-intensity or 75 min/wk of vigorous-intensity aerobic physical activity, or equivalent combination of the two. This should be spread over 3 d with no more than 2 consecutive days without exercise Additionally, muscle-strengthening activities that involve all major muscle groups should be performed on 2 or more days of the week Reduction in sedentary time is also recommended [206] Flexibility training and balance training are recommended 2–3 times/wk for older adults with diabetes
Children and teens with type 1 diabetes and type 2 diabetes	At least 60 min of physical activity daily, which should include vigorous-intensity aerobic activity, muscle-strengthening activities, and bone-strengthening activities at least 3 d of the week [206]
Pregnancy in women with diabetes	At least 30 min or more of moderate exercise daily if there are no medical or obstetric complications [206]

Source: Adapted from Colberg et al. 2016 [246].

Where possible, advice should be tailored to the individual, taking into account their interests, level of fitness, possible contraindications, and personal goals. There are many examples of people with diabetes competing at the highest level, so diabetes should not interfere with an individual's sporting goal and treatment should be adjusted according to the demands of the activity. For activities and competitions considered to be high risk for individuals with diabetes (e.g. car racing, flying, diving), individual governing bodies should be consulted regarding restrictions in competition. It is also important to note that the use of insulin is prohibited by the World Anti-Doping Agency, and elite-level athletes with diabetes will require a Therapeutic Use Exemption (TUE) certificate prior to competition.

Most guidelines recommend ≥ 150 minutes of moderate aerobic activity, and/or ≥ 90 minutes of vigorous aerobic exercise every week, and that this activity be spread over at least three days [246]. A day's activity need not occur in a single session, but may be accumulated in bouts of ≥ 10 minutes at a time, performed throughout the day. Performing ≥ 150 minutes of moderate activity is associated with greater benefit, so if an individual has reached the target of 150 minutes they should be encouraged to do more if possible.

In addition to aerobic exercise, many guidelines also suggest that resistance training should be carried out at least twice per week, as combining aerobic exercise with resistance training has the greatest effect on HbA_{1c}. Ideally at least three sets of resistance exercise should be performed at each session, as the resistance exercise studies that have used ≥ 3 sets have shown the greatest reduction in HbA_{1c} [49,152,247]. Weight lifting is safe in people with cardiac disease [248] and is not associated with increased proliferative retinopathy risk [248].

The guidelines recommend that people with diabetes should also reduce their sedentary time [246]. This is because higher sedentary

time is associated with a poorer metabolic profile in type 2 diabetes and reduced sedentary time improves metabolic profile [249].

Minimizing risk of exercise-related adverse events

Assessment

There is often concern about the safety of exercise for people with diabetes, although for most people the benefits of exercise will outweigh the risks. Prior to starting exercise for the first time or when beginning a programme of vigorous physical activity, people with diabetes should be assessed for conditions that might increase risks associated with certain types of exercise or predispose them to injury. Table 28.6 provides guidance on what pre-exercise assessment should be undertaken.

Specific exercise considerations for people with type 1 diabetes

In healthy individuals without diabetes, changes in insulin and counter-regulatory hormone secretion during exercise are dependent on the type of exercise being performed [250]. These changes facilitate an increase in liver glucose production to match skeletal muscle glucose uptake [162]. A change in the secretion of these hormones is also seen post-exercise to facilitate recovery and adaptation to exercise. As a result, blood glucose levels remain relatively stable before, during, and after exercise.

In people with type 1 diabetes, because insulin lies in subcutaneous depots and is not under regulation, insulin levels do not change in a physiological manner during exercise, thus they cannot fall in response to exercise and there may be impaired secre-

tion or action of counter-regulatory hormones. This impairs normal fuel regulation [251]. The inability of the pancreas to modulate insulin and counter-regulatory hormones (in particular glucagon) following exercise can also hamper recovery and adaptation to exercise. This increases the risk of hypoglycaemia both during and following exercise. Furthermore, hyperglycaemia prior to and following some types of exercise can be problematic [252]. Consequently, people with type 1 diabetes have three main problems when exercising:

- Problems controlling their blood glucose during and immediately following exercise.
- Unexplained severe hypoglycaemia, particularly at night.
- Reduced performance through excessive fatigue and reduced muscle strength.

To help overcome these problems, people need to understand how different exercises affect glucose, know when it is safe to exercise, and have strategies to manage glucose during and after exercise.

How different exercise affects blood glucose

Both intensity and exercise type will determine what happens to blood glucose concentrations (Figure 28.6). The most rapid drop in blood glucose occurs during aerobic or endurance exercise, when circulating insulin suppresses metabolic fuel production and increases muscle glucose uptake. With intermittent high-intensity exercise, there is a mixture of both aerobic and anaerobic exercise, which is characteristic of team sports and children's play; blood glucose is either stable or falls slowly [253]. High-intensity or anaerobic exercise tends to raise blood glucose, as a result of the increased catecholamines that are normally seen with these exercises [254].

When it is safe to exercise

Hypoglycaemia in the 24 hours preceding exercise blunts the counter-regulatory hormone response to exercise-induced hypoglycaemia, placing an individual at greater risk of exercise-induced

Table 28.6 Pre-exercise assessment and advice for people with diabetes complications.

Complication	Advice
Cardiovascular disease	Symptoms of cardiovascular disease should be asked about and where there is concern referral to a cardiologist for further assessment is indicated There is no evidence for screening of asymptomatic individuals Cardiovascular assessment is recommended for individuals with diabetic autonomic neuropathy
Peripheral neuropathy	It is vital to ensure that appropriate footwear is worn and feet are examined regularly, particularly if peripheral neuropathy is present Weight-bearing exercise should be avoided in those with active foot disease Walking does not increase the risk of ulceration in individuals with peripheral neuropathy Exercise delays the progress of neuropathy and so should be encouraged
Retinopathy	When proliferative or severe non-proliferative retinopathy is present, it may be sensible to avoid vigorous activity (both aerobic and resistance) because of the possible increased risk of vitreous haemorrhage or retinal detachment
Nephropathy	No evidence for restriction of any type of exercise in individuals with diabetic kidney disease Exercise can reduce progression and so should be encouraged

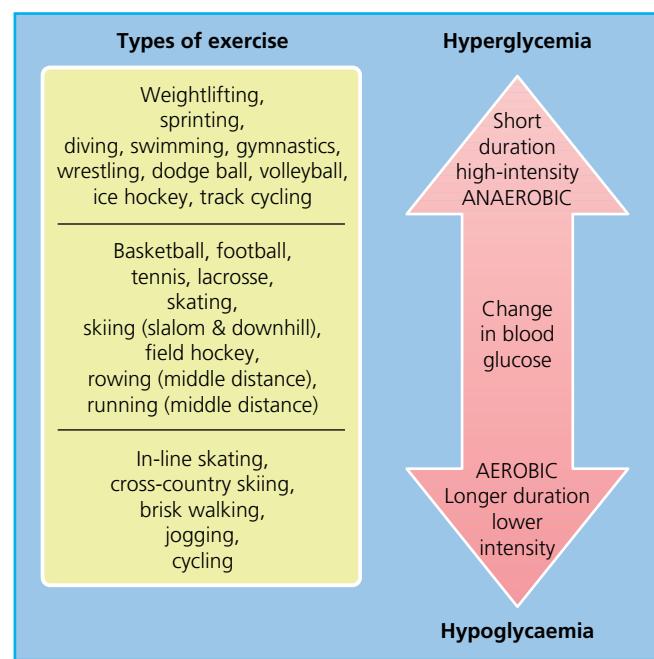

Figure 28.6 Effects of different sports on blood glucose concentrations.

Table 28.7 Insulin dose adjustment table for exercise.

	Duration	Intensity		
		Low (<50 MHR % or Borg scale 10)	Medium (50–75% MHR or Borg scale 10–15)	High (>75% MHR or Borg scale >15)
% Dose reduction	<30 min	10–20%	20–45%	40–60%
	30–60 min	20–30%	30–55%	50–75%
	>60 min	30–50%	45–70%	100%

MHR, maximum heart rate. Borg scale is based on the Borg rating of perceived exertion (see [265]).

hypoglycaemia. This risk is proportional to the severity of the preceding hypoglycaemia, with the effect starting at 3.9 mmol/l [255]. There is currently no evidence to guide individuals as to when it is safe to exercise following a hypoglycaemic episode. However, a consensus document suggests the following [256]:

- Not to exercise within 24 hours of severe hypoglycaemia requiring third-party assistance.
- Not to exercise within one hour of self-treated hypoglycaemia. If an individual insists on doing so, they should treat the hypoglycaemia and wait 45–60 minutes once the glucose is stable before commencing activity.
- Take extra precautions when there has been an episode of self-treated hypoglycaemia within the previous 24 hours. This would include more frequent glucose testing, exercising with an informed partner, and, if possible, including an anaerobic component to their training, because this will tend to raise their blood glucose.

If there is hypoglycaemia during exercise, exercise should be discontinued and the hypoglycaemia treated. The individual should wait at least 45 minutes before recommencing activity (or until blood glucose is stable). If an episode of severe hypoglycaemia occurs during exercise, then the activity should be stopped altogether because of the high risk of further hypoglycaemia.

When the blood glucose level is ≥ 15 mmol/l before exercise, the presence of ketones (capillary or urine) should be assessed [256]. If ketones are present, exercise is contraindicated and supplemental insulin should be considered (1 unit for 2–3 mmol/l glucose reduction). Exercise should only be commenced when ketone free and blood glucose is < 15 mmol/l [257]. Where the blood glucose level is ≥ 15 mmol/l and ketones are not present, advice depends on timing of the last meal (and, therefore, last quick-acting insulin dose). If a meal has been eaten in the last 1–2 hours, exercise may be commenced with close blood glucose monitoring. If the last meal was eaten ≥ 2 hours ago, then 30% of the usual correction dose should be given.

Strategies to manage glucose during exercise

An initial strategy for managing blood glucose during exercise is to replace the carbohydrate that will be used during exercise orally. In its simplest form, this is a fixed carbohydrate replacement regimen. In adults, we initially recommend 15 g of carbohydrate for every 30 minutes of exercise [258]. Although activities vary widely in terms of fuel requirements, this range represents a safe starting point for most people beginning moderate-intensity exercise. Estimates of carbohydrate requirement based on body mass can be used in preference to fixed-dose carbohydrate replacement. For

moderate and intensive activity, 0.5 g/kg/hr and 1 g/kg/hr, respectively, may be used [259].

An alternative approach that adjusts for the variable fuel requirements of different exercises is using standardized tables. These have been devised to help athletes of different body weight estimate carbohydrate requirements for different exercise intensities [260]. The maximum rate of enteral glucose absorption is 1 g/min. Therefore, carbohydrate requirement exceeding 60 g of glucose per hour would need to comprise a combination of glucose and fructose. In general, once carbohydrate requirements for exercise exceed 60 g/hr, we recommend altering insulin doses.

Several studies have examined insulin dose reductions for exercises of different intensities. This has enabled the development of dose reduction tables (Table 28.7). These tables tend to refer to changes to fast-acting insulin and therefore relate to exercise undertaken within two hours of eating (three hours if on soluble human insulin). To gain the most from these reductions, exercise is best conducted within 30 minutes after eating, and the meal or snack should predominantly contain low glycaemic index carbohydrate [261]. Reduction in basal insulin can, however, be helpful if people are undertaking prolonged exercise in the morning, or in the afternoon two hours after their meal.

Strategies to manage glucose post-exercise

Following exercise, carbohydrate is required to replenish muscle and liver glycogen stores. Protein is also needed for post-exercise muscle repair and synthesis. Failure to provide this increases the risk of hypoglycaemia in the subsequent hours, and fatigue in subsequent exercise sessions. Initially individuals should be advised to take snacks equivalent to 1 g/kg body weight of carbohydrate and 0.3 g/kg of protein [262]. This snack should be taken with insulin, as this increases carbohydrate storage in the exercising muscles and liver [263]. Initially we recommend a third of their normal insulin-to-carbohydrate ratio.

There is a risk of hypoglycaemia several hours after exercise through an increase in insulin sensitivity. If individuals have exercised during the morning or early afternoon, they should monitor their blood glucose and take extra carbohydrate as needed. If exercise has been undertaken in the late afternoon or evening, this may lead to nocturnal hypoglycaemia. To prevent this, people should reduce their evening basal insulin by 20% or take extra carbohydrates before going to bed.

High-intensity aerobic and anaerobic exercise can lead to post-exercise hyperglycaemia through increased hepatic glucose output

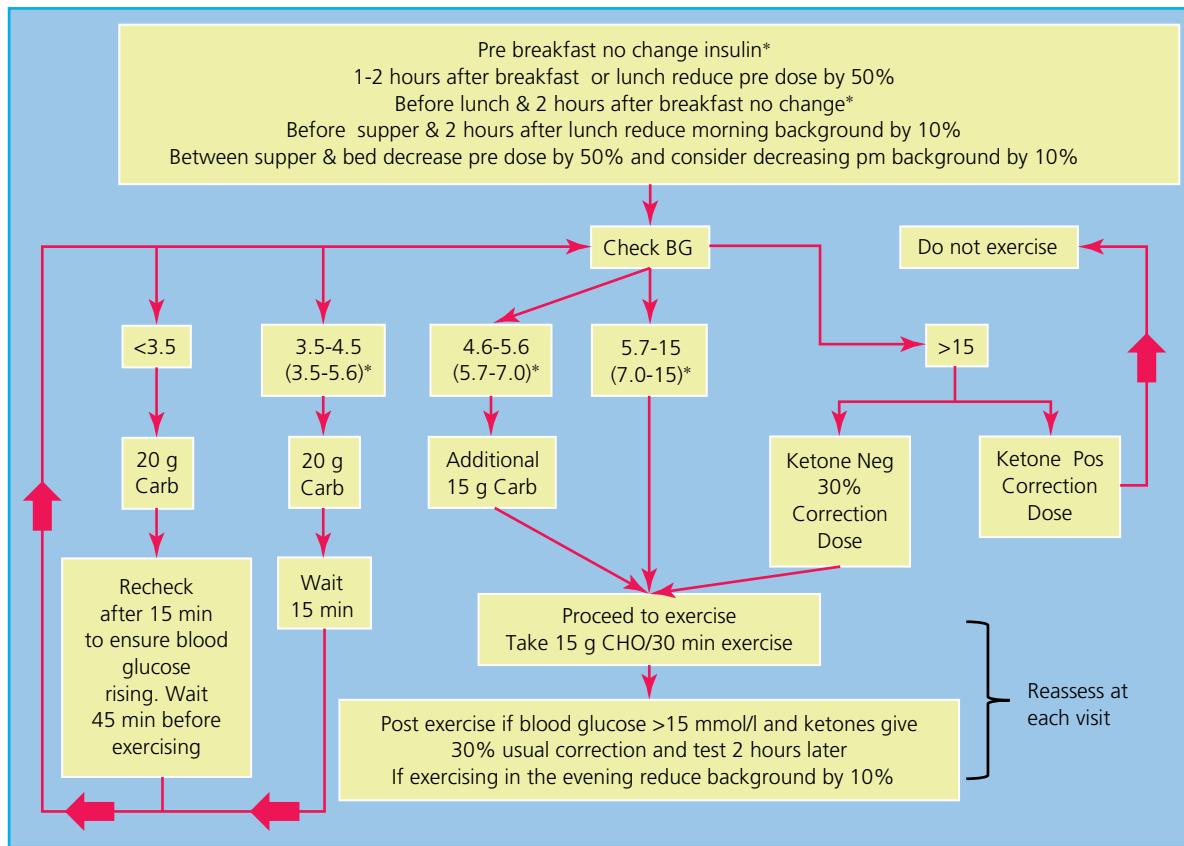

Figure 28.7 Algorithm for people with type 1 diabetes suggesting changes to insulin and carbohydrate (CHO) intake when exercising. Note that different blood glucose (BG) levels are used in this algorithm if exercising before breakfast or when exercising two hours after breakfast and before lunch, when no changes in insulin dosages are made – this is denoted by a star. Blood glucose values are given in mmol/l. To convert to mg/dl, these should be multiplied by 18.018.

and muscle insulin resistance, brought on by increased production of counter-regulatory hormones [264]. This means that additional insulin may be needed post-exercise. While there is currently no evidence to guide insulin correction dose, we recommend starting with 30% of the usual correction dose for blood glucoses ≥ 14 mmol/l post-exercise. Figure 28.7 shows a simple algorithm that brings together all this advice.

Specific considerations for people with type 2 diabetes

In people with type 2 diabetes, exercise does not typically cause hypoglycaemia and so carbohydrate supplementation is usually unnecessary. If blood glucose declines rapidly during exercise, as may occur in individuals taking oral anti-diabetes agents or insulin, the drug dosage should be reduced or withheld on exercising days.

Conclusion

Exercise improves well-being and reduces the risk of heart disease, cancer, and type 2 diabetes in the general population. In individuals with established type 1 diabetes or type 2 diabetes, regular exercise improves cardiovascular risk factors such as blood pressure and lipids and is associated with decreased mortality and decreased frequency and severity of diabetes-related complications. For individuals with type 2 diabetes, regular exercise improves metabolic management, as demonstrated by decreases in HbA_{1c}. This chapter has summarized the existing evidence about the effects of exercise in type 1 diabetes, type 2 diabetes, and gestational diabetes. A summary of current exercise recommendations is provided, along with practical advice on managing exercise training in individuals with both type 1 diabetes and type 2 diabetes.

Monitoring Diabetes

Emma English

Faculty of Medicine and Health, University of East Anglia, Norfolk, UK

Department of Clinical Biochemistry, Norfolk and Norwich University Hospital Trust, Norwich, UK

Key points

- Glycated haemoglobin ($\text{HbA}_{1\text{c}}$) is now used for both the long-term monitoring of people with diabetes and the diagnosis of type 2 diabetes. $\text{HbA}_{1\text{c}}$ and blood glucose remain the mainstay for monitoring glycaemic levels.
- $\text{HbA}_{1\text{c}}$ values are reported in SI units (mmol/mol) and derived % units using a stable master equation. All methods for $\text{HbA}_{1\text{c}}$ should now be standardized to the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) reference measurement procedure.
- People with type 1 diabetes should have $\text{HbA}_{1\text{c}}$ monitored every 2–6 months, depending on the level and stability of blood glucose and change in therapy.
- People with type 1 diabetes should be encouraged to self-monitor blood glucose with capillary blood glucose meters or continuous glucose monitoring systems. With treatment regimens intended to produce intensive glycaemic management, testing should be frequent (e.g. four or more times a day).
- For people with type 2 diabetes, glycaemic levels should be monitored using high-precision methods for measurement of $\text{HbA}_{1\text{c}}$ every 3–6 months, depending on the level and stability of blood glucose and change in therapy.

Why monitor?

The field of diabetes care has advanced significantly over the past 50 years and people with diabetes can expect to achieve optimal glycaemic levels through multiple pharmacological and non-pharmacological approaches. Coupled with the advances in treatment of the disease, methods for detecting diabetes and its complications have also advanced. Without accurate and precise measures of blood glucose and glycated haemoglobin ($\text{HbA}_{1\text{c}}$) to monitor the efficacy of any intervention, tight glycaemic levels would not be achievable in a safe manner. Therefore, it is essential that people with diabetes have a clear regimen for monitoring their diabetes and are supported with education programmes to understand the role that testing plays in their care.

The aim of monitoring in diabetes includes:

- Allowing people with diabetes to understand the nature of their disorder.
- Determining the optimum times for initiating therapeutic intervention.
- Guiding the day-to-day adjustment of treatment.

Choosing the optimal target for monitoring and which assay is important ensures the best outcomes not only for an individual, but also at a population level, where small differences between the performance of tests, the frequencies with which they are carried out, and their costs may lead to important differences in outcomes and overall costs of care.

$\text{HbA}_{1\text{c}}$ and blood glucose are the two most frequently used measures of glycaemia in current practice. $\text{HbA}_{1\text{c}}$ provides information

about overall glucose levels in the previous 6–8 weeks, allowing assessment of the need for therapy and therapeutic response with minimal within-person variation in measurement. Blood glucose measurements provide information about the day-to-day levels, variation in levels, and response to therapeutic intervention. This chapter will describe the tests for $\text{HbA}_{1\text{c}}$ and glucose levels, the characteristics of these tests, the technology used in measuring their levels, and their clinical application in type 1 diabetes and type 2 diabetes. Additionally it will explore the role of other glycated proteins and the increasing role of point-of-care testing in diabetes monitoring. Newer and emerging technologies to assess glycaemia, including continuous glucose monitoring (CGM), are covered in Chapter 32.

Tests and their characteristics

Glycated haemoglobin

$\text{HbA}_{1\text{c}}$ measurement plays a pivotal role in the management of people with diabetes and in the diagnosis of people with type 2 diabetes. $\text{HbA}_{1\text{c}}$ levels are associated with the response to treatment and the risk of developing complications, and therefore provide an evidence-based marker with which to judge the impact of glucose-lowering treatment and prognosis. The outcomes of trials such as the UK Prospective Diabetes Study (UKPDS), the Diabetes Control and Complications Trial (DCCT), and Epidemiology of Diabetes Interventions and Complications (EDIC) clearly demonstrate the association between improved glycaemic levels and microvascular and, to a lesser extent, macrovascular complications of diabetes.

Glycohaemoglobin, glycosylated haemoglobin, glycated haemoglobin, glucosylated haemoglobin, fast haemoglobins, HbA₁, HbA_{1a+b}, HbA_{1c} and total glycohaemoglobin have all been used to refer to haemoglobin with the addition of glucose. However, with the introduction of standardization of HbA_{1c} testing, many of these terms are no longer in use and the term HbA_{1c} (sometimes abbreviated to A_{1c}) is the commonly accepted term.

HbA_{1c} is reported in SI units (from the French Système International d'Unités) of mmol/mol (mmol HbA_{1c}/mol Hb A₀+HbA_{1c}). While this is the internationally recognized unit for HbA_{1c}, it is still common to see the former units of % (the proportion of glycated to total levels of haemoglobin) used in many texts [1]. There are numerous conversion tables available to convert between the two units.

HbA_{1c} is formed by the binding of glucose to the β chain of haemoglobin in circulating red blood cells. The reaction between circulating glucose and haemoglobin is spontaneous and non-enzymatic, therefore HbA_{1c} formation is dependent on glucose concentration and duration of exposure. HbA_{1c} is formed slowly and continuously throughout the ~120-day lifespan of the red cell; however, due to the continual turnover of red cells in circulation, the most recent 60 days account for up to 75% of the influence on HbA_{1c} concentration.

Glucose, in the open-chain format, binds to the N-terminal valine of the β chain of haemoglobin A₀ [2] to form an aldimine (Schiff base), before undergoing an Amadori rearrangement to form a more stable ketoamine [3, 4] (Figure 29.1). This is a non-enzymatic process that occurs continuously *in vivo* [4]. Glycation of haemoglobin is atypical, because the reaction occurs predominantly between glucose and the N-terminal valine of the β chain of haemoglobin to

form HbA_{1c} [5]. Although this is the favoured reaction *in vivo*, other aldoses (galactose, maltose, lactose) may form haemoglobin adducts and other amino groups (α-chain N-terminal, various ε-amino groups on both the α and β chains) can be glycated [6]; these adducts contribute to the measurement of total HbA_{1c}.

Clinical drivers for standardization of HbA_{1c}

Early studies indicated that monitoring of HbA_{1c} allowed changes in therapy and subsequent reduction of measured HbA_{1c}, but did not categorically show that these changes improved overall outcomes [7]. The lack of standardization, both in terms of analytical performance and clinical utility, meant there were no uniform HbA_{1c} target values for maintaining blood glucose; accordingly, there was no consensus on whether strict glucose targets were of benefit in improving outcomes. This changed, however, with the publication of the DCCT and UKPDS studies [8, 9]. These large longitudinal studies, involving people with type 1 diabetes and type 2 diabetes, respectively, addressed the question of whether tight management of glucose levels resulted in a decrease in complication rates.

The DCCT study was a multicentre, randomized clinical trial in people with type 1 diabetes. The study was designed to assess if intensive therapy could be used to prevent or delay the progression of early vascular or neurological complications, using retinopathy as the primary study outcome. The treatment goal for the conventional therapy group was an absence of symptoms attributable to glycosuria or hyperglycaemia, whereas the intensive therapy group targets were near-normal glucose levels. The primary outcome measure of the study was a sustained change in levels of retinopathy; over the mean follow-up period of six years, the intensive therapy reduced the adjusted mean risk by 76% ($p < 0.001$).

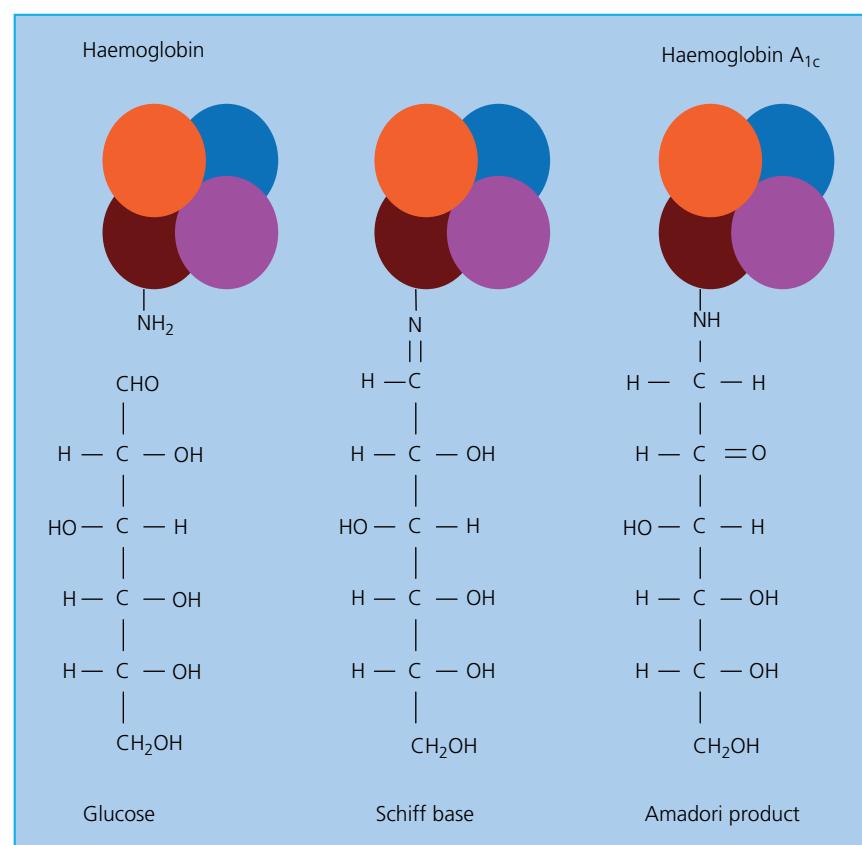

Figure 29.1 The Amadori reaction.

The EDIC study followed the individuals enrolled in the DCCT study for a further 20 years, with no attempt to formally continue the original therapy regimens of the DCCT study. Mean HbA_{1c} values converged between the two groups as a result of the changes in clinical practice brought about by the results of the original trial. The EDIC follow-on study showed that the reduction in risk for any fatal and non-fatal cardiovascular disease event (including confirmed angina, or the need for coronary artery revascularization) was 42% in intensive versus conventional treatment groups and 5% in fatal and non-fatal myocardial infarction and stroke [10].

The UKPDS study recruited individuals with newly diagnosed type 2 diabetes who were randomized by weight, then into conventional and intensive therapy regimens [9]. The conventional regimen aimed to avoid marked hyperglycaemia (fasting plasma glucose >15 mmol/l and/or symptoms of hyperglycaemia) and was primarily based on diet and lifestyle advice alone. The intensive therapy group aimed to achieve a fasting plasma glucose <6.0 mmol/l with treatment using insulin or sulfonylureas. Unlike the DCCT study, a target value of HbA_{1c} was not assigned in either of the therapy groups. In regard to the study endpoints, the reduction in microvascular complications was the most significant with a reduction of 25% in the intensive therapy group, predominantly attributable to retinopathy (two-stage progression of disease).

After the completion of the UKPDS, the individuals continued to be monitored in a follow-up study to determine if there were longer-term effects of the therapy regimens [11]. The follow-up showed a 24% risk reduction in microvascular complications, 15% risk reduction in myocardial infarction, and 13% risk reduction for all-cause mortality. This risk reduction, despite the loss in differences of HbA_{1c}, has been termed the *legacy effect*. When the relative risk profiles for micro- and macrovascular complications are compared, they show a significantly different profile: higher HbA_{1c} values contribute to a greater proportional risk in cases of microvascular disease, but a wider range of HbA_{1c} (including lower ‘non-diabetic’) values contribute to increased risk in macrovascular disease.

These two seminal trials showed that early, intensive therapy could significantly reduce the risk of a range of complications, even after the initial therapy has been discontinued. Accordingly, these studies established precise target HbA_{1c} values for treatment goals. This led to the urgent need for standardization of HbA_{1c} measurement for treatment targets to be globally applicable.

The lack of international standardization led to the development of national schemes for harmonization of HbA_{1c} results. The most commonly known is the US National Glycohemoglobin Standardization Program (NGSP), which uses the method utilized during the DCCT as a primary reference method. While this allowed reference to DCCT values, it suffered from interferences from non-HbA_{1c} components and there is no primary reference material.

In 1995 the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) established a working group with the remit of achieving uniform international standardization of HbA_{1c} [12]. In 1997 an international network of reference laboratories was formed to implement the newly devised reference measurement procedure for HbA_{1c}. Inter-comparison studies demonstrated a stable relationship between the IFCC reference measurement procedure and national harmonization schemes, allowing for the development of master equations to allow conversion between the more accurate IFCC values and national harmonization schemes such as the NGSP [13]. Due to difference in values between the systems, the decision was also made to adopt SI

units for HbA_{1c} to avoid confusion of apparently lower HbA_{1c} values and subsequent risk of misinterpretation of results, with the introduction of standardized values. The change of units also reduced potential confusion between reports of blood glucose levels in mmol/l and HbA_{1c} measurements. By contrast, in countries that still use mg/dl, the potential for confusion increased and this is one of the reasons why the American Diabetes Association (ADA) has not adopted the new units. Nevertheless, there is an ongoing need for a considerable education initiative to inform both people with diabetes and clinicians of the change.

The international reference network for HbA_{1c} standardization has now been established for nearly two decades and is the only recognized international system to which all manufacturers of HbA_{1c} test devices should be calibrated. Many of the secondary reference methods used by the IFCC network for assigning values to calibrator materials are also the NGSP secondary reference methods; this ensures that the master equation between the two systems remains stable and that measured HbA_{1c} values can be converted from SI units to % for those who still wish to understand the values in DCCT/UKPDS terms. Master equations for the conversion between IFCC and NGSP units are as follows:

$$\text{NGSP}(\%) = [0.0915 \times \text{IFCC}(\text{mmol/mol})] + 2.15$$

$$\text{IFCC}(\text{mmol/mol}) = [10.93 \times \text{NGSP}(\%)] - 23.50$$

The global consensus statement on HbA_{1c} states that HbA_{1c} results are to be reported by clinical laboratories worldwide in SI units (mmol/mol – no decimals) and derived NGSP units (% – one decimal), using the IFCC–NGSP master equation (DCCT units) [1]. The conversion equation is available on numerous websites and in other publicly available resources.

Diagnosis of type 2 diabetes using HbA_{1c}

The successful implementation of standardization of HbA_{1c} measurement paved the way for HbA_{1c} to be introduced for the diagnosis of type 2 diabetes [14]. An International Expert Committee, appointed by the ADA, the International Diabetes Federation (IDF), and the European Association for the Study of Diabetes (EASD), published a report in 2009 recommending the use of HbA_{1c} for the diagnosis of diabetes [15]. Based on the evidence that HbA_{1c} level correlates with adverse disease outcomes and the fact that HbA_{1c} targets are used for individual treatment, use of HbA_{1c} as a diagnostic tool seemed a logical progression. The committee proposed a diagnostic cut point of 48 mmol/mol (6.5%) HbA_{1c}. In 2011 the World Health Organization (WHO) also endorsed the use of HbA_{1c} for the diagnosis of type 2 diabetes, stating:

HbA_{1c} can be used as a diagnostic test for diabetes providing that stringent quality assurance tests are in place and assays are standardized to criteria aligned to the international reference values, and there are no conditions present which preclude its accurate measurement. [14]

Assays for measurement of HbA_{1c}

There are a wide range of methods used for the routine analysis of HbA_{1c}. They can be divided into methods that are based on charge differences, including cation-exchange high-performance liquid chromatography (HPLC) and capillary electrophoresis, and those that separate based on structural differences such as enzymatic, immunoassay, and boronate affinity separation methods. The analytical

performance goals for all methods have been defined and are based on sigma metrics. This allows both analytical imprecision and bias to be considered together, through a measure of total analytical error [16]. Quality targets are necessary for HbA_{1c} measurement, as the difference between HbA_{1c} values considered low risk for diabetes and the level diagnostic of diabetes is very small. In some countries this range is as low as 42–48 mmol/mol, meaning that relatively small levels of bias and imprecision can have a significant impact on a clinical diagnosis. For example, if a person's true HbA_{1c} value were 45 mmol/mol, a positive or negative bias of 2 mmol/mol and imprecision of 3% could easily generate values in the diagnostic range for diabetes or the low-risk range, respectively. Since the publication of these goals, there has been annual monitoring of laboratories around the world through national External Quality Assessment (EQA) schemes. The number of laboratories that participate in the EurA_{1c} trial is steadily growing, with >5000 participants within five years of the study commencing. The data generated give an overview of performance by country and by manufacturer, allowing targeted quality improvement measures to be devised and implemented [17].

Point-of-care HbA_{1c}

Point-of-care test devices are often considered a valuable addition to a clinician's armament in managing diabetes. They play an increasingly important role in wide range of clinical settings and there is increasing desire from clinicians to have access to more point-of-care tests [18]. Point-of-care testing is promoted as enabling faster clinical decision making, increased rapport with people with diabetes, and reduced referrals to secondary care and subsequent healthcare costs. However, there are also perceived barriers to implementation of point-of-care testing, including test accuracy, impact on individual pathways, and cost of testing [19].

Evidence of clinical utility for point-of-care testing for HbA_{1c} is mixed with some analyses suggesting a clear benefit, while others found an absence of clinical evidence for the use of point-of-care tests in clinical care [20, 21]. It is clear that there is a potential role for point-of-care testing; however, the accuracy, clinical utility, impact on care pathways, and cost of point-of-care testing should be considered before implementation.

The availability of point-of-care test devices for HbA_{1c} is rapidly expanding and while a small number of manufacturers currently hold market share, the number of providers is set to grow. Several studies have studied the accuracy of point-of-care test devices for HbA_{1c} and there are mixed results in performance [22]. Some devices have been extensively evaluated and can perform to the same level as laboratory devices. In future, pre-qualification of HbA_{1c} point-of-care test devices by the WHO will aid in decision making about the use of these devices more widely in clinical practice.

Factors affecting HbA_{1c} measurement

Both analytical and biological factors affect the measurement of HbA_{1c}. The importance of standardization and excellent analytical performance has already been described; however, there are a number of other factors that may lead to erroneous results in HbA_{1c} measurement (Table 29.1).

Accurate interpretation of HbA_{1c} requires a normal lifespan of erythrocytes. The presence of a shortened lifespan, for example with haemolytic disease or blood loss, can lead to underestimates of the true value. By contrast, iron-deficiency anaemia, which is associated with a longer lifespan, can be associated with an overestimate of the true value [23].

Table 29.1 Conditions that can affect the measurement of glycated haemoglobin (HbA_{1c}).

Haemoglobinopathies
Iron deficiency
Chronic kidney disease stage 4 and above
Ethnicity
Blood transfusion
Haemolysis (haemolytic anaemia)
Polycythaemia
A wide range of drugs including those used to treat HIV infection

Approximately 7% of the global population has a haemoglobin variant and these present both biological and analytical issues. The most common haemoglobin variants, in descending order of prevalence, are HbS, HbE, HbC, and HbD. Heterozygous carriers of these variants are often asymptomatic and generally have normal red-cell lifespans. There is no clear evidence on whether the structural changes in haemoglobin, due to the variants, directly affect glycation of the β chain at the N-terminal valine (to form HbA_{1c}); however, it is reasonable to assume that substitutions at the glycation site could alter the rate of glycation. Caution should be used when interpreting HbA_{1c} results from individuals with HbSS, HbCC, and HbSC, as the pathology of these diseases leads to anaemia, increased red-cell turnover, and transfusion requirements, which have adverse impacts on HbA_{1c} as a marker of long-term glycaemic levels. Alternative tests such as glycated serum protein (fructosamine) or glycated albumin should be considered for these individuals.

Some methods, such as ion-exchange chromatography and capillary electrophoresis, are capable of identifying the presence of a haemoglobin variant while others do not. Some methods are affected by haemoglobin variants and will give erroneous results. There is no set rule as to which method will or will not be affected by each variant, although the NGSP provides an updated list of methods and how they perform with common variants [24]. Some laboratories routinely report the identification of new variants; it is important to liaise with your local laboratory to assess the impact of potential variants on the local clinical population.

Chronic kidney disease affects 9% of the global population and has historically been cited as a cause of erroneous HbA_{1c} results due to the increased carbamylation of haemoglobin from urea. Modern HbA_{1c} methods are generally not affected by increased carbamylated haemoglobin and thus this is no longer a clinical issue. However, there is still a statistically significant divergence between HbA_{1c} values and fasting plasma glucose with increasing chronic kidney disease stages. Diabetes is a leading cause of chronic kidney disease and the two are often present concomitantly.

Studies so far suggest that chronic kidney disease stages 1–2 appear not to have a significant impact on HbA_{1c}, but chronic kidney disease stages 4–5 are consistently reported to influence HbA_{1c}, thus limiting its use in these stages. Most studies show that HbA_{1c} is underestimated compared to other markers of glycaemia either before or after the use of erythropoiesis-stimulating agents. Likewise, underestimation of HbA_{1c} is observed in individuals on dialysis, either haemodialysis or peritoneal dialysis. Nonetheless, despite the high prevalence of chronic kidney disease, little evidence of the effect of chronic kidney disease stages 3–4 on HbA_{1c} is available and, in particular, on the role of anaemia, which is a common

comorbidity. Individuals with diabetes and chronic kidney disease often develop anaemia, which can lead to increased HbA_{1c} values due to erythropoietin deficiency and iron-deficiency anaemia (through elongation of the erythrocyte lifespan) or decreased HbA_{1c} caused by reduced red blood cell survival, increased erythrocyte turnover, or administration of erythropoietin. Non-iron-deficiency anaemia, if present, may falsely decrease HbA_{1c} levels. Health professionals should be aware of these erroneous results when monitoring glycaemic levels or when using HbA_{1c} for diagnosis of type 1 diabetes.

Several studies report an increase in HbA_{1c} with increasing age, with mixed opinion as to whether this is a glucose-dependent or -independent process. Increases in HbA_{1c} may simply reflect a decline in glycaemia over time; however, there is evidence to suggest that the change in HbA_{1c} is not simply related to a change in glycaemia alone and that HbA_{1c} increases with age independent of glycaemia. The discordance between glucose and HbA_{1c} is more apparent between the two-hour glucose of an oral glucose tolerance test. While the overall increase in HbA_{1c} per decade is small, when considering this over a range of 70 years the absolute difference can be clinically meaningful.

Since the introduction of HbA_{1c} for the diagnosis of type 2 diabetes, there have been numerous studies that have shown that HbA_{1c} and fasting plasma glucose identify different populations. While there is considerable overlap between the two groups, there are still people who will be diagnosed with type 2 diabetes with one method but not the other. Some of the discrepancy is due to differences in ethnicity. A recent random effects meta-analysis of multiple studies demonstrated that HbA_{1c} ranged from 1.1 to 3.0 mmol/mol lower in White populations compared to Hispanic, East Asian, Black, and South Asian populations. However, it remains unclear whether there should be differentiated HbA_{1c} diagnostic thresholds for type 2 diabetes for different ethnic groups based on risk of clinical complications. Policy makers and clinicians should be aware of the evidence indicating racial or ethnic differences when delivering a more personalized medicine approach.

Fructosamine and glycated albumin

Fructosamine is the generic name for plasma protein ketoamines. Albumin is the predominant plasma protein and constitutes a significant proportion of the fructosamine value. Fructosamine reflects the average glycaemic exposure of the preceding 1–3 weeks. It may be useful in individuals where the measurement of HbA_{1c} is precluded, for example in pregnancy where glucose levels change rapidly, or in the preconception period where motivation to improve glycaemia is high and the changes can be evaluated at shorter intervals. Fructosamine measurement is not appropriate for routine use because the assay is markedly affected by excessive turnover or excretion of albumin in, for example, renal disease. Data are currently limited on the correlation between fructosamine and HbA_{1c}, with wide confidence intervals around the diagnostic cut point of 48 mmol/mol and no direct outcome data linking fructosamine and diabetes-related complications [25]. Indirect linkage via comparison with HbA_{1c} is of limited value at this stage and further work is needed to improve its clinical utility.

Glycated albumin is the most abundant glycated serum protein and has been advocated as a more sensitive marker of glycaemia than fructosamine due the reduced heterogeneity of the lifespan of the protein. While fructosamine levels tend to decrease in the third

trimester of pregnancy, due to the dilutional effects of an increased blood volume, glycated albumin levels tend to remain relatively constant in women without diabetes, because it is measured as a ratio of glycated to total serum albumin.

Albumin has a shorter lifespan in comparison to erythrocytes (~20 days). Therefore, glycated albumin is a better measure of shorter-term glycaemic levels than HbA_{1c} and is more likely to be affected by rapid fluctuations in blood glucose levels; this means that it may better reflect post-prandial increases in plasma glucose in comparison to HbA_{1c}. To date there is increasing evidence of the correlation of glycated albumin and HbA_{1c} values especially in diabetes, but there is currently limited translation of this into a marker of complications. As such, glycated albumin may be a useful marker in individuals where HbA_{1c} cannot be used. Methods for glycated albumin have now been harmonized and are relatively well characterized, meaning they may become an increasingly useful tool in the management of people with diabetes.

Measurement of blood glucose

The measurement of glucose is used for both diagnosis and monitoring of diabetes. Glucose measurement can enable the diagnosis of diabetes, impaired glucose tolerance, or impaired fasting glycaemia; the latter two are intermediate states of abnormal glucose metabolism that exist between normal glucose homeostasis and the overt hyperglycaemia of diabetes. Analysis of glucose in a blood sample is performed either in a clinical laboratory or by point-of-care testing (either by people with diabetes themselves or by health-care professionals at the bedside or in clinic). Blood glucose measurement is a term that is frequently used without precise definition. Measurement of glucose levels is usually carried out on either capillary or venous specimens of blood; serum analysis is less common. Under usual circumstances, the concentration of glucose in whole blood is ~10–15% lower than in plasma. This is because a given volume of red blood cells contains less water than the same volume of plasma. Capillary blood glucose concentrations are very similar to venous blood levels in the fasting state; however, after a glucose load capillary samples may be up to 25% higher than simultaneously drawn venous blood samples [26]. Table 29.2 shows the equivalent measurements from the different sample types.

Blood glucose levels are expressed in SI units as millimoles/l (mmol/l). The traditional unit for measuring blood glucose is milligrams/decilitre (mg/dl), although use of these units is now largely confined to the USA. To convert mmol/l glucose to mg/dl, multiply by 18 (Table 29.2). Blood specimens for analysis of glucose levels need to be taken under controlled conditions as they are subject to

Table 29.2 Differences in blood glucose values dependent on sample type.

Time of measurement	Glucose concentration (mmol/l) ^a			
	Plasma		Whole blood	
	Venous	Capillary	Venous	Capillary
Fasting	≥7.0	≥7.0	≥6.1	≥6.1
2 h after a glucose load	≥11.1	≥12.2	≥10.0	≥11.1

^a 1 mmol/l = 18 mg/dl.

continuing glycolysis by red blood cells, which is enhanced by the presence of leucocytosis. The continuing glycolysis should be avoided by collection onto ice, rapid centrifugation, and analysis within 30 minutes [27]; however, this is impractical in many routine clinical settings. The use of blood collection tubes containing sodium fluoride inhibits further glucose metabolism, although there is still some loss of glucose for the first two hours post-collection, when the amount of glucose lost could be as much as 15% of the original concentration. If an individual has an intravenous line *in situ*, blood should be drawn from the arm opposite to the one with the line to prevent contamination of the sample from any infusion. Clinicians should be aware of these potential limitations of blood glucose measurement.

There are three basic approaches to the laboratory measurement of blood glucose concentration: reducing methods, condensation methods, and enzymatic methods. Most laboratories utilize hexokinase and glucose oxidase enzymatic methods, with only a small proportion of laboratories using glucose dehydrogenase methods. Reducing methods and condensation methods are cheaper than enzymatic methods, but they are more prone to interferences from strong reducing agents or other sugars.

Point-of-care test devices for blood glucose

Glucose oxidase and glucose dehydrogenase methods are those most commonly used in handheld point-of-care test devices. Most systems include strips that contain all the reagents necessary for analysis in a single-use disposable unit. Blood is applied to the end of the strip either directly or through capillary action by touching the strip to the blood droplet being analysed.

Some meters additionally incorporate the facility to measure blood ketone levels, of particular importance for people with type 1 diabetes. Other meters have the facility to calculate insulin bolus requirements or to download blood glucose results for evaluation of the pattern of glucose levels over time.

Most of the currently marketed handheld capillary blood glucose meters give results as an equivalent to venous plasma glucose, but this is not always the case. The same type of handheld meter may be calibrated to report whole blood glucose in one country and plasma values in another. The calibration of a meter should be checked and the thresholds for action set accordingly. Factors that affect the accuracy of point-of-care test devices for blood glucose are shown in Table 29.3.

Table 29.3 Factors that affect the accuracy of point-of-care test devices for blood glucose.

- Direct chemical interferences with substances such as acetaminophen and ascorbate (vitamin C)
- Blood oxygen concentrations in systems using glucose oxidase
- Changes in blood viscosity and haematocrit
 - Oedema
 - Dehydration
 - Hyperosmolar hyperglycaemia syndrome
 - Sepsis
 - Poor sampling by massaging sample site
- Errors arising from transcription errors (when not electronically linked)
- Impact of environmental conditions
 - Temperature
 - Humidity
 - Altitude

Point-of-care testing, utilizing capillary blood glucose measurement, can be used to replace venepuncture in many settings, with greater comfort and more rapidly available results for monitoring individuals in an acute situation. Standards have been laid down to ensure that bedside glucose determinations can be made accurately and include the need for well-defined policies, which incorporate adequate training, quality control procedures, and regular maintenance of equipment [28]. This guidance differs from that provided for devices that are intended for self-monitoring of blood glucose by individuals with diabetes.

Self-monitoring blood glucose devices

Devices used for self-monitoring of blood glucose must meet ISO 15197:2013 standards; in addition other standards may be dictated by national or local guidance. It is of note that people with diabetes often assume that their devices are accurate because they meet the standards prescribed or carry approval from the US Food and Drug Administration (FDA) or the European Conformité Européenne (CE) mark, although this is not always the case and education plays a key role in supporting people with diabetes to identify incorrect data from their device [29]. Despite their imprecision, blood glucose meters remain particularly helpful at higher blood glucose values, where, for example, it is of less importance to distinguish a plasma glucose of 11 mmol/l (198 mg/dl) from one of 14 mmol/l (252 mg/dl). In such circumstances, the aim of management is to achieve a substantial reduction in plasma glucose. At lower plasma glucose levels, however, the consequences of imprecision of 15% are much greater.

Accuracy of devices is dependent on both the user and the device, therefore evaluation of the individual's technique when using their device is advised at regular intervals. Correct sampling for self-monitoring of blood glucose devices is important for accurate results and is detailed in information for users for each device, as well as in publications such as the WHO Guidelines on Drawing Blood (Figure 29.2) [30]. The most common site of sampling is the pad of the finger; alternative sites for sampling include the base of the thumb, forearm, and thigh. Pre-meal readings will be the same between sites, but at times of rapid glucose change

Figure 29.2 The correct technique for self-monitoring of blood glucose improves the accuracy of testing.

(in the post-prandial period or during hypoglycaemia), forearm and thigh results will be different from fingertip results, because glucose changes lag behind the fingertip results.

Newer devices can store and upload data to mobile devices or computers, may allow reapplication of blood to the sample strip if the first sample is insufficient, and utilize very small volumes of blood. This allows for smaller, thinner lancets to be used, which reduces discomfort for the individual and encourages ongoing testing. Calibration and issues such as erroneous readings when test strips are incorrectly inserted have largely been ameliorated with updates in technology and thus further reduce the risk of errors.

Continuous glucose monitoring

CGM devices use a broad range of analytical techniques to assess glucose levels. The development of these devices has arisen from the increasing awareness of the need for individuals to have optimal glycaemic levels. CGM devices use a range of techniques, from predominantly non-invasive through to invasive methods. All of these devices work on the sampling of interstitial fluids on the basis that this correlates with blood glucose levels. For further details refer to Chapter 32.

Estimated average glucose

Estimated average glucose (eAG) values have been derived from the correlation between mean HbA_{1c} levels and mean blood glucose levels in the A_{1C}-Derived Average Glucose (ADAG) study [31,32]. The mean glucose levels were determined from self-monitoring of blood glucose and CGM measurements and calculated by combining weighted results from at least two days of CGM performed four times, with seven-point daily self-monitoring of capillary glucose performed at least three days per week. Numerous calculators are available online for the calculation of estimated average glucose from HbA_{1c}. The ADA and the American Association for Clinical Chemistry have determined that the correlation in the ADAG data is strong enough to justify inclusion in the Standards of Medical Care in Diabetes [33]; however, this is not a universally accepted calculation due to the wide range in glucose levels reported for each HbA_{1c} level.

Measurement of glucose in urine

The presence of glycosuria can be identified by semi-quantitative or quantitative glucose methods. The use of dry reagent test strips for urine dipstick analysis allows cheap, rapid, and portable urine analysis. Urine specimens should be analysed immediately, preserved at pH<5 to inhibit bacterial metabolism or stored at 4°C. Chemical reactions and subsequent visual assessment of the colour against a printed colour chart yield a semi-quantitative result. As a consequence of their condition, many people with diabetes are prone to visual difficulties and this has been a major operator-dependent step with visually monitored systems, in particular distinguishing the small variations in blues and blue-green colours produced by many of the test strips. Automated urinalysis machines are now available that can accurately determine colour changes in samples, making them a cheap and rapid method for screening large numbers of samples. Quantitative methods utilize hexokinase or glucose dehydrogenase methods.

The clinical utility of urine glucose measurement is limited, as it does not reflect the changing levels of hyperglycaemia with any accuracy. In addition, the renal threshold above which glucose is excreted in the urine varies between individuals and during pregnancy and with ageing. Nevertheless, it may have a role in resource-poor settings where identification and treatment of individuals with suboptimally managed diabetes are the highest priority.

Measurement of ketones

Diabetic ketoacidosis (DKA) is a commonly encountered diabetes-related emergency with appreciable morbidity and mortality. Reports of euglycaemic DKA in people with diabetes using sodium-glucose cotransporter 2 (SGLT-2) inhibitors means that clinicians and people with diabetes should be aware of the possible testing options [34]. Ketone bodies are derived from the catabolism of free fatty acids to form acetoacetate, acetone, and β-hydroxybutyrate. Acetoacetate and β-hydroxybutyrate are normally present in equimolar concentrations; however, due to increased levels of nicotinamide adenine dinucleotide + hydrogen (NADH) present in severe diabetes, the ratio may shift towards β-hydroxybutyrate up to 6:1, and thus methods for ketones that only detect acetoacetate may significantly underestimate the degree of ketosis. Therefore, methods that measure β-hydroxybutyrate are preferable in the monitoring of individuals with DKA. Like all laboratory and point-of-care testing methods, rigorous quality assurance procedures should be in place, along with training of users to understand the limitations of the devices and where to seek help and advice in their use.

Clinical approaches to monitoring in diabetes

Effective monitoring of glycaemia requires a partnership between healthcare professionals and the person with diabetes. Optimal testing intervals and the balance between use of laboratory testing and self-monitoring require consideration of a range of factors, extending from wholly clinician-directed testing (e.g. during acute illness in a hospital setting) to self-monitoring by a person with diabetes in the community who is otherwise well. The approach to this discussion with people with diabetes should be person centred and communication should be strength based, with a focus on active listening to ensure that the individual's beliefs, abilities, and barriers to care can be fully considered. As well as person-centred communication, care should be offered from multidisciplinary teams to present a holistic approach to treatment.

Self-monitoring of blood glucose

Self-monitoring of blood glucose, in conjunction with diabetes self-management education and support, is an integral part of self-care for people with type 1 diabetes to maintain levels of blood glucose that minimize risks of complications. In addition, it is required for people with type 2 diabetes using insulin, and for some people with type 2 diabetes who have specific indications [35,36]. When correctly done, glucose monitoring enables people with diabetes to assess their individual response to therapy and provide insight into their achievement of their target goals. The ability to accurately record data from self-monitoring of blood glucose devices in the

individual's records enables more effective diabetes management and guides medical nutrition therapy, physical activity, identification of risk of hypoglycaemia, and adjustment of medications (particularly prandial insulin doses). The individual's specific needs, capabilities, and goals should dictate the frequency of self-monitoring of blood glucose and timing or the consideration of CGM use. For further detail on testing using CGM including frequency, refer to Chapter 32.

is a representative example. Blood glucose levels for critically ill individuals should be maintained between 7.8 and 10.0 mmol/l (140 and 180 mg/dl), although a lower target of 6.1–7.8 mmol/l (110–140 mg/dl) may be aimed at, provided that there is no increase in the incidence of severe hypoglycaemia [40]. Self-management of diabetes in the hospital setting may be appropriate where adult individuals are alert, able to self-manage their diabetes at home, and have stable requirements for insulin. This may also offer an opportunity for providing support in learning techniques of insulin adjustment in line with carbohydrate intake.

Monitoring in type 1 diabetes

Glycaemia should be assessed using HbA_{1c} measurement in all adults with type 1 diabetes every 3–6 months. This could be increased if a person's blood glucose is thought to be rapidly changing due to treatment changes or when they are not meeting their treatment goals [33, 37]. As detailed in the previous sections, HbA_{1c} methods should be calibrated to the IFCC standardization and enrolment in an EQA scheme is strongly recommended. In the USA and some other countries, methods are also expected to be certified by the NGSP. Targets for HbA_{1c} vary between different guidelines and are dependent on multiple factors. Goals are set to minimize risk of long-term complications, but individualized targets should be agreed based on lifestyle and previous experience of hypoglycaemia. HbA_{1c} values of 48 or 53 mmol/mol (6.5% or 7.0%) are common goals, although these may differ in older adults and those with multiple comorbidities [33, 37].

Adults with type 1 diabetes should also be encouraged and supported to routinely undertake self-monitoring of blood glucose, and test at least four times a day (including before each meal and before bed). This may be increased to up to ten times a day when treatment goals are not being reached, when hypoglycaemic episodes are increasing in frequency, when the individual's employment or legal restrictions require it, during increased activity, or during periods of illness. The use of CGM devices for monitoring is becoming increasingly common.

Education is an essential tool to empower individuals with diabetes to monitor their blood glucose, and they should be taught how to use the blood glucose data to adjust food intake, exercise, or pharmacological therapy to achieve specific goals. However, tight glucose levels bring with them the risk of hypoglycaemia, which in turn may occur more frequently in people with suboptimally managed diabetes [38]. Additional checks on blood glucose levels should be made in relation to the risk of hypoglycaemia, for example before exercise or driving and in the presence of symptoms that may indicate hypoglycaemia.

Targets for blood glucose level vary between different guidelines. The ADA guidance recommends pre-prandial capillary plasma glucose of 4.4–7.2 mmol/l (80–130 mg/dl) and peak post-prandial capillary plasma glucose of 10.0 mmol/l (<180 mg/dl) [33].

Children and young adults with type 1 diabetes and their caregivers should be given age-related and culturally appropriate education for self-monitoring of blood glucose. Guidance on frequency varies from a minimum to five times a day and upwards; CGM is also advocated [39]. Glucose concentration targets are similar to those of adults; however, HbA_{1c} targets vary more widely depending on the source of the guidelines.

Guidance for monitoring diabetes in a hospital setting varies depending on the guideline and the resources available; the following

Monitoring in type 2 diabetes

For people with type 2 diabetes, the overall level of glycaemia should be monitored using HbA_{1c} every 3–6 months until stable and there is no change in therapy. For those with stable blood glucose levels and no changes in therapy, every 6 months is sufficient. The majority of HbA_{1c} values are still provided via centralized laboratories; however, there is increasing interest in the use of point-of-care test devices to enhance community-based care pathways. Currently there is no guidance that actively supports routine use of point-of-care HbA_{1c} for diagnosis of diabetes, although there are examples of effective use of point-of-care HbA_{1c} in the community-based care of people with type 2 diabetes, such as the Norwegian Organization for Quality Improvement of Laboratory Examinations (Noklus) system [41].

Setting HbA_{1c} targets for people with type 2 diabetes is important to guide decisions about treatment and to provide feedback to the individual and clinician about the effectiveness of treatment. The level at which targets should be set for an individual remains widely debated. Although guidelines provide advice about generally accepted targets, individuals need to be involved in decisions about their own HbA_{1c} target. Once available, the results of tests should be used to encourage people to achieve and maintain their target unless they develop hypoglycaemia.

If HbA_{1c} measurement is unavailable, then a fasting plasma glucose measurement can be used to indicate need for, or response to, a treatment that leads to a reduction in fasting hyperglycaemia (e.g. metformin or a sulfonylurea). A fasting capillary plasma glucose level of 3.9–7.2 mmol/l is recommended as a target.

The approach to self-monitoring of blood glucose in people with non-insulin-treated type 2 diabetes is mixed. Guidelines for treatment of people with type 2 diabetes draw attention to the lack of evidence for effectiveness and cost-effectiveness of routine use of self-monitoring of blood glucose and recommend that it should not be routinely used. Although there is some evidence that testing may improve glycaemic levels in some people, there is similarly evidence that data are frequently not acted on and that the benefit does not outweigh the cost. It continues to have a place where there are concerns about hypoglycaemia (e.g. use of sulfonylurea) or HbA_{1c} measurements are not possible or do not provide an accurate measure of glycaemia.

For people with type 2 diabetes who are using insulin, self-monitoring of blood glucose is needed to adjust insulin dose and check that glucose levels are maintained, although optimal use remains to be established. Frequency and targets are similar to those with type 1 diabetes.

Diabetes in pregnancy

Diabetes in pregnancy and gestational diabetes (diabetes first identified during pregnancy) are rising in prevalence. Pre-conception care for women with diabetes is important, with glycaemic targets as near normal as possible ($\text{HbA}_{1c} < 48 \text{ mmol/mol} (< 6.5\%)$) to reduce the risk of complications during pregnancy and birth, including macrosomia, pre-eclampsia, and congenital abnormalities. The results of the Continuous Glucose Monitoring in Women with Type 1 Diabetes in Pregnancy Trial (CONCEPTT) demonstrated that the use of CGM was associated with improved neonatal outcomes and led to the recommendation that all pregnant women with type 1 diabetes, or those without type 1 diabetes but on intensive insulin therapy, be offered CGM [42]. Further details are provided in Chapter 71.

Monitoring of diabetes in special situations

Bariatric surgery

Bariatric surgery is being increasingly used in the management of people with type 2 diabetes and obesity. Post-surgery, blood glucose levels may return to near-normal levels for prolonged periods of time, with HbA_{1c} values within the normal range. These individuals are determined to have diabetes in remission. While each of the measures used to diagnose diabetes is valid, the preferred test for identification of diabetes remission is HbA_{1c} at $< 48 \text{ mmol/mol} (< 6.5\%)$ for three months or more with no glucose-lowering pharmacological intervention; the same caveats to the use of HbA_{1c} for diagnosis and monitoring apply to this situation. As implied by the term *remission*, there is a need for ongoing monitoring of these people for complications of diabetes, including retinal screening, renal function, foot evaluation, and measurement of blood pressure and weight, in addition to ongoing monitoring of HbA_{1c} . The frequency of HbA_{1c} measurement should not be more often than every three months nor less frequent than yearly to confirm continuation of the remission, in line with monitoring of stable type 2 diabetes [43].

Low-resource settings

While data and guidance advocate timelines and tests for monitoring of diabetes, the management of diabetes is very costly. Estimates of test costs vary immensely, but it is unlikely that the cost of prescribed monitoring can be met in many low-resource settings. The myriad of different environmental and economic factors around the use of diabetes testing mean that testing is often suboptimal. While urine dipsticks for glucose are inexpensive and portable, they are non-specific, non-quantitative, and not sensitive to small changes in blood glucose levels. Blood glucose testing necessitates adequate fasting and temperature-sensitive reagents, and CGM devices are very expensive. HbA_{1c} is a preferred monitoring test as fasting is not required and it is a longer-term marker of glycaemic levels, but point-of-care test devices are still quite cumbersome and not yet truly adapted for the low-income setting. WHO and other non-governmental organizations are actively engaged with the development and assessment of point-of-care devices for diabetes testing, and this is an area that is likely to see significant investment, research, and improvement in the future.

Conclusion

Glycaemic levels should be monitored regularly for all people with diabetes. The optimal method of determining risk of long-term complications is through HbA_{1c} measurement, although if this is not available then examination of a series of blood glucose measurements, including fasting tests, may provide guidance. HbA_{1c} methods should be standardized to the IFCC reference measurement procedure and units of reporting are the SI units mmol/mol, with derived percentage units in brackets. The role of CGM in diabetes monitoring is increasing and is likely to become a prominent feature of diabetes care in the future. New considerations for diabetes monitoring, such as in the remission of diabetes post-surgical intervention, will continue to be identified, and there is a critical need for investment and research into low-cost, robust, and accurate testing for low-resource settings.

- Precision medicine is an emerging concept to personalize healthcare decision making and treatment selection according to an individual's demographic, physical, and clinical data.
- The unprecedented progress in molecular and genetic technologies has resulted in a better insight into the pathophysiology of diabetes and response to treatment.
- In monogenic diabetes where a mutation in a single gene can cause the disease, various examples of the utility of genetic-based approaches to tailor treatment are available.
- The pathophysiology and response to treatment are more complex and heterogeneous in type 2 diabetes and are determined by variations in multiple genes and other factors such as lifestyle and environment.
- Multiple factors thus have to be considered in a complex disease like type 2 diabetes when making tailored treatment choices.
- Pharmacogenetics and use of protein markers can inform precision medicine approaches for the treatment of diabetes.

Introduction

According to the International Diabetes Federation (IDF), approximately 463 million people were living with diabetes in 2019 [1]. Estimates from the IDF indicate that this number will rise to 700 million people in 2040. The commonest types of diabetes are type 1 diabetes and type 2 diabetes. Type 1 diabetes is caused by the autoimmune destruction of β cells in the pancreas, which leads to a discontinuation of insulin production [2]. Type 2 diabetes results from a combination of inadequate insulin secretion in the face of reduced insulin action. The pathophysiology is based on genetic and lifestyle factors [3]. In addition to type 1 diabetes and type 2 diabetes, monogenic varieties of diabetes exist, but their prevalence is much lower and they account for ~3% of cases of diabetes diagnosed in children [4,5].

Diabetes increases the risk of micro- and macrovascular complications. Exposure to high blood glucose levels damages the microvasculature in the kidney and eye, resulting in chronic kidney disease and blindness [6]. Diabetes-related kidney disease occurs in 30–40% of all people with diabetes and diabetic retinopathy is the major cause of blindness in adults in most countries in the world [7,8]. Cardiovascular disease is a manifestation of injury to larger blood vessels in the heart and peripheral vasculature. Cardiovascular disease occurs frequently in people with diabetes and accounts for approximately one-third to one-half of all diabetes-related deaths [9].

Diabetes, in particular type 2 diabetes, frequently clusters with other risk factors for cardiovascular and kidney disease, such as hypertension, hypercholesterolemia, obesity, and microalbuminuria [10,11]. The first aim of diabetes treatment is to correct hyperglycaemia to ameliorate diabetes symptoms, such as polyuria, tiredness,

and blurred vision. Long-term treatment goals include the prevention of micro- and macrovascular complications. Landmark clinical trials have shown that intensive glycaemic management in people with type 1 diabetes and type 2 diabetes reduces the long-term risk of diabetes-related complications, including retinopathy and kidney and cardiovascular disease [12–14]. However, for the optimal prevention of long-term complications, other risk factors such as obesity, hypertension, and hypercholesterolemia should be managed as well. Blood pressure lowering with an angiotensin-converting enzyme (ACE) inhibitor confers micro- and macrovascular protection [15]. In addition, cholesterol lowering with statins decreases the incidence of cardiovascular events in people with diabetes [16]. Thus, targeting multiple risk factors simultaneously is necessary to enhance protection against micro- and macrovascular events. In the Steno 2 trial, 160 individuals with type 2 diabetes were randomly assigned to intensive multifactorial risk factor management or conventional treatment [17]. Multifactorial risk factor management significantly improved cardiovascular outcomes and during the 21-year follow-up, the risk of kidney failure or mortality was reduced by 47%, highlighting the importance of targeting multiple cardiovascular risk factors rather than glycaemic management alone [18].

Various oral anti-diabetes drugs have been developed in the last decades, including dipeptidyl-peptidase 4 (DPP-4) inhibitors, glucagon-like peptide-1 receptor agonist (GLP-1 RA), and sodium-glucose cotransporter-2 (SGLT-2) inhibitors. These drug classes significantly improve glycaemic levels when added to the traditionally used drugs such as metformin, sulfonylurea derivatives, and insulin. Importantly, GLP-1 RA and SGLT-2 inhibitors reduce body weight and blood pressure and improve cardiovascular outcomes. Moreover, SGLT-2 inhibitors have favourable effects beyond

improving glucose levels: they also reduce blood pressure, body weight, uric acid, and the risks of kidney and heart failure [19–21].

Based on past trials, current clinical practice guidelines recommend monitoring and optimizing multiple cardiovascular risk factors of kidney and cardiovascular disease in people with type 2 diabetes. Most guidelines also recommend the use of GLP-1 RA and SGLT-2 inhibitors as an adjunct to metformin [22,23]. However, despite the use of these newer agents, many individuals with diabetes still experience cardiovascular and kidney diseases [24,25]. This is illustrated in well-conducted large clinical trials demonstrating that even during treatment with GLP-1 RA and SGLT-2 inhibitors, the

risk of cardiovascular outcomes, heart failure hospitalizations, and kidney failure remains high (Figure 30.1) [19,20,26]. Part of the suboptimal protection can be explained by an insufficient response to the currently used drugs. For example, ~35% of treated individuals do not show a reduction in glycated haemoglobin (HbA_{1c}) in response to metformin, the first choice of glucose-lowering treatment for people with type 2 diabetes [27,28]. This variation in response is observed not only for glucose-lowering agents, but for other drugs used in the management of diabetes. For example, 35% of the treated individuals show no reduction in blood pressure to an ACE inhibitor or angiotensin receptor blocker (ARB) [29,30].

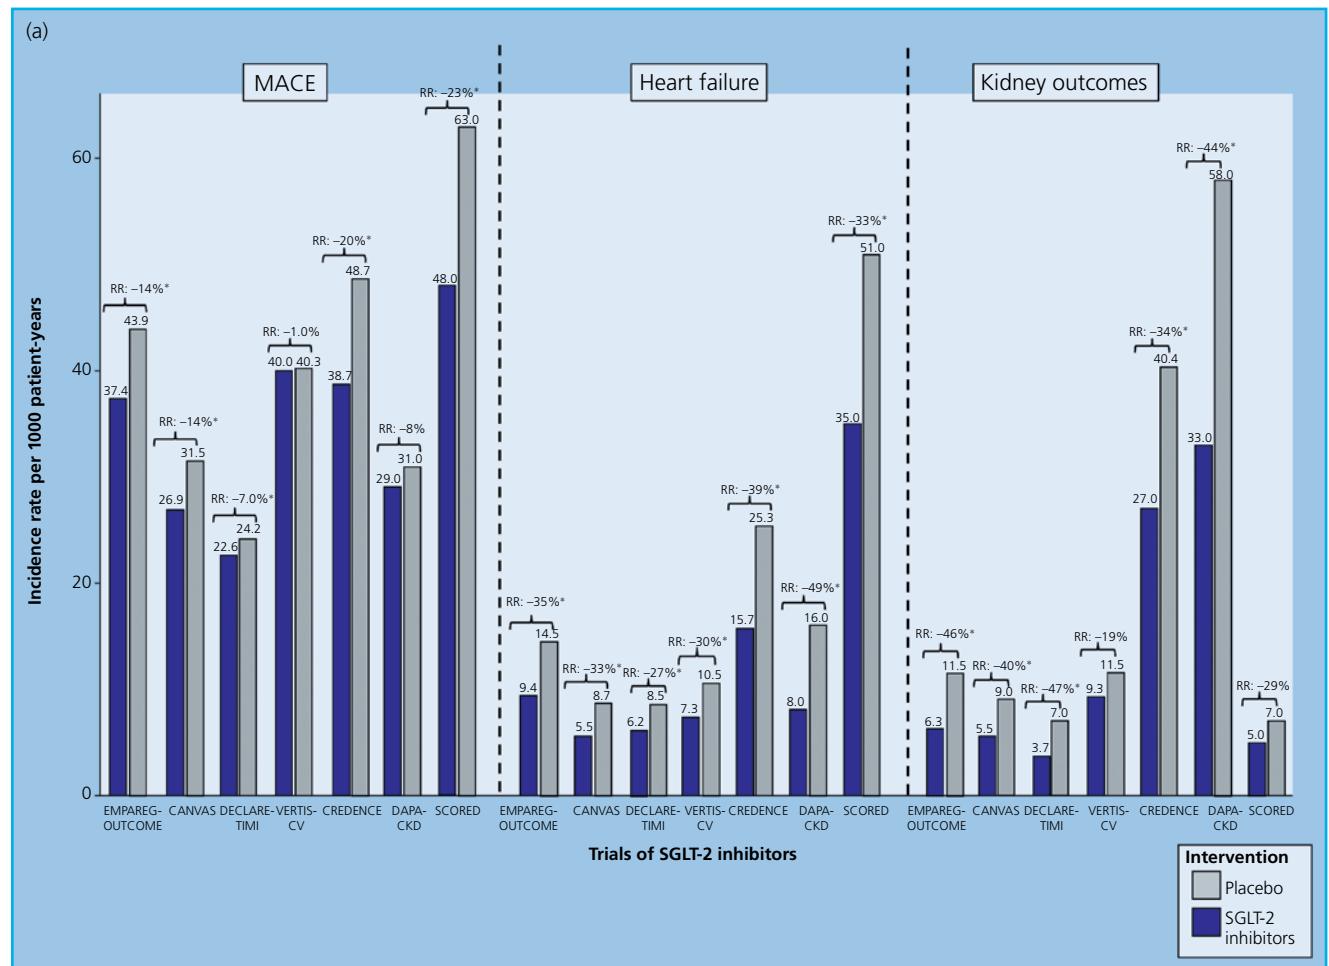

Figure 30.1 (a) Incidence rate per 1000 person-years for the occurrence of major adverse cardiovascular events (MACE), heart failure, and kidney outcomes in randomized controlled trials of the sodium-glucose cotransporter-2 (SGLT-2) inhibitors. MACE outcome is defined as a composite of death from cardiovascular causes, non-fatal myocardial infarction, or non-fatal stroke. Heart failure outcome is defined as hospitalization for heart failure. The definition of kidney outcomes for each trial is as follows: (i) EMPAREG-OUTCOME – doubling of serum creatinine level accompanied by estimated glomerular filtration rate (eGFR) of $45 \text{ ml/min}/1.73 \text{ m}^2$, initiation of renal replacement therapy, or death from renal disease; (ii) CANVAS – 40% reduction in eGFR, end-stage kidney disease (ESKD), or death from renal causes; (iii) DECLARE-TIMI – sustained decrease in eGFR by at least 40% to less than $60 \text{ ml/min}/1.73 \text{ m}^2$, ESKD, or renal death; (iv) VERTIS-CV – death from renal causes, renal replacement therapy, or doubling of the serum creatinine level; (v) CREDENCE – ESKD, doubling of serum creatinine, or renal death; (vi) DAPA-CKD – composite of decline in eGFR of $\geq 50\%$, ESKD, or death from renal causes; (vii) SCORED – sustained decrease of $\geq 50\%$ in eGFR from baseline for ≥ 30 days, long-term dialysis, renal transplantation, or sustained eGFR of $< 15 \text{ ml/min}/1.73 \text{ m}^2$ for ≥ 30 days. * in RR indicates a significant risk reduction.

a significant risk reduction. (b) Incidence rate per 1000 person-years for the occurrence of MACE, heart failure, and kidney outcomes in randomized controlled trials of glucagon-like peptide-1 receptor agonists (GLP-1 RAs). MACE outcome is defined as a composite of death from cardiovascular causes, non-fatal myocardial infarction, or non-fatal stroke (in ELIXA* it consists of MACE and hospitalization for unstable angina). Heart failure outcome is defined as hospitalization for heart failure (in HARMONY OUTCOMES it consists of a composite of heart failure and cardiovascular death). Definitions of kidney outcomes in the other trials were (i) LEADER – new-onset persistent macroalbuminuria, persistent doubling of serum creatinine level, and eGFR of $\leq 45 \text{ ml/min}/1.73 \text{ m}^2$, the need for continuous renal replacement therapy, or death from renal disease; (ii) SUSTAIN-6 – persistent macroalbuminuria, persistent doubling of serum creatinine with creatinine clearance $< 45 \text{ ml/min}/1.73 \text{ m}^2$, and need for renal replacement therapy; (iii) EXSCEL – composite of 40% eGFR decline, renal replacement, and renal death; (iv) REWIND trial – development of macroalbuminuria, sustained 30% or greater decline in eGFR, or new chronic renal replacement therapy comprising dialysis or renal transplantation. * in RR indicates a significant risk reduction.

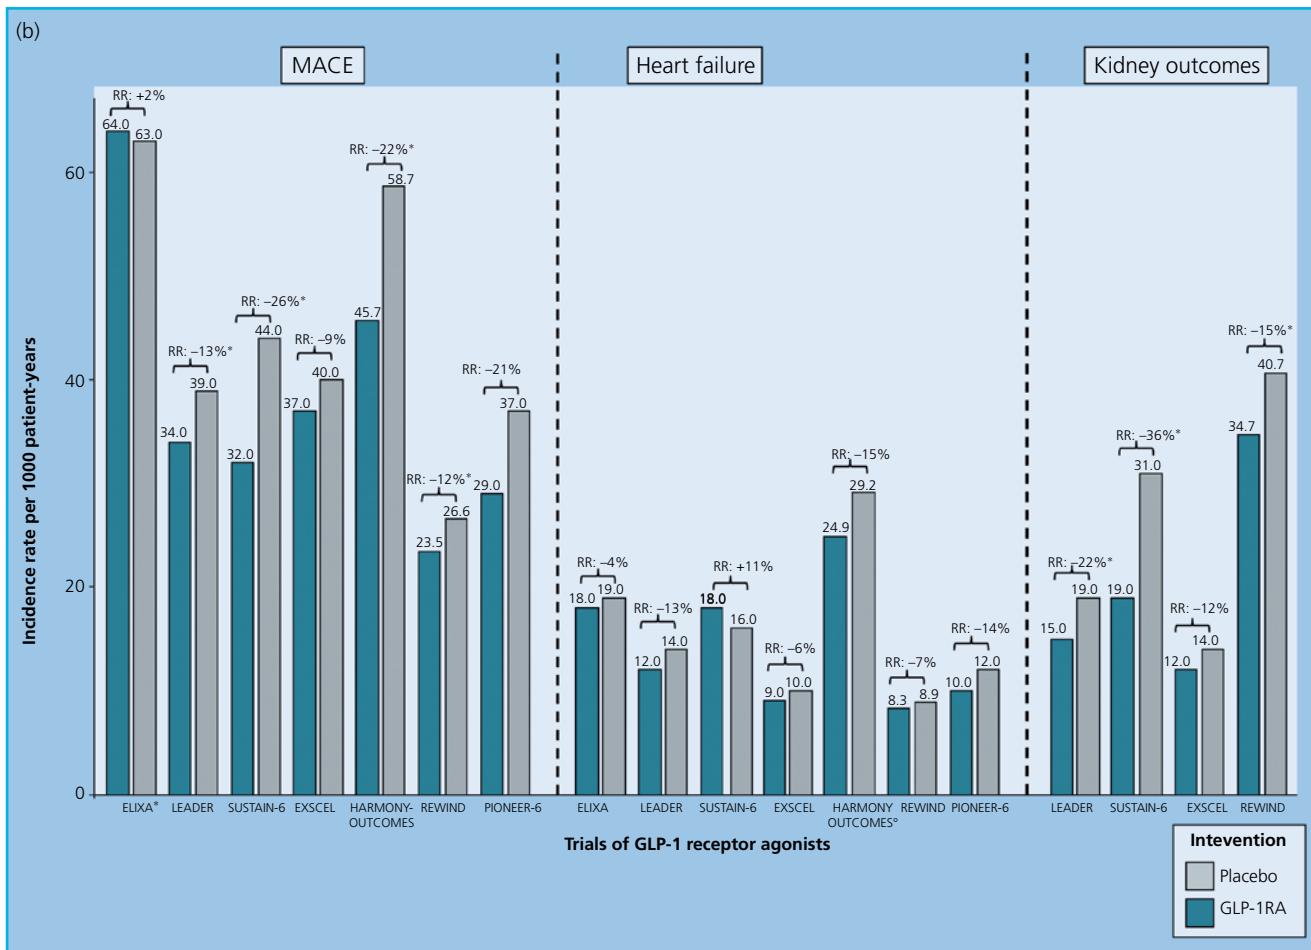

Figure 30.1 (Continued)

Understanding the underlying mechanisms of therapy resistance may stimulate the development of new strategies to improve the pharmacotherapy of diabetes and pave the way for more individualized and effective drug use in clinical practice.

In the past, the pharmacological treatment of diabetes used the same drugs for all people with diabetes. However, there has been significant interest in incorporating clinical laboratory data, lifestyle and environmental information, and data from human genetics in treatment decisions to individualize and tailor pharmacotherapy. More recent guidelines have started to adopt this approach and, for example, recommend individualized glycaemic targets and drug choices for subgroups of individuals [31]. Recent advances in genetics and simultaneous measurements of numerous proteins and metabolites have increased expectations that in the near future treatment decisions will be able to be further tailored to the individual based on specific personal characteristics [32–34]. This concept, which is termed *personalized medicine*, is usually defined as a medical model that separates people into different groups, with medical decisions, practices, interventions, and/or products being tailored to the individual based on their predicted response or risk of disease [35]. According to this definition, diagnostic testing is used to select the most appropriate treatment based, for example, on the genetic make-up of an individual. Furthermore, other factors, including concomitant diseases, clinical chemistry information, and lifestyle and environmental factors, are used to guide medical decision making for the individual.

In this chapter, we review the variation in drug response to commonly used drugs in people with diabetes to guide personalized treatment choices. We start the chapter with a summary of examples from monogenic diseases to illustrate how pharmacogenetics can be used to tailor therapy decisions. In the second part, we focus on oral agents for the treatment of type 2 diabetes. In contrast to monogenic diseases, the pathophysiology and response to treatment in type 2 diabetes are heterogeneous and complex, making individualized treatment more difficult. We close the chapter by summarizing the challenges and future research directions for implementing personalized medicine in clinical practice.

Precision medicine in monogenic diabetes

Monogenic diabetes due to polymorphism in a single gene accounts for 1–6% of all cases of diabetes at a young age [4, 5]. The two major forms of monogenic diabetes are neonatal diabetes mellitus (NDM), which commonly manifests prior to 6 months of age, and maturity-onset diabetes of the young (MODY), which usually occurs in adolescence or early adulthood [36]. Other forms of monogenic diabetes include multisystem monogenic insulin resistance syndromes such as Alström syndrome, Bardet-Biedl syndrome, or Wolfram syndrome. Genetic polymorphisms in various forms of monogenic diabetes and their pathophysiological consequence are presented in Table 30.1 [37]. Development of targeted next-generation DNA sequencing has enabled rapid and comprehensive testing for genetic aetiologies of monogenic diabetes [38].

Table 30.1 Molecular diagnosis, pathophysiology, and treatment of neonatal diabetes and maturity-onset diabetes of the young (MODY).

Monogenic disease	Genetic polymorphism	Pathophysiology	Treatment
Subtypes of neonatal diabetes			
Transient	6q24	Abnormal β -cell function with impaired insulin secretion	Sulfonylurea derivatives, insulin
Transient	HNF1B		Insulin
Permanent	GCK		Insulin
Transient/permanent	KCNJ11		Sulfonylurea derivatives, insulin
Transient/permanent	ABCC8		Sulfonylurea derivatives, insulin
Transient/permanent	INS		Insulin
Subtypes of MODY			
Genetic polymorphism in the transcriptional factors			
MODY1	HNF4A	Pancreatic β -cell dysfunction	Sulfonylurea derivatives, insulin
MODY3	HNF1A		Sulfonylurea derivatives, insulin, GLP-1 RAs, SGLT-2 inhibitors
MODY4	PDX1/IPF1		OADs, insulin
MODY5	HNF1B		Insulin
MODY6	NEUROD1		OADs, insulin
MODY7	KLF11		OADs, insulin
MODY9	PAX4		OADs, insulin
MODY11	BLK	Impairment in insulin secretion	OADs, insulin
Mutations in glucokinase enzymes regulating glucose metabolism			
MODY2	GCK	Impairment in glucose-sensing mechanism	Treatment not required
Protein misfolding disorders			
MODY8	CEL	Defects in endocrine and exocrine pancreatic function	OADs, insulin
MODY10	INS	Structurally defective insulin molecules	OADs, insulin
Mutations in the K_{ATP} regulating insulin secretion			
MODY12	ABCC8	Impairment in insulin secretion	Sulfonylurea derivatives
MODY13	KCNJ11		Sulfonylurea derivatives
Signal transduction error			
MODY14	APPL1	Impairment in insulin secretion	OADs, insulin

GLP-1 RA, glucagon-like peptide-1 receptor agonist; K_{ATP} , potassium ATP; OAD, oral anti-diabetes drug; SGLT-2, sodium-glucose cotransporter-2.

Neonatal diabetes

About 22 genetic causes of NDM have been identified so far [39]. NDM can be subdivided into transient and permanent forms, depending on the affected gene. Individuals with transient NDM due to methylation of chromosome 6q24 tend to have hyperglycaemia, which resolves within the first year after birth, although relapses during childhood or puberty are possible [40,41]. On the other hand, diabetes does not relapse and usually persists lifelong among individuals with NDM due to gene mutations in the potassium ATP (K_{ATP}) channel KCNJ11/ABCC8/INS.

The treatment goal for all individuals with NDM comprises optimizing glycaemic levels with oral anti-diabetes agents or insulin. However, a large variation in response to these drugs exists, which is partly explained by the underlying genetic variances. Sulfonylurea derivatives, for example, act by promoting the closure of the K_{ATP} channel, thereby stimulating insulin secretion from the pancreatic β cells. The long-acting sulfonylurea derivative glibenclamide is most commonly used for NDM. Other sulfonylurea derivatives such as glipizide, glipizide, and glimepiride have been used, but were inferior to glibenclamide [42]. For individuals with transient NDM due to 6q24 methylation abnormalities, low-dose sulfonylurea derivatives are effective, whereas for those with K_{ATP} channel polymorphisms, high-dose sulfonylurea derivatives are required to optimize glucose

levels [43]. With respect to insulin treatment, rapid-acting insulin (e.g. lispro, aspart, glulisine) is the first-choice agent to achieve HbA_1c targets [44]. There is some evidence that children with NDM and alterations in the insulin coding genes benefit most from early aggressive insulin therapy to prevent misfolding of the insulin proteins [45].

Maturity-onset diabetes of the young

MODY is a genetically heterogeneous disorder accounting for 1–5% of all diabetes cases, but often remains undiagnosed [46]. In the past, a combination of clinical factors and biomarkers was used to guide identification of individuals with MODY [47,48]. These included (i) age of onset; (ii) family history of diabetes in three consecutive generations; (iii) absence of insulin resistance and obesity; (iv) negative auto-antibodies; and (v) C-peptide levels. Early establishment of the molecular diagnosis facilitated individual treatment selection for individuals with MODY, to optimize blood glucose levels and prevent long-term complications. Around 14 different genetic mutations are implicated in the aetiology of MODY, with each differing in clinical presentation, extra-pancreatic features, risk of complications, and response to treatment [49]. The commonest types of MODY are the transcription factor linked (HNF1A, HNF4A, and HNF1B-MODY) and the enzyme linked (GCK-MODY).

In terms of prognosis, the risk of developing micro- and macrovascular complications is similar between individuals with MODY-HNF, type 1 diabetes, and type 2 diabetes. The rate of developing such complications is closely related to the individual's overall glycaemic levels [5, 50]. The prognosis for individuals with MODY is to some extent dependent on the underlying genotype. For example, individuals with GCK-MODY have a lower risk for developing vascular or other diabetes-related complications compared to people with type 1 diabetes or type 2 diabetes. The lower risk of complications in these individuals is attributed to the preserved insulin secretion and the non-progressive nature of the disease [51].

With regard to treatment, sulfonylurea derivatives are often prescribed in people with MODY. Those with HNF1A and HNF4A mutations respond well to low-dose sulfonylurea derivatives. DPP-4 inhibitors and GLP-1 RA can be further added to optimize glycaemic levels [48]. In contrast, individuals with the HNF1B mutation require insulin therapy, since they respond minimally or not at all to oral anti-diabetes agents [52]. Individuals with GCK-MODY in general require no treatment and do not respond to either oral anti-diabetes agents or insulin therapy [53].

Precision medicine in type 1 diabetes and type 2 diabetes

The two commonest forms of diabetes are traditionally classified as type 1 diabetes and type 2 diabetes. The diagnosis of type 1 diabetes or type 2 diabetes is based on the presence (type 1 diabetes) or absence (type 2 diabetes) of antibodies against pancreatic islet β -cell antigens, insulin secretion assessed by C-peptide measurement and age (onset of type 1 diabetes generally occurs at a younger age). Approximately 80% of all people with diabetes have type 2 diabetes. However, type 2 diabetes is a heterogeneous disease. A refined classification of diabetes has been proposed, which identifies at diagnosis the individuals at greatest risk of complications who will need intensified treatment. In this new classification, diabetes is stratified into five subtypes with different rates of complications and response to treatment [54]. However, this approach is not routinely used in clinical practice, where the classification of diabetes still relies on the traditional antibody tests and age of onset.

Oral anti-diabetes drugs

The management of individuals with type 1 diabetes and type 2 diabetes encompasses several interventions such as education on physical activity, diet, reduction of cardiovascular risk factors (e.g. smoking cessation, blood pressure control), and the attempt to achieve near normoglycaemia. Early identification and appropriate treatment of the individual are important to minimize the risk of long-term complications. Insulin was discovered in 1921 and since its discovery many other orally available anti-diabetes drugs have been developed. Metformin and sulfonylureas were the first orally available drugs. Metformin remains the first-choice agent in most people with type 2 diabetes. When metformin cannot be prescribed because of contra-indications or side effects, the most recent guidelines recommend SGLT-2 inhibitors and GLP-1 RAs as alternative options, in particular when other comorbidities are present such as cardiovascular disease, chronic kidney disease, or heart failure. Other glucose-lowering agents such as sulfonylurea derivatives or DPP-4 inhibitors can be added as necessary.

There is considerable variation in individual response to all oral drugs in persons with diabetes, which is most likely explained by the marked underlying heterogeneity of the disease. In addition, several other contributing factors are involved, such as medication taking and social and educational status. Multiple studies have been conducted to improve the stratification of people with diabetes and identify subgroups who respond particularly well to a specific drug class. Here we summarize these findings and review the main therapeutic drug classes used in the management of type 2 diabetes.

Metformin

Clinical practice guidelines recommend metformin as the first-line treatment for hyperglycaemia because of its long safety record and broad clinical experience. Metformin principally acts by reducing the synthesis of glucose in the liver through inhibition of gluconeogenesis. Furthermore, it stimulates insulin-mediated glucose utilization in peripheral tissues and decreases food intake, leading to body weight loss. However, metformin is contraindicated in several conditions due to the risk of lactic acidosis, including severe kidney dysfunction (estimated glomerular filtration rate [eGFR] below 30 ml/min/1.73 m²), active liver disease, and conditions associated with hypo-perfusion of various organs, such as heart failure and sepsis.

The response to metformin varies among individuals, with older age and lower body mass index (BMI) being associated with a larger HbA_{1c} reduction following initiation of metformin [27, 55, 56]. Interestingly, the likelihood of a more favourable response to metformin increases if the drug is started earlier in the course of diabetes, which highlights the importance of early identification of individuals at risk of developing diabetes or in the early stages of diabetes [55, 56].

In addition to clinical and laboratory predictors, several genetic determinants of the pharmacokinetic and pharmacodynamic response to metformin have been described. Genetic variants in the *SLC22A1* gene, encoding the organic cation transporter-1 (OCT-1), and the *SLC47A1* gene, encoding multidrug and toxin extrusion 1 transporter (MATE-1), influence the pharmacokinetic properties of metformin, such as the oral absorption, hepatic uptake, and renal excretion (Figure 30.2). OCT-1 is an organic cation transporter expressed in the brush border of intestinal cells and in basolateral membranes of liver and kidney cells, and has an important role in metformin absorption as well as hepatic and renal secretion of metformin. MATE-1 is a transporter expressed in the luminal membranes of renal proximal tubules and bile canalicular membranes of hepatocytes, which mediates the efflux of metformin and other substrates. Variations in genes encoding these transporters have been associated with differences in the pharmacodynamic response to metformin treatment. The variant rs622342 (AA) in the *SLC22A1* gene, encoding OCT-1, predicted a greater HbA_{1c} reduction in response to metformin compared to individuals carrying the minor C allele [57]. This finding was explained by reduced OCT-1 activity in individuals with C alleles in whom metformin transport across the hepatocyte membrane is decreased. Other OCT-1 genetic variants such as R61C, G410S, 420del, and G465R predicted a lesser response to metformin [58]. A single-nucleotide polymorphism (SNP) in rs2289669 of MATE-1 was associated with a larger HbA_{1c} reduction [57]. This is likely explained by reduced action of MATE-1 transporters, resulting in a reduced efflux of metformin

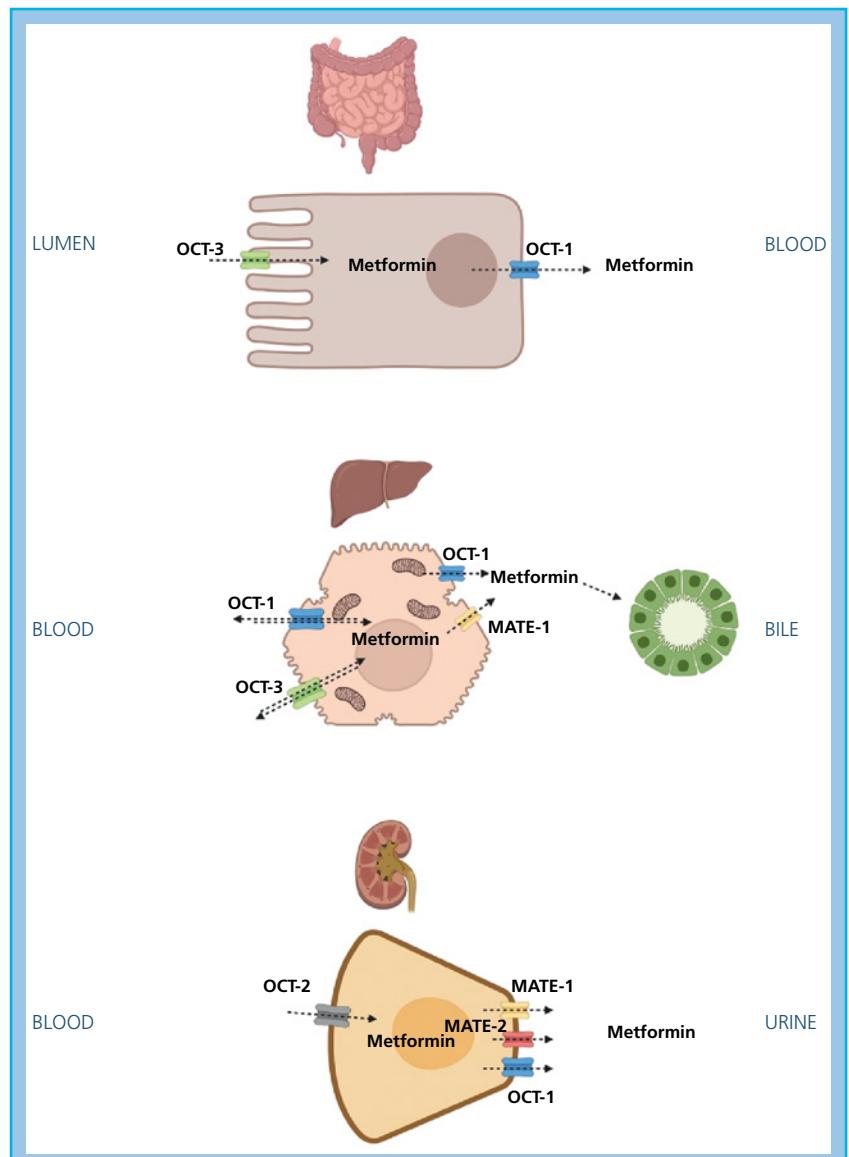

Figure 30.2 Metformin is absorbed from the intestine into enterocytes by several transporters, including organic cation transporter (OCT)-3. OCT-1, which is mainly located on the basolateral side of the enterocytes, enables the transfer of metformin from the enterocytes into the blood. Metformin is absorbed from the bloodstream into hepatocytes by OCT-1 and OCT-3. Multidrug and toxin extrusion (MATE)-1 is present in bile canalicular membranes of hepatocytes and mediates the excretion of metformin with the bile. OCT-2, which is expressed by the basolateral membranes of kidney tubules, is engaged in the uptake of metformin from the bloodstream into the tubular cells. MATE-1, MATE-2, and OCT-1 are responsible for the secretion of metformin from the tubular cells (apical side) into the urine. Genetic polymorphisms in these transporter can alter the disposition of metformin.

from the renal brush borders and from hepatocytes, leading to increased levels of plasma metformin and a stronger inhibition of gluconeogenesis in the liver, with overall a reduction in blood glucose levels.

There are other genetic polymorphisms that may explain the variability in response to metformin. The minor allele (C) of rs11212617 in the ataxia telangiectasia mutated (ATM) locus is associated with a better response to metformin. ATM influences the effect of metformin on 5' adenosine monophosphate-activated protein kinase (AMPK) and is involved in insulin signalling and pancreatic β -cell dysfunction [59]. In particular, ATM activates AMPK via the phosphorylation of the AMPK α -subunit and it regulates the mitochondrial biogenesis via AMPK [60]. ATM is required for a complete response to metformin [61]. The SLC2A2

gene encodes GLUT2, a transmembrane protein, which is involved in glucose transport. Genetic variations in GLUT2 have been associated with increased risk for hyperglycaemia and severity of type 2 diabetes symptoms [62]. Individuals with the C allele (rs8192675 variant) of the GLUT2 gene showed a larger HbA_{1c} reduction in response to metformin. The most likely reason is that individuals with this genetic variant have decreased GLUT2 activity in the liver. Hence, glucose has less ability to enter hepatic cells, leading to a reduction in glucose clearance.

Gastrointestinal side effects are observed in ~20–40% of individuals following metformin initiation [63]. The likelihood of developing these side effects is partly determined by genetic polymorphisms. For example, genetic variants of the SLC22A1 gene were implicated in the occurrence of side effects. Alterations in

metformin transport via OCT-1 led to increased metformin concentrations in the gut, which are in turn responsible for alteration of the intestinal microbiome and intestinal serotonin concentration. Variants of OCT-1 with reduced function are also directly associated with increased systemic concentration of metformin, with consequent metformin intolerance [64]. In addition, drugs that inhibit OCT-1 such as verapamil and proton pump inhibitors are also associated with the severity of gastrointestinal side effects from metformin [58, 65, 66].

Taken together, these genetic findings explain in part the large variation in metformin response with respect to its efficacy and safety. However, the implementation of these findings in routine diabetes care is lagging behind. Most studies have lacked independent validation, which is essential for implementation. In addition, for many physicians it is unclear how these research findings can be implemented in their daily practice. Developing algorithms that can be used easily in clinical practice could be one approach to improve implementation of these findings in daily clinical care.

Sulfonylurea derivatives

Sulfonylurea derivatives act by stimulating the release of insulin from pancreatic β cells, thus determining lower blood glucose concentrations. They inhibit the K_{ATP} channels on pancreatic β cells, leading to cell membrane depolarization and consequently calcium influx and stimulation of insulin secretion [56]. Although sulfonylurea derivatives are effective in lowering blood glucose levels, they may cause weight gain and hypoglycaemia as adverse events. Hypoglycaemia occurs more frequently in individuals with impaired kidney function ($eGFR < 60 \text{ ml/min}/1.73 \text{ m}^2$), for whom short-acting sulfonylurea derivatives (e.g. gliclazide, glipizide) are preferred. Several predictors of response to sulfonylurea derivatives have been discovered. Men respond better to sulfonylurea derivatives, and this is probably due to the different activity of cytochrome P450 between men and women [56, 67]. Sulfonylurea derivatives are metabolized by the liver, with *CYP2C9* being crucial in this function [68]. Some sulfonylurea derivatives have active metabolites that are excreted with urine [27, 56, 69, 70]. A shorter diabetes duration is inversely correlated to the response to sulfonylurea derivatives, indicating that the probability of responding to sulfonylurea derivatives increases if the drug is started early after the diagnosis of diabetes.

Variations in several genes influence the pharmacokinetics and pharmacodynamics of sulfonylurea derivatives. Individuals with variants in *CYP2C9* encoding cytochrome P450 2C9 with reduced enzymatic activity have higher exposure to sulfonylurea derivatives and greater response during the initial phase of treatment [71–73]. These individuals generally require a reduced dose to normalize glycaemic levels [72] and to avoid hypoglycaemia [73].

Regarding the genetic determinants of the pharmacodynamic response to sulfonylurea derivatives, variants of transcription factor 7-like 2 (*TCF7L2*) genes, which are involved in regulation of β -cell function, predict a worse response to sulfonylurea derivatives. In a study of 901 people with type 2 diabetes, those with a homozygotes TT genotype for the SNP rs1225372 are twice as likely to be unable to achieve the HbA_{1c} goal of $< 7\%$ (53 mmol/mol) within one year of sulfonylurea derivatives initiation [74]. Furthermore, variants in *KCNJ11* and *ABCC8*, both encoding the sulfonylurea derivatives receptor, are associated with an increased glycaemic response to sulfonylurea derivatives in type 2 diabetes [71–73, 75]. The Ser1369Ala variant of the *ABCC8* gene and the rs5210 and E23K variants of the *KCNJ11* gene predict a greater response to

sulfonylurea derivatives. Other variants that influence the sulfonylurea derivatives response are across genes *IRS-1* and *NOS1AP*. The Arg⁹⁷² variant of *IRS-1* (insulin receptor substrate-1), which is involved in insulin signalling, predicts failure in response to sulfonylurea derivatives [76]. Individuals with risk alleles in *NOS1AP*, encoding a cytosolic protein that binds to the signalling molecule nNOS, were linked to a low response to the sulfonylurea derivative glibenclamide [77].

Dipeptidyl peptidase-4 inhibitors

DPP-4 inhibitors act by inhibiting the enzyme DPP-4, which deactivates several substrates including glucose-dependent insulinotropic polypeptide (GIP) and GLP-1. They stimulate glucose-dependent insulin release from the pancreatic β cells. The great advantage of these drugs is that they exhibit a low risk of hypoglycaemia. There are several clinical and genetic determinants of response to DPP-4 inhibitor treatment. Markers of insulin resistance such as high BMI, serum triglycerides, C-peptide levels, and homeostatic model assessment (HOMA) index are associated with decreased response to DPP-4 inhibitors, measured as absolute change in HbA_{1c} from baseline to six months after start of treatment. Lipotoxicity has an additional effect in reducing response to DPP-4 inhibitor treatment [78].

The genetics of pharmacokinetic variation have largely not been investigated, mainly because these drugs do not interfere with cytochrome P450 and do not act as inhibitors or inducers of the cytochrome system [79]. DPP-4 inhibitors are mainly excreted via the kidney. Conversely, there are several genetic determinants of pharmacodynamic variation. The rs7202877 variant close to *CTRB1* and *CTRB2*, both encoding the enzyme chymotrypsin, predicts a low response to DPP-4 inhibitors [80]. The SNP rs6923761 in the GLP-1 receptor gene predicts a smaller response to sitagliptin or vildagliptin, whereas individuals with variation in rs3765467 of the same gene respond better to these DPP-4 inhibitors [81–83]. Polymorphisms in genes *KCNQ1* and *KCNJ11*, both encoding potassium channels involved in incretin secretion from endocrine intestinal cells, have been associated with increased response to DPP-4 inhibitors [84, 85]. Similar associations have been found with other genetic variants such as *PRKD1* (encoding a kinase involved in regulation of cell proliferation, differentiation, and apoptosis), *CDKAL1* (encoding cyclin-dependent kinase 5, which is involved in regulation of insulin secretion), interleukin-6 (IL-6), *TCF7L2* (encoding transcription factor 7-like 2, which regulates the pancreatic GLP-1 signal), DPP-4, and *PNPLA3* (patatin-like phospholipase 3) [86–88].

Glucagon-like peptide-1 receptor agonists

GLP-1 receptor agonists improve glucose levels via multiple mechanisms, including stimulation of glucose-dependent insulin secretion, suppression of glucagon release, decreased appetite and food intake, and slowed gastric emptying. GLP-1 RA do not cause hypoglycaemia unless they are combined with other therapies that increase the risk of hypoglycaemia, such as sulfonylurea derivatives and insulin. Variations in pharmacodynamic response to GLP-1 RA have been investigated. Polymorphisms in the GLP-1 receptor gene (rs6923761) are associated with a greater weight reduction in response to the GLP-1 RA liraglutide, whereas polymorphism in allele T of rs10305420, a polymorphism that causes an amino acid substitution – from proline to leucine – was associated with less weight loss and less HbA_{1c} reduction in response to exenatide [89, 90].

A variant in the cannabinoid receptor 1 (*CNR1*) gene, rs1049353, which is involved in appetite and body weight regulation, was associated with improvement in insulin resistance in response to liraglutide [89]. The gene *TCF7L2* has a diabetogenic effect by altering insulin secretion in type 2 diabetes; an SNP of *TCF7L2* determines a greater reduction of post-prandial insulin peak in people with type 2 diabetes treated with exenatide [91]. The impact of the *TCF7L2* gene polymorphism on therapy response to sulfonylurea derivatives, GLP-1 RA, or DPP-4 inhibitors is depicted in Figure 30.3. As a final comment, the sortilin-related VPS10 domain containing receptor 1 (*SORCS1*) is involved in insulin secretion in humans. Individuals carrying the genotype *SORCS1* rs1416406 GG may benefit more from exenatide, since it is associated with a greater reduction in the proinsulin/insulin ratio, which is a marker of insulin resistance and β -cell dysfunction [96]. Thus, various gene polymorphisms are involved in the metabolic response to GLP-1 RA. Most studies have assessed surrogate markers and the extent to which these polymorphisms determine the effect on clinical outcomes during GLP-1 RA treatment remains to be investigated.

Sodium glucose cotransporter-2 inhibitors

SGLT-2 inhibitors promote the renal excretion of glucose by blocking the proximal tubular glucose reabsorption in the kidney, and therefore lower blood glucose levels in individuals with type 2 diabetes. They also have a natriuretic effect and thus lower blood pressure and body weight [21]. Clinical and demographic predictors of response to SGLT-2 inhibitors have been found and represent potential tools for precision medicine [97]. Individuals with higher eGFR appear to show a larger HbA_{1c} reduction in response to SGLT-2 inhibitors. This is likely explained by the fact that, at a higher eGFR, more glucose is filtered in the glomeruli. In the absence of SGLT-2 inhibitors, the filtered glucose would be reabsorbed. SGLT-2 inhibitors inhibit the glucose reabsorption, leading to a larger glucosuric effect and more pronounced reduction in HbA_{1c}. Whether this has clinical consequences in terms of prevention of clinical outcomes is unlikely, as it appears that the long-term benefit of SGLT-2 inhibitors is unlikely to be mediated by reductions in HbA_{1c}.

Some studies have suggested that men experience a greater response to SGLT-2 inhibitors. This may be attributed to a higher

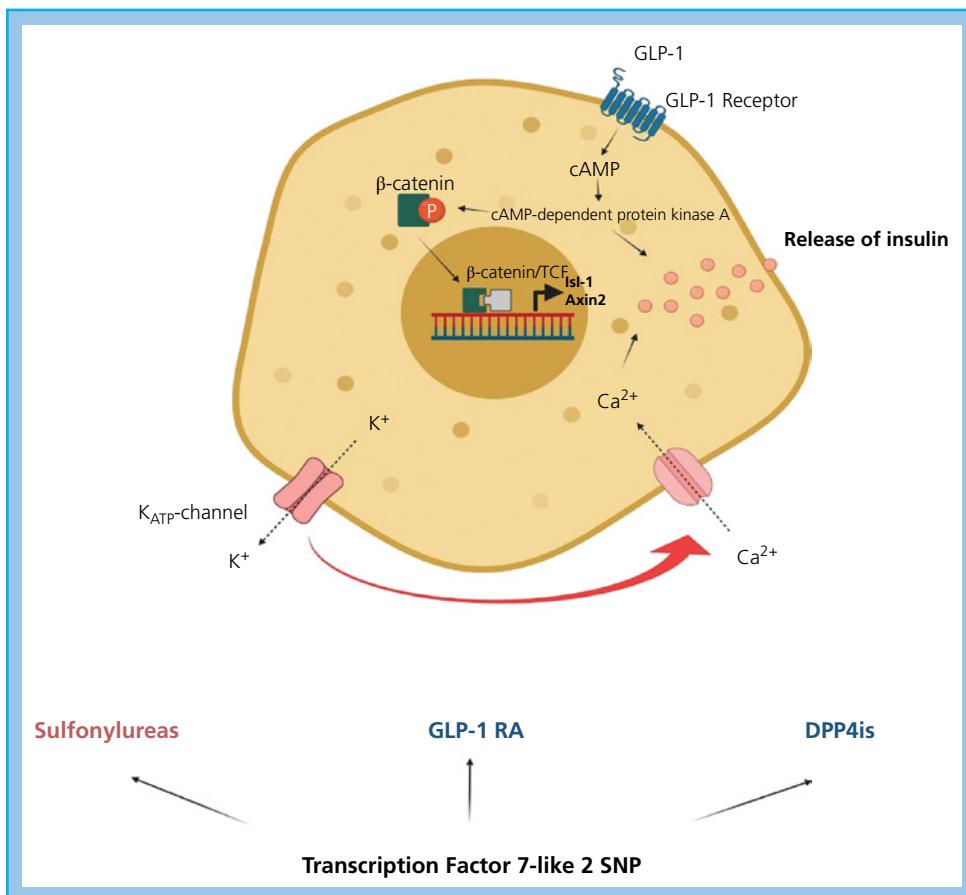

Figure 30.3 Influence of single-nucleotide polymorphisms (SNPs) in the *TCF7L2* gene in response to treatment with sulfonylurea derivatives, glucagon-like peptide-1 receptor agonists (GLP-1 RAs), and dipeptidyl-peptidase 4 (DPP-4) inhibitors. In pancreatic β cells, GLP-1 phosphorylates β -catenin via cyclic adenosine monophosphate (cAMP)-dependent protein kinase A (PKA). This abrogates the degradation of the β -catenin that subsequently accumulates, enters the nucleus, and forms the transcription factors β -catenin/TCF. As a result of this mechanism, Wnt/TC expression is enhanced and related genes are activated, including *Isl-1* and *Axin2*. This pathway leads to pro-insulin processing, β -cell protection from interleukin-1 β , and interferon- γ mediated apoptosis; stimulates β -cell proliferation; and mediates

glucose and GLP-1-stimulated insulin secretion [92–94]. Individuals with *TCF7L2* gene variants (particularly T allele carriers) have altered *TCF7L2* expression in pancreatic β cells, resulting in reduced insulin secretion and impaired response to incretins (GLP-1 RAs, DPP-4 inhibitors) and sulfonylurea derivatives. Whereas impaired response to GLP-1 RAs and DPP-4 inhibitors likely depends on the direct effect of *TCF7L2* on PKA and insulin secretion patterns, the lower response to sulfonylurea derivatives is partially elucidated and seems to be dependent on the general reduction in β -cell insulin secretion and overall β -cell metabolic dysfunction in individuals with these genetic variants [95].

expression of SGLT-2 transporters in men than in women, although this is not consistently observed in all studies [98]. Markers of insulin resistance also predict the response to SGLT-2 inhibitors: proinsulin/insulin ratio and HOMA index are independent predictors of four-week HbA_{1c} reduction in response to SGLT-2 inhibitors, whereas free fatty acid levels predict 24-week HbA_{1c} reduction [97].

Although genetic studies on SGLT-2 inhibitor response are still in progress, both pharmacokinetic and pharmacodynamic variations in SGLT-2 inhibitor response have been reported. Two variants in gene *UGT1A9*, encoding the UGT enzyme, are involved in the metabolism of canagliflozin and other SGLT-2 inhibitors influence their pharmacokinetics. Carriers of the variants UGT1A9*3 and UGT2B4*2 have a higher exposure to canagliflozin and thus a better drug availability [99, 100]. In addition, genetic variants of the *SLC5A2* gene, which encodes the SGLT-2 cotransporter, have been described (Figure 30.4). However, none of the SNPs was significantly associated with response to empagliflozin in terms of change in HbA_{1c}, body weight, or systolic blood pressure [101].

Randomized studies have shown that SGLT-2 inhibitors reduce the risk of cardiovascular and renal outcomes, such as cardiovascular fatal and non-fatal events or end-stage kidney disease [102, 103]. The benefits of SGLT-2 inhibitors in reducing the risk of kidney failure and heart failure are remarkably consistent among individuals and are present irrespective of the degree of kidney impairment, and the presence of heart failure, cardiovascular disease, and even diabetes. This suggests that many people with diabetes would benefit from these drugs and the concept of precision medicine is less relevant. Although this may be true, a clinical trial with dapagliflozin showed that ~20% of treated individuals did not respond to this drug, in terms of systolic blood pressure or albuminuria reduction. Importantly, the same individuals did not respond when they were re-exposed to the same drug (dapagliflozin) at the same dose after a six-week wash-out period [104]. Such an exposure–re-exposure study provides useful information regarding the variability in treatment response, and should be performed for other treatments used for people with diabetes to delineate an individual's drug response and develop strategies to overcome therapy resistance.

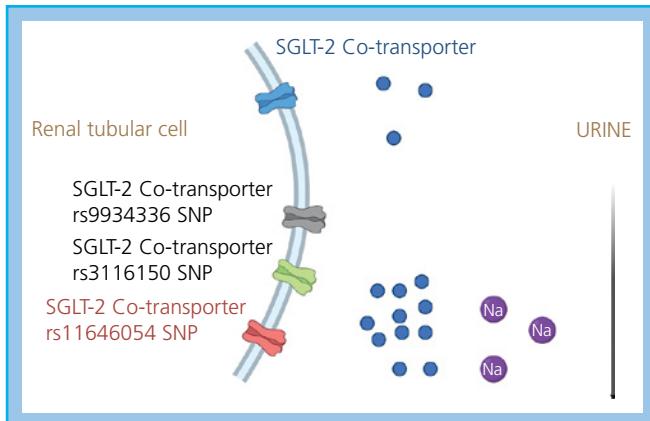

Figure 30.4 The AA genotype rs9934336 in the SGLT-2-encoding gene *SLC5A2* is associated with an SGLT-2-mediated increase in glucose excretion in the urine. Moreover, single-nucleotide polymorphisms (SNPs) rs3116150 and rs11646054 in the *SLC5A2* gene determine a loss of function in SGLT-2 cotransporter with higher excretion of glucose and sodium. This may impact the effect on blood pressure (larger reduction in systolic blood pressure) and glucose control in response to SGLT-2 inhibitor treatment. Studies to test this hypothesis are ongoing.

There is great interest in using these drugs in clinical practice following the results of large clinical trials. However, since not every person benefits maximally or tolerates SGLT-2 inhibitors, and some people experience genital infections or volume depletion, future studies into the underlying pathways of variability in drug response are desired.

Blood pressure-lowering drugs

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers

Blood pressure lowering with ACE inhibitors or ARBs is recommended for individuals with type 2 diabetes at high risk of cardiovascular or renal events [105, 106]. The efficacy of ACE inhibitors and ARBs goes beyond their effect on blood pressure. Both drug classes reduce albuminuria, which is an important contributor to the long-term cardiovascular and renal effects [15, 107]. The change in blood pressure and albuminuria varies between individuals and is reproducible on re-exposure to the same drug at the same dose [108] (Figure 30.5). This indicates that the variation in response does not only reflect measurement variation, but is a true variation in pharmacological response. Several determinants may independently or in combination contribute to this response variation. Determinants of therapy response include the type and severity of renal lesions, obesity, insulin resistance, as well as genetic and dietary factors.

The efficacy of ACE inhibitors and ARBs to lower blood pressure and albuminuria is less in individuals with overweight and obesity [110]. The precise underlying mechanisms are not completely understood, but emerging data demonstrate that adipose tissue has endocrine actions [111]. For example, the adipocyte-derived

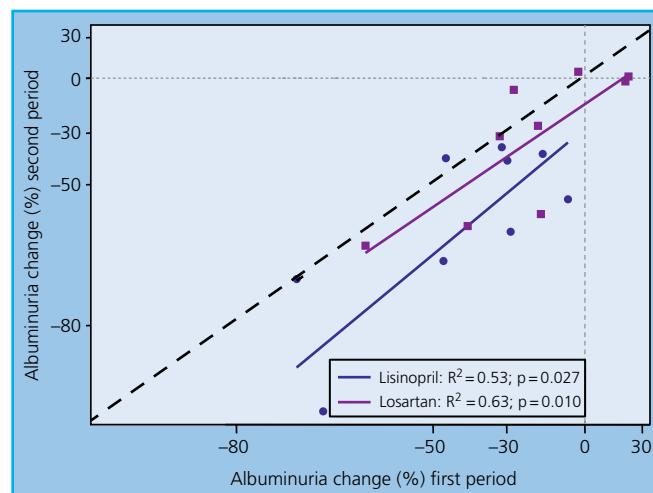

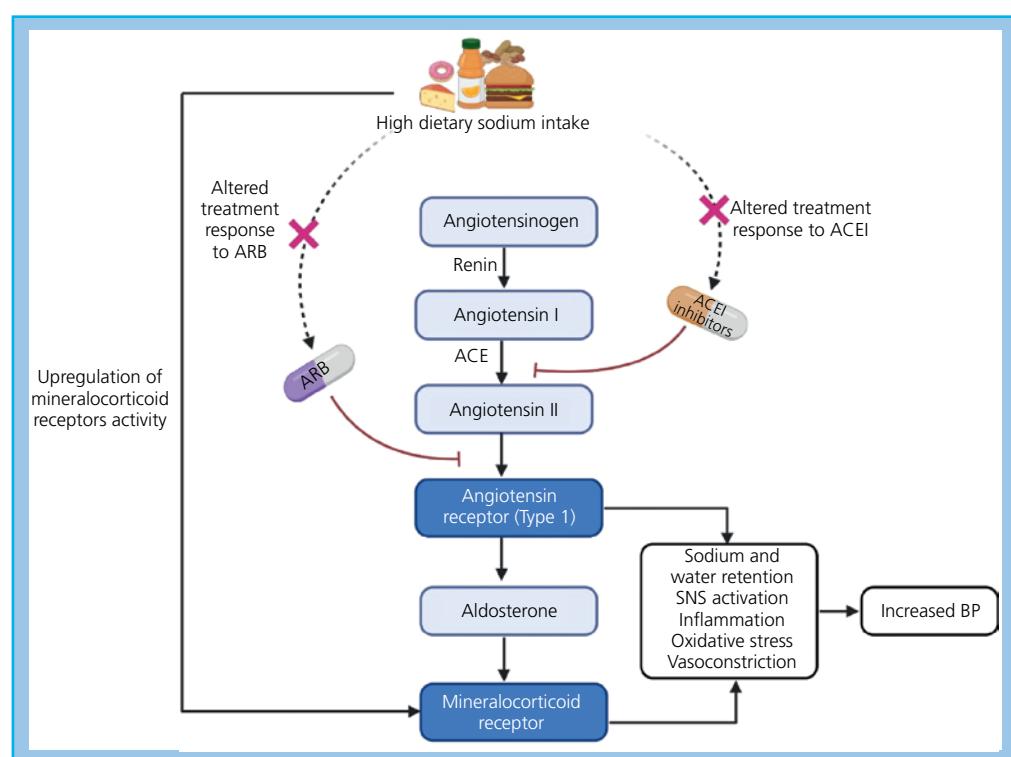

Figure 30.5 Albuminuria response variation to angiotensin-converting enzyme (ACE) inhibitor lisinopril and angiotensin receptor blocker (ARB) losartan during two consecutive exposures separated by a wash-out period. The correlation between the change in albuminuria during exposure and re-exposure to lisinopril and losartan indicates that individuals who did not respond the first time to these drugs also did not respond on re-exposure. This indicates that the variation in response between individuals is not only caused by measurement variation, but also by true drug response variation. Source: Data derived from Petrykiv et al. 2017 [109].

hormone leptin may activate inflammatory mediators such as transforming growth factor (TGF)- β and the renin–angiotensin–aldosterone system (RAAS) and may thereby blunt the efficacy of ACE inhibitors and ARBs.

Another important clinical determinant of therapy resistance to ACE inhibitors and ARBs is sodium status and extracellular volume. Higher volume status is associated with a poor response and interventions that decrease extracellular volume, such as a moderate-sodium diet or diuretic treatment, enhance the blood pressure and albuminuria response to ACE inhibitors and ARBs [112–114]. Moreover, analyses from large clinical trials in people with chronic kidney disease with or without diabetes demonstrated that the efficacy of these drugs to prevent clinically important renal and cardiovascular outcomes was more pronounced in individuals with a lower compared to higher dietary sodium intake [115–117]. These data emphasize the importance of following the World Health Organization (WHO) recommended dietary sodium intake of 5–6 g per day, not only to optimize blood pressure, but also to enhance the efficacy of ACE inhibitors and ARBs (Figure 30.6) [119].

Genetic factors are also involved in the response to ACE inhibitors and ARBs. An insertion (I) or deletion (D) polymorphism of the *ACE* gene modifies the activity of the circulating and renal RAAS, with higher activity in individuals with the deletion polymorphism (Figure 30.7). The blood pressure response to ACE inhibitors is more pronounced in individuals with the DD *ACE* genotype compared to the II genotype, although this finding was not confirmed in all studies. In individuals with chronic kidney disease with or without diabetes, two independent large clinical trials demonstrated that those with the DD genotype were at higher risk of disease progression, but also showed a proportionally larger risk reduction in response to the ACE inhibitor ramipril or ARB losartan [30,120]. Polymorphisms in the AT-1 receptor gene are also present, but none of these consistently modified the response to an ARB [121].

Figure 30.6 The effect of increased sodium intake on the renin–angiotensin–aldosterone-system. Increased dietary sodium could cause direct activation of the mineralocorticoid receptors by enhancing the expression of angiotensin-converting enzymes in the body, leading to a cascade of sodium and water retention, increased inflammation, and sympathetic nervous system activation. In addition, high dietary sodium intake is associated with reduced effect of angiotensin receptor blocker (ARB) in reducing blood pressure and albuminuria among persons with type 2 diabetes, as shown in the *post hoc* analyses of the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) and the Irbesartan Diabetic Nephropathy Trial (IDNT) trials [118]. ACEi, angiotensin-converting enzyme inhibitors; BP, blood pressure; SNS, sympathetic nervous system.

Lipid-lowering drugs

Hypercholesterolaemia is often observed in people with type 2 diabetes and is an independent risk factor for macrovascular complications [122]. Various drug classes improve lipid profiles and the best known are the 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins). Other drugs known to improve lipid profiles are fibrates, ezetimibe, and proprotein convertase subtilisin kexin type (PCSK9) inhibitors, but they are less frequently used than statins [123–125].

Statins significantly reduce low-density lipoprotein (LDL) cholesterol, leading to a reduction in cardiovascular events by 20–50% [126–128]. The benefits of these drugs extend beyond LDL cholesterol lowering alone, with evidence showing broad anti-inflammatory, anti-fibrotic, anti-oxidant, and renal protective effects, which are beneficial to people with diabetes [129–131]. Figure 30.8 shows the detailed molecular mechanism for the effect of statins on cholesterol synthesis, and various pharmacokinetic and pharmacodynamic factors modifying treatment response to lipid-lowering drugs.

HMG-CoA reductase inhibitors – statins

Statins act via competitive inhibition of the rate-limiting enzyme HMG-CoA reductase responsible for cholesterol biosynthesis in the hepatocytes [134]. The present guideline of the American Diabetes Association (ADA) recommends moderate-intensity statin therapy for all individuals with diabetes aged between 40 and 75 years without atherosclerotic cardiovascular disease for primary prevention. High doses of potent statins (atorvastatin or rosuvastatin) are recommended as first-line agents for people with diabetes of all ages to prevent cardiovascular disease [135]. These recommendations were derived from large clinical trials and meta-analyses that demonstrated that every 1 mmol/l (39 mg/dl) reduction in LDL

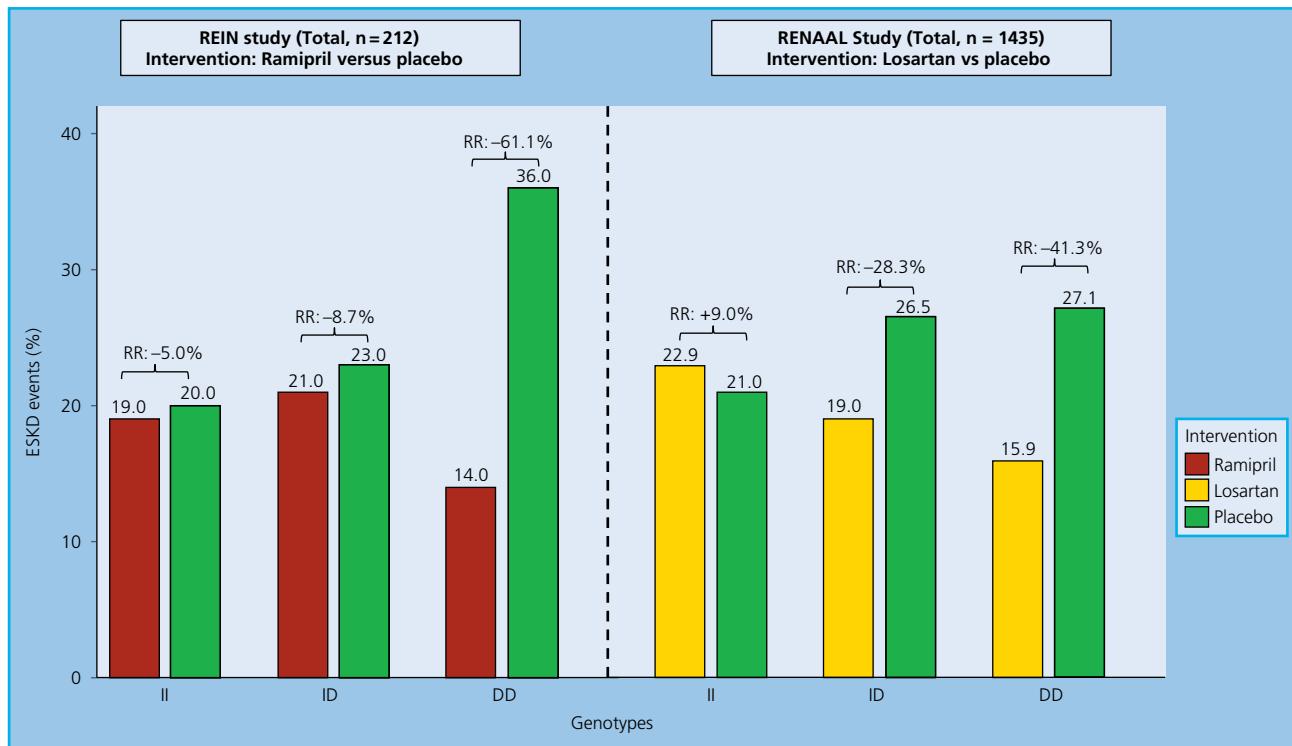

Figure 30.7 In the REIN study (left), individuals with the DD genotype receiving ramipril had a significantly lower number of end-stage kidney disease (ESKD) events (14% vs 36%, $p = 0.04$), and a relative risk reduction of 61.1%, compared to placebo-treated individuals with the II (5.0%) or ID genotype (8.7%). In the RENAAL study (right), the treatment effect of losartan was greatest among losartan recipients with the DD genotype (a relative risk reduction of 41.3%), compared to individuals with the II (+9.0%) or ID (-28.3%) genotypes for the ESKD endpoint. Source: Data derived from Perna et al. 2016 [30] and Parving et al. 2008 [120].

cholesterol led to a 9% reduction in all-cause mortality and 13% reduction in cardiovascular mortality [16]. In general, statins do not only reduce LDL cholesterol, they also improve high-density lipoprotein (HDL) cholesterol, lower plasma triglyceride, and exert anti-inflammatory effects, which may contribute to their cardiovascular protective effects [136].

The degree of LDL cholesterol lowering varies among individuals. As a consequence, some people do not achieve their target cholesterol level and remain at higher risk for cardiovascular events [137]. Several factors may contribute to the variation in treatment response. Phenotypic factors such as older age, male sex, lower waist circumference, and less alcohol intake were associated with a greater LDL cholesterol reduction following initiation of statins [138–141]. In addition, clinical trials suggested that statins are less efficacious among people who smoke [142]. In the Cholesterol and Pharmacogenetics Study, people who smoke showed significantly less LDL cholesterol and Apo-B reduction (by ~4 mg/dl) in response to simvastatin when compared to non-smokers [138].

SNPs in drug-metabolizing enzymes, such as cytochrome P450, hepatic influx transporters (SLCO1B1), or efflux transporters (ABCB1, ABCC2, ABCG2, and ABCB11), are considered to be major determinants of statin disposition and pharmacokinetic response [143]. Furthermore, lovastatin and simvastatin are lactone pro-drugs requiring *in vivo* activation into β -hydroxy-acid and undergo extensive first-pass hepatic metabolism via CYP3A4 [144]. Individuals with increased CYP3A4 expression have more active metabolites and might derive more pronounced LDL cholesterol

reduction with lovastatin, simvastatin, or atorvastatin [145, 146]. Conversely, other statins, such as fluvastatin, are metabolized by CYP2C9, and pravastatin is metabolized via the sulfation process; both are administered as an active hydroxy acid form [147]. Individuals with higher expression of CYP2C9 have better LDL cholesterol reduction when treated with fluvastatin or rosuvastatin due to increased hepatic metabolism [148, 149]. Apart from drug metabolism, transporter proteins are important for the absorption, distribution, and hepatobiliary excretion of statins. Genetic variations in these transporters can also alter statin response. For example, a mutation in the organic anion uptake transporter OATP1B1 results in a lower bioavailability of pravastatin and a reduced LDL cholesterol response [150]. Polymorphism in the ABCB1 gene decreases drug transport from the intra- to the extracellular compartment. This leads to enhanced intracellular bioavailability of simvastatin and atorvastatin and increased efficacy to inhibit hepatic HMG Co-A synthesis [151, 152].

Polymorphisms in several other genes including apolipoprotein (APO), lipoprotein (a) (LPA), and cholesterol ester transfer protein (CETP) are implicated in the pharmacodynamic response to statins. Mutation of apolipoprotein E impairs the transport of very low-density lipoprotein (VLDL) particles and chylomicrons from the systemic circulation to the liver [153]. As a result, individuals carrying the Apo-E4 allele mutation have more efficient cholesterol clearance from the plasma, thus markedly reduced LDL cholesterol lowering on statin therapy, compared to those carrying Apo-E2 or Apo-E3 [154].

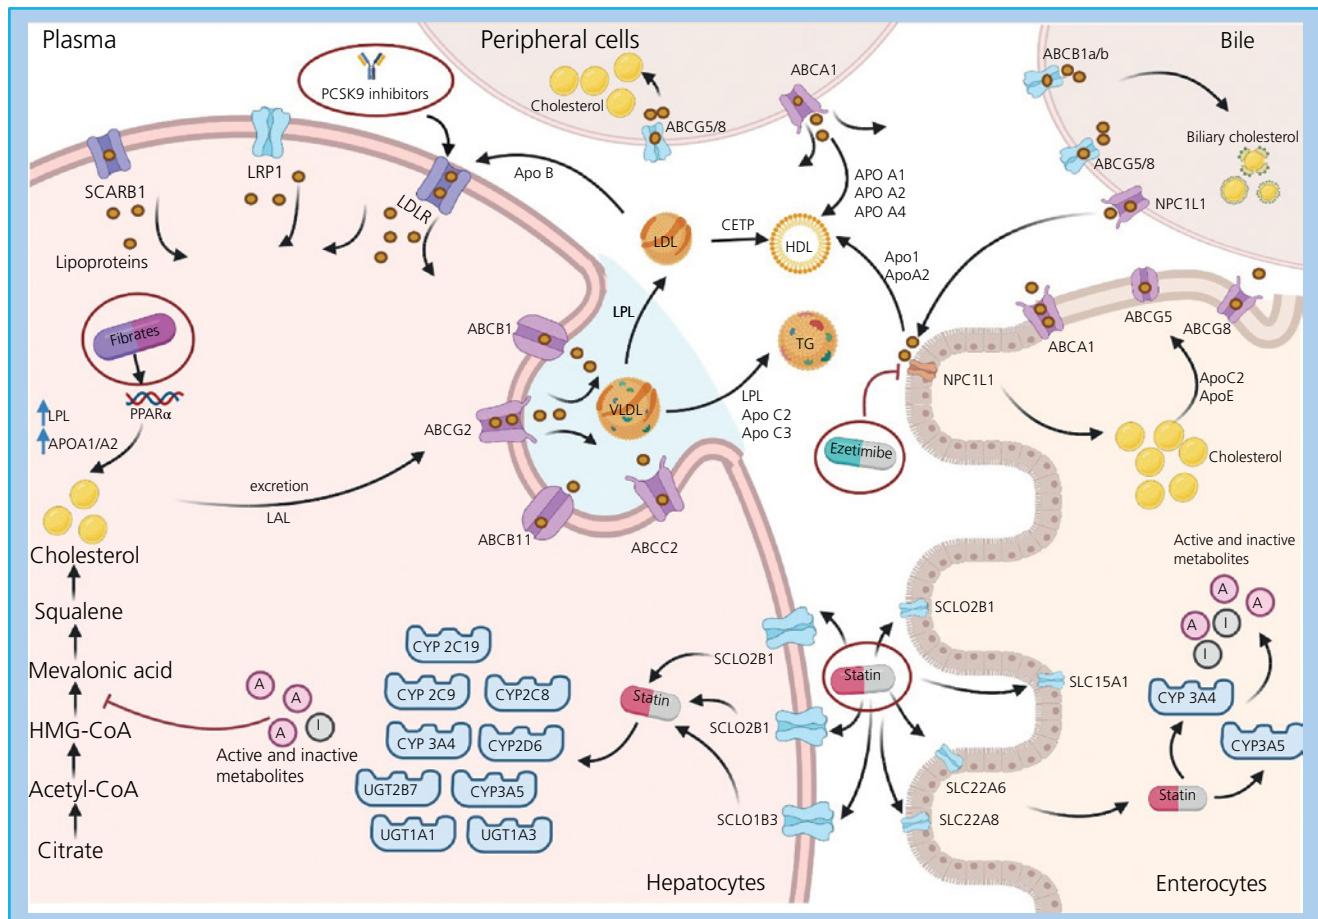

Figure 30.8 Molecular mechanism for the effects of lipid-lowering agents on cholesterol synthesis and the metabolism pathway. Drug transporters on the cell membrane regulate the pharmacokinetics (absorption, distribution, and excretion) of lipid-lowering drugs. Together with the metabolizing enzyme, they modulate the bioavailability and clinical response of the drug. Genetic polymorphism in the cytochrome P450, hepatic influx transporter (*SLCO1B1*), or efflux transporter (*ABCB*) genes thus partly determine the individual response and the degree of lipid lowering with statins. In addition, polymorphism in the genes encoding for lipoprotein receptors, lipid transporters, or enzymatic function can also affect the pharmacodynamic response to these lipid-lowering drugs. For example, polymorphism of the *LDLR* gene leads to familial hypercholesterolaemia and varying response to statin treatment [132]. Polymorphisms in the apolipoprotein-E (*ApoE*) gene affect hepatic clearance of triglyceride-rich lipoprotein on statin treatment.

The polymorphism of cholesterol ester transfer protein (*CETP*), particularly the Taq1b variant, modifies the catalytic process between high-density lipoprotein (HDL)-C and triglyceride-rich lipoproteins, and as a result may determine the response to statin therapy [133]. HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; LAL, lysosomal acid lipase; LDL, low-density lipoprotein; LDLR, low-density lipoprotein receptor; LPL, lipoprotein lipase; LRP1, low-density lipoprotein receptor-related protein 1; NPC1L1, Niemann-Pick C1-Like 1; PPAR α , peroxisome proliferator-activated receptors; SRARB1, scavenger receptor class B (type I); TG, triglycerides; VLDL, very low-density lipoprotein. ABCB1, ABCG2, ABCB11, ABC2, ABCA1, ABCG5, ABCG8 – human ABC proteins; CYP2C8, CYP2C9, CYP2C19, CYP3A4, CYP3A5, CYP2D6 – cytochrome enzymes; SCLOB1, SCLO2B1, SCLOB3 – *SLCO1B1* genotype; SLC22A6, SLC22A8, SLC15A1 – SLC22 genotype; UGT2B7, UGT1A1, UGT1A3 – UDP-glucuronosyltransferases.

Personalized medicine: implementation in clinical practice and future research directions

Clinical and genetic markers can predict the response to many drugs used in the management of diabetes [155–157], but translation of these research findings into clinical practice is slow. This is in part because many studies were not specifically designed to study the variation in drug response and as a consequence their results are considered to be hypothesis generating. In 2021, regulatory guidance recommends only one specific precision medicine approach, namely that genetic testing should be considered for glucose-6-phosphate dehydrogenase deficiency before the use of some sulfonylurea derivatives because of concerns of potential

haemolytic anaemia [158]. Nevertheless, clinical practice guidelines have started to make recommendations of drugs for certain subgroups. For example, less stringent HbA_{1c} targets are recommended for older people with diabetes as well as for individuals with severe kidney disease [159], while DPP-4 inhibitors, GLP-1 RA, and SGLT-2 inhibitors are recommended for people with a medical history of recurrent hypoglycaemia. Additionally, individuals with established chronic kidney disease or heart failure should receive SGLT-2 inhibitors and individuals with established cardiovascular disease either a GLP-1 RA or SGLT-2 inhibitor, because of the proven benefits of these drugs on cardiovascular outcomes [22, 23, 160]. Although these are first attempts to tailor glucose-lowering recommendations, further stratification is required to prescribe the right drug for the right individual. All aspects of the disease and treatment response should be considered to further

tailor the medication to the individual. As well as the pathophysiology of the disease, an individual's personality, coping mechanisms, preferences, social network, financial resources, and unique life circumstances should be included, as these factors will also determine when and how a given disease will manifest and how that individual will respond to treatment.

Medication taking is an important aspect, as a poor therapy response often results from suboptimal medication taking. This has been described for many drugs used by people with diabetes and is furthermore not restricted to anti-diabetes drugs. Poorer medication taking is independently associated with a higher risk of diabetes-related complications and increased rates of hospital admission [161, 162]. Understanding why some people do not take medication as prescribed will help improve the delivery of diabetes care, therapy response, and ultimately the prognosis of people with diabetes.

Implementation of precision medicine is challenging without the availability of comparative effectiveness data of various drugs and few insights from the prospective use of genetic and biomarker studies to inform long-term drug efficacy. Ideally, rotation studies or $n = 1$ studies are performed to compare the efficacy and safety of multiple drugs in a single person [163]. The GRADE study (clinical trial registration NCT01794143) is a head-to-head comparison of four commonly used anti-diabetes agents including a sulfonylurea derivative (glimepiride), DPP-4 inhibitor (sitagliptin), GLP-1 RA (liraglutide), and insulin (glargine) among people with type 2 diabetes with less than 10 years of diabetes duration who are receiving standard metformin therapy. The preliminary results of the GRADE study suggest that liraglutide and insulin may result in better glycaemic management than glimepiride and sitagliptin among people with type 2 diabetes in real-world clinical settings. Further analyses will help inform prescribers on which of these agents should be prescribed to each person with diabetes. A couple of other such studies are ongoing: in the MASTERMIND study (clinical trial registration NCT01847144), individuals with type 2 diabetes were randomly assigned to a sulfonylurea derivative (gliclazide 80 mg) or DPP-4 inhibitor (sitagliptin 100 mg) for four weeks followed by a two-week wash-out period, to investigate individual variation in

glycaemic response. Finally, the ROTATE trials (clinical trial registration NCT03504566) test in a crossover design how each individual with type 1 diabetes or type 2 diabetes responds to four different kidney-protective drugs: SGLT-2 inhibitors, DPP-4 inhibitors, ARBs, and Janus kinase–signal transducer and activator of transcription (JAK–STAT) inhibitors. These studies will help to address some of the current gaps with respect to variation in response to treatment and the potential impact of the metabolic milieu on the response to glucose-lowering therapies, and may aid in appropriate treatment selection.

Another important initiative is the *All of Us* Research Program. This was started in 2018 and aims to include ~1 million US inhabitants. It is the world's largest longitudinal study conducted so far. The program aims to collect health data (e.g. health-related questionnaires, electronic health record data, physical measurement) and biospecimens (e.g. blood, urine, tissues, DNA, RNA, or proteins) from at least a million people with a diverse background to build a centralized national cohort to study and foster personalized medicine [164]. The ultimate goal of this repository is then to serve as a platform for researchers and healthcare practitioners to advance diagnosis, prognosis, and treatment therapy for the individual, taking into account each individual's lifestyle, environmental, socio-economic, and biological factors.

Despite the increasing body of evidence that clinical and genetic factors determine the variation in drug responses in monogenic diabetes and type 2 diabetes, translation of basic and clinical science findings to clinical practice is lagging behind. This is partly because of a lack of appropriate independent validation studies and a paucity of implementation studies demonstrating prospectively the benefit of biomarker/genetic-based personalized medicine approaches in reducing long-term clinical outcomes. To implement the research findings in practice, the diabetes community should follow the example from other therapeutic areas such as oncology. A joint commitment from multiple stakeholders including scientists, regulators, physicians, and people with diabetes is necessary to implement personalized medicine approaches to move from a one-size-fits-all to a one-fit-for-each approach.

²Institute of Biomedical Research, The Medical School, University of Birmingham, and The Queen Elizabeth Hospital, Birmingham, UK

Key points

- Insulin is a peptide hormone essential for life. It is released by the pancreatic β cells in the fasting state to limit catabolism. Post-prandially, insulin secretion is increased to ensure energy storage as carbohydrates, proteins, and lipids, and to stop endogenous glucose production.
- Insulin therapy is necessary in absolute insulin deficiency, as in type 1 diabetes or post-pancreatectomy; however, insulin therapy is also used frequently in states of relative deficiency of endogenous insulin due to insulin resistance, such as type 2 diabetes or gestational diabetes.
- The challenge of insulin replacement therapy is to reproduce a normal physiological insulin profile with low burden to the person with diabetes.
- In 1993, the Diabetes Control and Complications trial showed that intensive insulin therapy can reduce chronic complications of hyperglycaemia, such as retinopathy, nephropathy, neuropathy, and cardiovascular disease, in people with type 1 diabetes. The UK Prospective Diabetes Study demonstrated a reduction of diabetes-related complications through tight glycaemic management in people with type 2 diabetes. However, the risk of hypoglycaemia and insulin-induced weight gain remains a major barrier for treatment intensification.
- Early insulins were extracted from the pancreases of pigs and cows, but optimal glycaemia was difficult to achieve due to impurities in the preparation. Newer and purer insulins, and later synthetic human insulins and insulin analogues, are better tolerated and more predictable in terms of their glucose-lowering effect.
- A range of modern insulin preparations with differing durations of actions are available. These include rapid- and ultra-rapid-acting insulin analogues (duration of action ~2–3 hours), soluble insulin (~6–8 hours), neutral protamine Hagedorn (NPH) insulin (12–18 hours), long-acting insulin analogues (~24 hours), and ultra-long-acting insulin analogues (~40 hours).
- Current recommendations for the injection of insulin are to use the abdomen, upper buttocks, upper arms, and upper thighs, and to rotate injection sites to avoid lipohypertrophy. The needle should be injected at right angles to the skin and left there for 10 seconds before removing the needle. Injection needle lengths should be as short as possible to minimize trauma and to avoid intramuscular delivery. For those using insulin pens, 4 mm needles are available. Syringe needles remain at 8 mm. Alternative routes of insulin delivery such as continuous subcutaneous insulin infusion can also be highly effective.
- Multiple-dose insulin (MDI) therapy is an appropriate initial approach to reproduce the physiological insulin profile in people with absolute insulin deficiency such as those with type 1 diabetes. This comprises a long-acting insulin preparation administered usually once a day to meet the basal insulin requirement, with the injection of a short-acting insulin preparation with each meal.
- Novel technologies, such as insulin pumps that administer rapid-acting insulin continuously through a subcutaneous catheter, provide more flexibility for people with type 1 diabetes. Sensor-augmented smart pump therapy, with automated delivery adapted by an algorithm, reduces the combined rate of severe and moderate hypoglycaemia in people with type 1 diabetes.
- Different insulin injection regimens are available for people with varying degrees of residual endogenous insulin production and insulin resistance, including those with type 2 diabetes, who may already be treated with non-insulin-based therapies. These include a once-daily injection of a long-acting insulin, twice-daily injections of insulin mixtures, or a combination of mealtime short-acting and once-daily long-acting insulins. In addition, insulin can be administered in a co-formulation with other injectables such as glucagon-like peptide 1 receptor agonists.

Discovery and early days of insulin therapy

Insulin is a potent anabolic hormone, and its absence induces a profound catabolic state that affects fat, carbohydrate, and protein stores. Absolute insulin deficiency, as in type 1 diabetes, will result in death if left untreated. In the pre-insulin era, the most effective therapy appeared to be severe nutritional restriction, perhaps most popularly

expounded by Frederick Allen from the Rockefeller Institute in New York [1]. This, however, was a difficult regimen that did not appear to prolong life expectancy significantly, and when death came it was unclear whether it was the result of diabetes or starvation.

The relevance and therapeutic potential of insulin arose from the seminal experiments of Frederick Grant Banting and his student Charles Best, although there had been several previous attempts at

identifying a pancreatic agent that could regulate blood glucose, most notably by the Romanian physiologist Nicolas Paulescu. With the logistical support of John Macleod and help from biochemist James Collip, Banting and Best succeeded in the isolation and purification of an *internal pancreatic secretion* that could normalize glycaemia in pancreatectomized dogs (Figure 31.1). For this work, Banting and Macleod shared the Nobel Prize in Medicine in 1923. In recognition of the essential contributions of the team members, Banting split his prize money with Best, and Macleod shared his portion with Collip. Banting, Best, and Collip shared the patent for insulin, which they sold to the University of Toronto for one Canadian dollar [2]. This remarkable scientific progress took place 100 years ago, and the first dose of insulin was administered to a person with diabetes on 23 January 1922.

Commercially available insulin was initially extracted from porcine and bovine pancreases. This procedure resulted in insulin with a purity of 80–90%, the contaminants largely being pancreatic polypeptides and glucagon. Though this insulin was effective, its use was often complicated by immune-mediated side effects, in particular lipoatrophy and antibody-mediated insulin resistance [3], both of which could profoundly influence the kinetics of insulin action. It was not until 1980 with the introduction of recombinant DNA technology that human insulin therapy became widely available, with purification achieving 99.5–99.9% insulin purity, thus virtually eliminating problems associated with immune-mediated side effects [4].

Figure 31.1 Charles Best and Frederick Banting on the roof of the medical building at the University of Toronto, Summer 1921.

Both beef- and pork-derived insulin remain available in many countries, but leading insulin manufacturers have phased out animal insulins in favour of modern recombinant human insulins. A meta-analysis of 45 randomized controlled trials involving 2156 participants comparing animal and human insulin did not show a significant difference in achieved glucose levels between these two therapies [5].

Advances in insulin manufacturing involved the manipulation of the insulin molecule, resulting in the design and production of shorter- and longer-acting insulin analogues [6]. Analogue insulins are currently favoured due to the closer mimicry of the physiological insulin profile and reduced risk of hypoglycaemia, although generally they are more expensive than human insulin. While those responsible for healthcare budgets seek persuasive clinical trial data on improved overall glycaemic levels, it is most unlikely that we will ever see direct head-to-head studies that provide incontrovertible data one way or another. Most of the benefits of the insulin analogues lie in the increased flexibility and protection against hypoglycaemia, and although some of the individual benefits appear small, collectively they are likely to have an impact on many people with diabetes [7].

Modern insulin formulations to reproduce physiological insulin delivery

Insulin is a peptide hormone of 51 amino acids that is secreted by the pancreatic β cells within a narrow physiological range. In the fasting state, insulin circulates at a concentration of 15–20 mU/l to limit catabolism. Post-prandially, insulin secretion increases to 60–80 mU/l to ensure energy storage of nutrients as carbohydrates, proteins, and lipids, and to stop endogenous glucose production (Figure 31.2). The secretion and action of insulin are covered in more detail in Chapters 7 and 9, respectively.

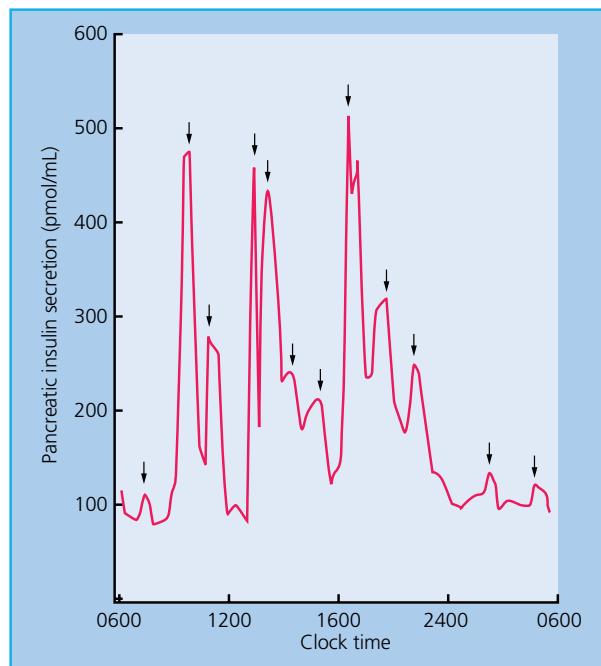

Figure 31.2 Pancreatic insulin secretion in healthy individual with normal body weight. Meals were consumed at 09.00, 13.00, and 18.00. Statistically significant pulses of secretion are shown by the arrows. Source: Polonsky et al. 1988 [8]. Reproduced with permission from the American Society for Clinical Investigation.

Insulin is stored in the β cells as hexamers stabilized by zinc ions (Figure 31.3). When secreted, the zinc-insulin hexamers are diluted in the bloodstream, disassembling into monomers, the active state of insulin. In exogenous insulin administration, hexamer formation can be induced by additives to form stable solutions for vials and cartridges. Classic additives are zinc, a phenolic preservative (m-cresol and/or phenol) that serves a dual purpose as an antibacterial agent and a hexameric stabilizer, and a buffer to maintain the correct pH. Following injection, fluid is drawn into the injected insulin depot through osmosis. This leads to dilution of the insulin and dissociation of the insulin molecules; this is a spontaneous but gradual process that must occur before insulin crosses the capillary walls as monomers into the blood circulation [10]. People with diabetes are therefore advised to inject their soluble insulin 15–20 minutes before a meal to ensure that circulating insulin levels are optimal at the time their meal is being absorbed. A significant proportion of people with diabetes find it hard to follow this advice because of the planning required. Even when they do, the calculated doses may be inaccurate, particularly if the preparation and presentation of the meal are not under the individual's control.

In order to mimic the endogenous insulin response as closely as possible, the time-action profiles of insulins and formulations have

been modified over time with the creation of insulin analogues (Figure 31.3). To reproduce the basal and post-prandial insulin secretion, a combination of short-acting and intermediate or long-acting insulin formulations is used [9].

Short-acting formulations

The biological action of soluble human insulin lasts 5–6 hours. The first rapid-acting insulin analogues were designed to form less stable insulin hexamers, ensuring that the insulins would more readily become monomeric, thus moving into the bloodstream more rapidly after subcutaneous injection. These changes result in faster absorption of insulin into the bloodstream and allow it to be injected closer to the mealtime, often just before starting to eat.

One way to reduce the association between insulin molecules is to change the amino acid sequence, usually focusing on the B28–29 amino acids [11]. To date, three such rapid-acting analogues have become available. Insulin lispro (Humalog®, Eli Lilly, Indianapolis, IN, USA) differs from human insulin at position B28 where the amino acid proline is replaced by lysine, and the lysine in position B29 is replaced by proline. Insulin aspart (NovoRapid®, Novo Nordisk, Bagsvaerd, Denmark) also has a substitution at B28, with proline replaced with

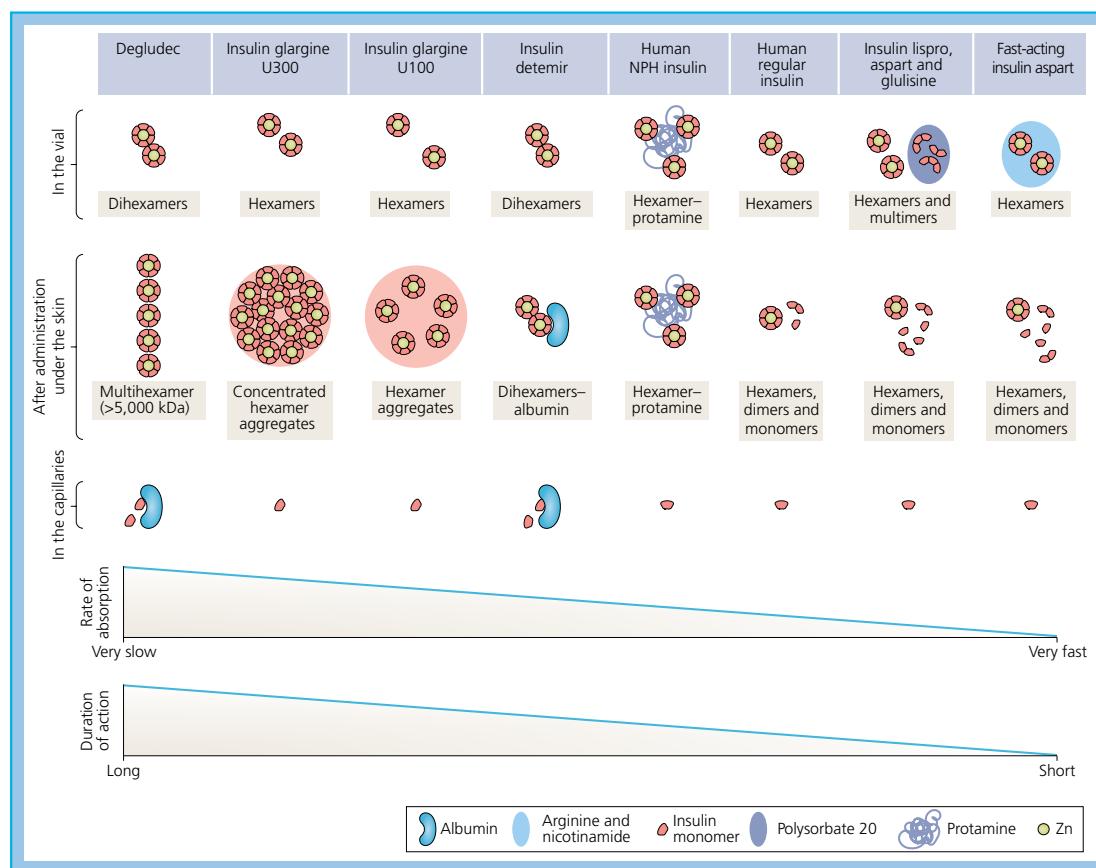

Figure 31.3 Different determinants of absorption and duration of action of human and analogue insulins. Degludec forms weak hexamers in solution in the vial and stable multihexamers after administration at the injection depot, thereby slowing its absorption. Reversible binding to albumin in the circulation further prolongs its action. Insulin glargine U300 precipitates at physiological pH, forming compact aggregates at the injection depot, leading to a reduced surface area from which absorption can occur, causing slow absorption and prolonged duration of action. Insulin glargine U100 also precipitates at physiological pH but is less compact than insulin glargine U300. Insulin detemir forms weak dihexamers in the vial and strong dihexamers at the injection depot. Reversible binding to albumin, both at the injection depot and in circulation, further slows the absorption rate and prolongs the duration of action. Neutral protamine Hagedorn (NPH) insulin co-crystallizes with protamine, both in the pharmaceutical preparation and at the injection site, slowing absorption and action. The classic rapid-acting insulin analogues (lispro, aspart and glulisine) dissociate into dimers and monomers more rapidly than does human regular insulin, causing a more rapid absorption and shorter duration of action. For glulisine, polysorbate 20 is used as a stabilizing agent, and formation of hexamers is prevented by absence of zinc (Zn). More rapid absorption and earlier action of fast-acting insulin aspart is caused by addition of arginine and nicotinamide to the formulation, thereby increasing the rate of formation of monomers at the injection depot and increasing the rate of absorption.

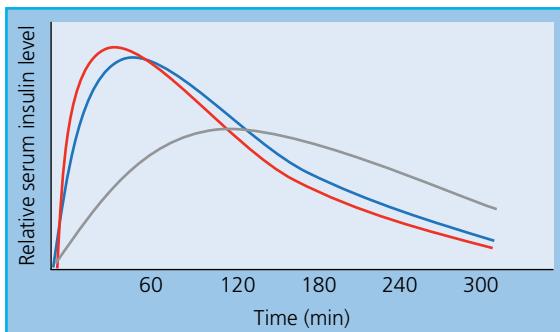

Figure 31.4 Time-action profiles of short-acting insulin formulations. Pharmacokinetic profile of human regular insulin (depicted in grey), rapid-acting insulin analogues (insulin lispro, aspart, glulisine; blue), and ultra-rapid-acting insulin analogues (faster insulin aspart and ultra-rapid lispro; red).

aspartic acid. For insulin glulisine (Apidra®, Sanofi, Paris, France), the lysine at position B29 is replaced by glutamic acid, and asparagine at position B3 is replaced by lysine. These analogues act more quickly (within 10–20 min) and have a shorter duration of action (3–5 h) than soluble insulin (30–60 min and 6–8 h, respectively) [12] (Figure 31.4).

Numerous studies have demonstrated the safety of rapid-acting analogues in both type 1 diabetes and type 2 diabetes, as either part of a *basal-bolus* insulin injection regimen combined with intermediate-acting insulins, or in continuous subcutaneous insulin infusion [13]. The time-action profile of rapid-acting analogues is well suited to mimicking the requirement at mealtimes, and therefore they probably control post-prandial hyperglycaemia more effectively than soluble insulin. As a result, individuals can achieve better glycaemic levels and fewer episodes of hypoglycaemia with rapid-acting analogues than with soluble insulin. The benefits of rapid-acting analogues over soluble insulin appear to be clearer in studies involving people with type 1 diabetes than type 2 diabetes, and when using insulin pumps rather than multiple-dose injections [12].

Recently, the addition of excipients to expedite absorption from the subcutaneous space has led to novel formulations of ultra-rapid-acting insulin analogues. Faster insulin aspart (FIASP®, Novo Nordisk) contains L-arginine as a stabilizer and niacinamide to increase absorption by increasing subcutaneous blood flow. Similarly, ultra-rapid lispro (Lyumjev®, Eli Lilly) contains additional citrate to increase absorption by enhancing local vascular permeability and treprostinil to increase local vasodilatation [14]. While both formulations reach peak insulin levels a few minutes earlier, have an earlier offset of action, and achieve a greater reduction in post-prandial glucose compared with rapid-acting insulin analogues, the added value for clinical practice is unproven, and their use in pumps and compatibility with pump catheters need to be studied further.

Intermediate and long-acting formulations

To avoid the frequent painful injections of early insulin preparations, attempts were made in the 1920s and 1930s to provide the daily insulin requirement in just one injection. Modifying agents such as lecithin, oil, and cholesterol were used [15], but the duration of action varied significantly from injection to injection, which limited their clinical utility. In 1936, a method was reported incorporating the addition to insulin of protamine, a highly basic protein derived from the sperm of salmon or trout, to form a poorly soluble complex, thus slowing its absorption [16]. This technique was later refined by adding protamine and zinc in stoichiometric proportions (so that there was no free protamine or zinc) to form isophane or

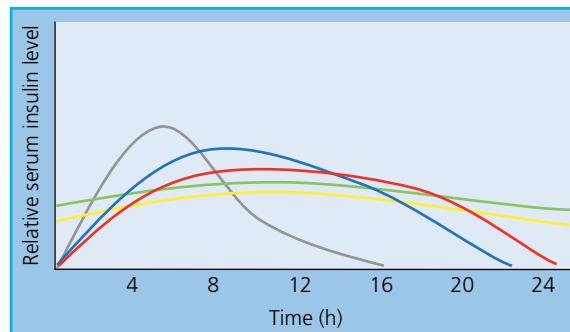

Figure 31.5 Time-action profiles of intermediate and long-acting insulin formulations. Pharmacokinetics profile in steady state of neutral protamine Hagedorn (NPH) insulin (depicted in grey), insulin glargine U100 (red), insulin detemir (blue), insulin glargine U300 (yellow), and insulin degludec (green). Care must be taken when interpreting the curves as the experimental setting in which the data were gathered differed among studies.

neutral protamine Hagedorn (NPH) insulin. Though the action of NPH insulin is delayed and can cover a 12–24-hour period, significant variation in duration of action and absorption persisted [17]. Consequently, attempts at stringent glucose management using these formulations as basal insulin are associated with an increased risk of hypoglycaemia.

As for rapid-acting analogues, modification of the insulin molecule primary amino acid sequence can also result in a longer and more reproducible duration of action. There are currently three such insulin analogues. Glargine (Lantus®, Sanofi) achieves prolonged insulin action through amino acid substitutions that make the insulin molecule less soluble. Glargine insulin forms microcrystals following subcutaneous injection that dissolve slowly over an 18–26-hour period (Figure 31.5) [18]. In non-inferiority studies, insulin glargine achieves similar glycaemic levels as isophane insulin, but does so with less hypoglycaemia [19]. Insulin detemir (Levemir®, Novo Nordisk) has a fatty acid side chain addition to the insulin molecule that promotes binding to circulating albumin, which then slowly dissociates, giving it a duration of action just a little short of glargine insulin. Detemir is as efficient as isophane insulin at improving glycaemic levels, but again does so with less hypoglycaemia and interestingly less weight gain [20].

The most recent commercially available addition to the long-acting insulin analogues has been insulin degludec (Tresiba®, Novo Nordisk). Degludec also has a fatty acid side chain, but structured in such a way as to encourage it to form long multihexamer chains following subcutaneous injection. This chain disassembles very slowly and gives degludec a very long duration of action (half-life exceeding 25 h), such that it has been termed an ultra-long-acting insulin analogue [21]. This long duration of action allows a very flat insulin profile and a more reproducible duration of action that is not significantly affected by variations in the time of day-to-day administration. Non-inferiority studies have shown that insulin degludec achieves similar glycaemic levels to insulin glargine, but with less overall and nocturnal hypoglycaemia [22].

Comparative studies of the long-acting analogue insulins have been designed to demonstrate equivalence rather than superiority in terms of glycaemia [23]. They do, however, demonstrate that the same level of glycaemia can be achieved with less hypoglycaemia, and some with less weight gain (detemir). These benefits come to date at a cost, with insulin analogues costing more than double the price of NPH insulin.

Biosimilars

Several patent protections for insulin analogue preparations have expired, and the pharmaceutical industry has explored these opportunities to develop *copycat* insulins to compete with original formulations. Because insulins are currently produced biologically (i.e. through expression in living cells), they are more correctly termed *biological* or *biosimilar* drugs than generic drugs. Biosimilars (such as peptide hormones and monoclonal antibodies) are already in clinical practice and are required to undergo more rigorous testing than standard generic drugs. This testing includes direct comparison of the biological activity, pharmacology, clinical safety, and efficacy of the biosimilar with the reference insulin. While the development costs of biosimilars are higher than those for other generic drugs, they are not as expensive as developing the original insulin, and any cost savings will likely be magnified through long-term prescription. Therefore, these insulins will likely be cheaper, thus expanding market competition and increasing availability for people with diabetes. Currently, several biosimilars of insulin have been approved by various regulatory agencies: glargine (Abasaglar®, Eli Lilly) by the European Medicines Agency (EMA; 2014) and US Food and Drug Administration (FDA; 2015); Basalin® (Gan & Lee, Beijing, China) by China (2005); Semglee® (Biocon Biologics/Mylan, Bangalore, India/Canonsburg, PA, USA) by Australia (2018); and insulin lispro (Admelog®, Sanofi) by the FDA (2017) [24].

Concentration

Insulin *units* were introduced to address and compare the blood glucose-lowering potency of insulin preparations. One unit of insulin generally has the potential to drop blood glucose by 50 mg/dl (2.8 mmol/l), although it can range from 30 to 100 mg/dl (1.7–5.6 mmol/l), depending on individual insulin sensitivity. Injecting large volumes of insulin, as is required in those who are insulin resistant, slows absorption kinetics and reduces the effectiveness of the insulin. Furthermore, it can be more painful. Splitting the dose across different injection sites can reduce the volume. However, in some people the use of more concentrated insulin is more appropriate. Insulin preparations are currently standardized to 100 U; that is, 100 units of biological activity per ml of insulin. Concentrating human insulin, however, typically leads to a protraction of its action [25] and ultra-concentrated human insulin (for example, human regular insulin U500) has a pharmacokinetic profile that is intermediate between U100 and NPH [26].

Concentrated formulations of analogue insulins are available for clinical use and have been demonstrated to be clinically effective [27–29]. While the U100 and U200 formulations of short-acting lispro and long-acting degludec have bioequivalence, for one insulin analogue hyperconcentration from U100 to U300 has led to the ‘creation’ of a new commercial entity (U300 glargine, Toujeo®, Sanofi). U300 glargine has a protracted action exceeding that of U100 glargine, with a duration of action of 25 hours. In clinical trials comparing U100 and U300 glargine, similar glycaemic levels were demonstrated, with a reduced risk of (nocturnal) hypoglycaemia in those using the U300 formulation.

Insulin administration

The early experiments of Frederick Banting quickly revealed that the oral route of insulin administration was not an effective means of insulin delivery, as the insulin molecule is functionally degraded by gut peptides. Subcutaneous injection of insulin has become the most popular route of insulin delivery, because of its relatively reproducible kinetics of absorption and the ease with which it can be administered, but it is worth considering some of the other routes.

Subcutaneous insulin injections

Subcutaneous insulin injections are the most used insulin therapy. The recommended sites for injection are the abdomen, upper arms below the deltoid region, upper thighs, and upper buttocks (Figure 31.6). The area should be clean and free from signs of infection or lipohypertrophy.

Insulin can be directly dialled up on a pen device or drawn up using a disposable syringe. If the insulin preparation is cloudy (e.g. NPH), it should be gently rolled and inverted 10 times. This will allow the insulin crystals to disperse and for the mixture to turn to a milky-white suspension. If using a pen device for insulin delivery, the device should be properly primed and a drop of insulin should be visible at the tip of the needle. Similarly, if an insulin syringe is being used, the barrel should be tapped and any air excluded by squeezing the plunger. These manoeuvres ensure that air is not contributing to the volume of insulin that has been dialled or drawn, and that an accurate dose of insulin is delivered.

The needle should enter the skin at right angles to the surface in a smooth process, the plunger squeezed gradually and completely, and left there for 10 seconds to allow the insulin to enter the tissue.

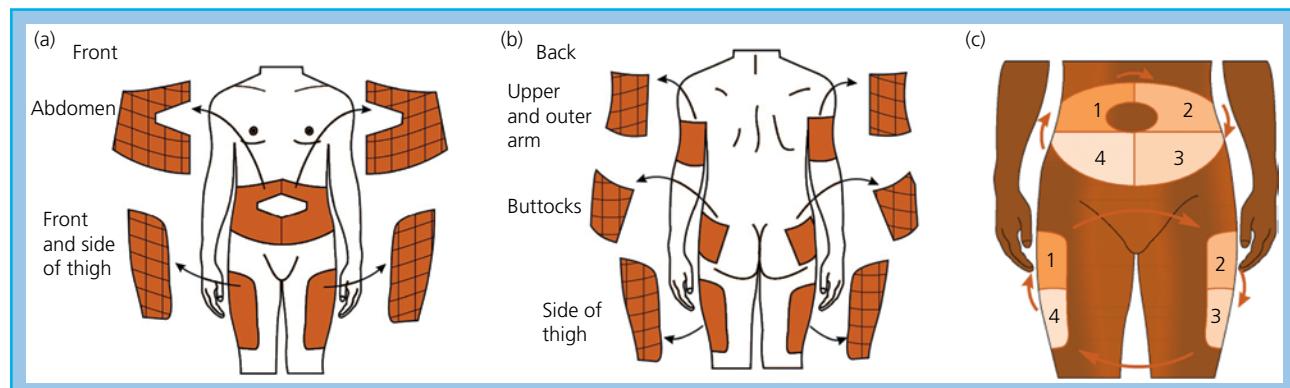

Figure 31.6 Insulin injection sites and rotation of insulin injection sites. The areas recommended for insulin injections as viewed from the front (a) and back (b). They may be divided up into smaller areas, so that each area is injected not more than once a day. (c) A method that can be adopted to rotate insulin injections. Source: Adapted from Bahendeka et al. 2019 [30].

Disposable syringes should be replaced at each injection; for pens it is considered good practice to change the needle for every injection, but this should be done at least once daily. Rubbing of the skin following injection is discouraged because this increases the rate of insulin absorption and may increase the risk of hypoglycaemia.

Syringe needle lengths are currently restricted to 8 mm. Pen needles come in a variety of lengths, including 4, 5, 6, and 8 mm. There is no indication to use needles longer than 8 mm because longer needles increase the risk of intra-muscular injection, with the associated rapid absorption and risk of hypoglycaemia. Currently 4 mm needles are recommended for many adults and most children, and these can often be used without the need to lift skin folds. Injecting into lifted skin folds is appropriate in children, slim adults, and when there is a risk of injecting into muscle. The correct technique for lifting skin folds needs to be taught; it should not lift up underlying muscle, nor be so tight as to cause blanching of the skin (Figure 31.7). The use of lifted skin folds is recommended for all people who use 8 mm needles. Injecting through clothing is discouraged because as needle lengths get shorter, there is a risk of intradermal injection.

Studies of absorption of subcutaneously administered insulin have used various techniques, including measuring the rate of loss of I^{125} -labeled insulin from the site of injection using a gamma counter [32]. They show that the rate can vary significantly between individuals, but also from one injection to another within the same individual [17]. Absorption rates in individuals with obesity are slower than in people without obesity, and there do not appear to be any clear differences in the rate of absorption between the different injection sites. In lean individuals, the absorption of insulin analogues (both rapid- and long-acting) does not appear to vary by injection site [33,34]. However, in these individuals absorption of human insulin from the abdomen appears to be faster than from the arm or leg [35], and the upper abdomen faster than the lower abdomen [36]. This difference can be utilized to good effect, for example injecting NPH insulin into the thigh or buttock ensures slower absorption, and soluble mealtime insulin in the abdomen more rapid absorption.

Repeated injection of insulin at the same site leads to local hypertrophy of adipose tissue, resulting in slower and more erratic insulin absorption. People with diabetes should always be advised to rotate their insulin injection sites to avoid this complication and should be shown an easy-to-follow rotation scheme (Figure 31.6). Other local factors such as oedema or local inflammation can influence rates of absorption. Exercise results in greater blood flow to the skin and can lead to faster uptake of insulin, particularly when that is injected into an area close to the muscle groups being exercised. Individuals who are planning to run, for example, should be advised that injection

into the leg may be less favourable than injecting into the arm or abdomen [37]. Similarly, temperature influences cutaneous blood flow and can affect insulin absorption [38]. Hot climates or sitting in the sauna may result in a rapid surge in insulin levels, whereas the converse, travelling to cooler climates, can result in a slower uptake. There are also reports that hypoglycaemia and smoking can reduce the rate of insulin absorption [39,40].

Standard insulin preparations have a shelf life of 4–6 weeks when stored at under 25 °C. Storage for longer periods will require that they be kept in a fridge (4 °C), which then allows them to be stored until their expiry date. Exposure of insulin to high temperatures or to microwaves can render it inactive.

Continuous subcutaneous insulin infusion

Next to delivery by pen or disposable syringes, insulin can be administered to the subcutaneous space using a pump device, which is discussed in detail in Chapter 33.

Alternative routes of insulin administration

Intramuscular injection is more painful, and absorption more rapid, than subcutaneous injection and is not recommended for any insulin formulation [41]. However, this route can be useful in the emergency situation when intravenous access is difficult. Inadvertent intramuscular administration should be considered in lean individuals who complain of pain on insulin injection, and who may experience erratic glucose levels and hypoglycaemia. The correct choice of insulin needles can help address this problem.

The delivery of insulin directly into the peritoneal space, for example, with implantable pumps or directly via a port [42] mimics physiological insulin secretion, in that insulin bypasses the systemic circulation and directly enters the portal circulation. The theoretical advantages of portal delivery include rapid insulin absorption, near physiological carbohydrate and lipid metabolism, and avoiding peripheral hyperinsulinaemia [43]. The clinical advantages of intra-peritoneal insulin delivery have been explored in a number of clinical trials [44]. While some evidence exists for improved glycated haemoglobin (HbA_1c) and quality of life in selected people with type 1 diabetes [45], the use of this delivery method is limited. However, research is ongoing and the role of implantable pumps in the development of a true artificial β cell remains appealing.

Insulin administration via the respiratory mucosal surface avoids degradation by gut peptides and can be an effective route for insulin delivery, particularly for those who have needle phobia [46]. Inhaled insulin was made available in Europe (Exubera[®], Pfizer, New York, USA) in 2006, but was withdrawn within a year due to poor uptake

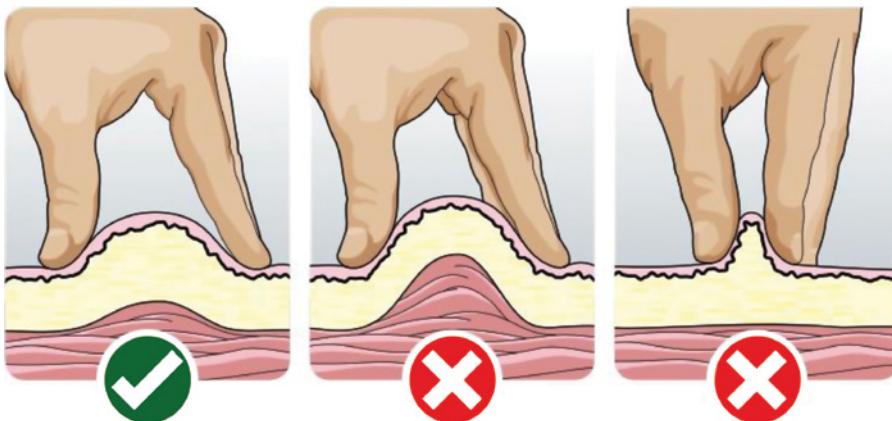

Figure 31.7 The recommended technique for lifting skin folds for subcutaneous injection of insulin.

by people with diabetes and healthcare professionals. In 2015, Technosphere insulin, a dry-powder formulation of human regular insulin adsorbed onto microparticles that are inhaled, was approved in the USA for use as a mealtime rapid-acting insulin (Afrezza®, MannKind, Westlake Village, CA, USA). With both formulations, there is a reduction in lung function that reverses when the therapy is stopped, and there is the potential risk of lung cancer in heavy smokers. Afrezza is not recommended in people who are current smokers, or in those with reactive airway diseases such as asthma or chronic obstructive pulmonary disease. While trials of newer inhaled insulins are awaited, systematic reviews of previous formulations suggest they are as clinically effective, but not as cost-effective, as short-acting injectable insulin in unselected people with diabetes [47].

Complications of subcutaneous insulin therapy

The major and most feared complication of insulin injections, which affects most people using insulin, is hypoglycaemia. The causes, avoidance, consequences, and management of hypoglycaemia are discussed in Chapter 40. The fear of hypoglycaemia may be a major barrier to insulin initiation and intensification.

Insulin not only restores fat and muscle mass in newly or suboptimally treated people requiring insulin, but can lead to excessive weight gain [48]. This remains a major concern for many people, particularly those with type 2 diabetes who already have overweight and can no longer be managed with oral anti-diabetes agents. Weight gain is also becoming a growing issue for people with type 1 diabetes, limiting the appeal of intensive insulin therapy [49]. Weight gain can be reduced by concomitant dietary advice and an insulin regimen tailored to the requirement of the individual, which wherever possible provides most insulin when needed; that is, at mealtimes. Overaggressive insulin titration regimens leading to low blood glucose and stimulation in appetite can lead to excessive weight gain. The management of diabetes for some people, particularly but not exclusively young women, can be challenging when insulin doses are reduced to suboptimal levels to manipulate body weight (Chapter 65).

Immune responses to the older animal insulins have been well reported, but such responses to current human and analogue insu-

lins are less common [50]. Allergies may rarely develop in response to the insulin molecule (this may become a more common issue with the introduction of biosimilar insulins where folding may differ) or to components of the insulin preparation (such as protamine or metacresol). Most commonly, allergic reactions manifest as local acute urticarial reactions. These are best managed with intradermal skin testing of 1:20 dilutions of different insulin preparations, and then switching to that which is best tolerated [51]. Antihistamines may be of benefit, as too may high-dose steroids in exceptional circumstances. More rarely, widespread systemic reactions develop as a reaction to the insulin and these individuals may benefit from referral to clinical immunology services.

Local complications of insulin therapy include lipoatrophy and lipohypertrophy. Lipoatrophy, in which subcutaneous tissue at the site of injection disappears or atrophies, is an allergic response predominantly with the older animal insulins and is rarely seen today. In contrast, lipohypertrophy occurs commonly. It is not an allergic response, but develops because of a trophic response of adipose tissue to insulin. It is most commonly seen in those with a poor injection technique and usually in people who do not rotate their insulin injection sites. Sustained injections into sites of hypertrophy can lead to poor and delayed insulin absorption, with consequent effects on blood glucose levels [52]. Lipohypertrophy generally resolves within two months if injecting into the affected area is avoided. Occasionally mild ulceration, pitting, and, more commonly, bruising can occur at injection sites. Rotating injection to another site and selecting a shorter needle may be indicated.

Importance of education and assessment of glycaemia

Diabetes self-management education and support is a central component of diabetes therapy for all those living with diabetes [53]. Education should target lifestyle and complication prevention, but in the case of those treated with insulin, glucose monitoring, adaptation of insulin doses, overall nutritional advice, and specifically carbohydrate assessment and glucose monitoring should be central (Chapter 26) (Figure 31.8).

Figure 31.8 A pictorial representation of the standards for diabetes self-management and structured education programmes for people with type 2 diabetes (in the UK).
Source: Adapted from Hadjiconstantinou et al. 2021 [53].

While national and international guidelines have made recommendations on glycaemic targets based predominantly on HbA_{1c} [54], self-monitoring of blood glucose not only helps people with diabetes achieve HbA_{1c} targets by adjustment of insulin doses, but also helps them better understand their own diabetes and blood glucose levels (Chapters 29 and 32).

People with insulin-dependent forms of diabetes, including type 1 diabetes and pancreatic forms, who are treated with intensive insulin therapy, should monitor their glucose levels intensively, to assess glucose levels and take them into account when deciding on insulin doses, taking into account exercise and meal carbohydrate content. More and more continuous glucose monitoring systems (intermittent scanning or continuous glucose monitoring devices) are being used, and time in range (TIR) (Chapter 32) is rapidly becoming the standard to assess overall glucose levels.

To achieve strict glycaemic targets and avoid long-term hyperglycaemic complications, as supported in the Diabetes Control and Complications trial for type 1 diabetes [48] and later in the UK Prospective Diabetes Study for type 2 diabetes [55], pre-meal blood glucose readings should range between 4 and 7 mmol/l and post-meal levels from 4 to 10 mmol/l, with a value >7 mmol/l before bed. While individual specialists often follow their own dose adjustment algorithms, in general terms a change in dose of 2 units or 10% of a dose (whichever is the greater) is a sensible adjustment for most people taking insulin. A TIR (70–180 mg/dl; 4–10 mmol/l) of 70% is the target in most people living with type 1 diabetes [56].

Similar targets may be sought for people with type 2 diabetes, although trials based on achieving very tight HbA_{1c} targets, with some aiming for <6% (42 mmol/mol), serve to highlight the dangers of hypoglycaemia [57]. The frequency of blood glucose testing is extremely variable, with people being recommended to test anything from seven times a day down to four or five tests a week.

The most important aspect of regular self-monitoring by people on insulin is that the test result should be used as part of a management plan to help decide prospectively on insulin dose. There are, however, other points that should be considered when advising on when to self-test, including times of intercurrent illness to adjust insulin dose, symptoms and treatment of hypoglycaemia, driving, and foreign travel [58].

Place of insulin therapy in people with different types of diabetes

Insulin deficiency leads to hyperglycaemia, the hallmark of diabetes mellitus. Diabetes mellitus, however, comprises a heterogeneous group of diseases with regard to clinical presentation and progression. The classification of diabetes into type 1 diabetes and type 2 diabetes, which relies primarily on the presence or absence of auto-antibodies against pancreatic islet β-cell antigens and age at diagnosis (younger for type 1 diabetes), is making room for a paradigm with a more individual assessment of remaining endogenous insulin production and insulin resistance [59].

Absence of endogenous insulin secretion, including type 1 diabetes

In people who are no longer producing endogenous insulin at levels that suffice to maintain normoglycaemia, such as people with type 1 diabetes or after total pancreatectomy, the administration of exogenous insulin is necessary to provide 24 h background and

meal-time coverage, unless they are in the early stages of type 1 diabetes, have some residual β-cell function, or have been fortunate to become insulin independent following a pancreas or islet cell transplant. For many this coverage is provided by the *basal bolus regimen*, involving a combination of short- and long-acting insulin preparations. The advantage of such an approach is that it is generally better at providing a more physiological insulin replacement with a greater degree of 24 h flexibility than premix insulins injected once or twice daily. While it has the disadvantage of involving more daily insulin injections and requiring more frequent blood glucose monitoring, it provides a much greater degree of flexibility throughout the day. Importantly, for example, it allows the individual to vary the mealtime and size during the day to accommodate different daily activities and meal sizes. For some, this freedom is less important and the administration of only two injections a day sways them towards an insulin premix.

Insulin pumps can provide even more flexibility and responsiveness regarding glycaemia throughout the day and night. In case of pronounced diurnal variation in insulin sensitivity such as the *dawn effect* or related to intensive physical exercise, basal insulin infusion rates can be set and modified per hour, so that a more physiological insulin profile can be mimicked more closely than with the stable release of long-acting basal insulins. In specific circumstances, for example for children or for women attempting to become pregnant or who are pregnant, insulin pumps are becoming increasingly popular as a tool to achieve tight glycaemic levels. Furthermore, several novel *closed-loop* and *smart pump* devices enable automated reduction or increase in basal insulin delivery rate depending on the glucose level recorded by a coupled sensor; these devices have proven to be especially useful during the night [60, 61]. In addition, pumps may be more convenient to administer inter-meal correction bolus insulin or titrate the mealtime bolus to the anticipated carbohydrate load using the incorporated bolus calculators. The need to observe and react more directly with pump systems, however, requires more active involvement of the person with diabetes, while some people do not wish to have an external device and/or catheter attached to their body. Furthermore, pumps systems are more expensive (Chapter 33).

Insulin resistance and relative insulin deficiency, including type 2 diabetes

Exogenous insulin administration also has a place in the diabetes management of people with remaining, but insufficient, endogenous insulin production to cope with growing insulin resistance, such as those with type 2 diabetes or gestational diabetes. Insulin may be used with other anti-diabetes agents. Given the pandemic prevalence of type 2 diabetes, more people with type 2 diabetes use insulin than people with type 1 diabetes [62].

The recent European Association for the Study of Diabetes (EASD)/American Diabetes Association (ADA) consensus statement for type 2 diabetes treatment recommends choosing second-line therapies after metformin based on the presence of cardiovascular- and/or kidney-related comorbidities, risk of weight gain and hypoglycaemia, and cost [54]. Most guidelines worldwide recommend that people with established atherosclerotic cardiovascular disease, chronic kidney disease, or heart failure should be treated with a sodium glucose cotransporter 2 (SGLT-2) inhibitor or glucagon-like peptide 1 receptor agonist (GLP-1 RA). Consequently, the use of insulin in people with type 2 diabetes has been moved to later stages of the disease, as add-on therapy to other anti-diabetes agents. However, in case of obvious signs of catabolism, such as

unintentional weight loss, an HbA_{1c} higher than 10% (86 mmol/mol), or glucose levels higher than 300 mg/dl (16.7 mmol/l), insulin should be considered without delay.

Despite all guidelines giving clear indications on the importance of tight glycaemic levels, clinical inertia resulting in the delayed management of type 2 diabetes with insulin has been noted for decades. This clinical inertia involves not only the initiation of insulin therapy in people with type 2 diabetes and elevated HbA_{1c} despite other therapies, but also the intensification of insulin therapy [63]. For example, a real-world analysis of 6054 individuals with type 2 diabetes noted that insulin therapy was initiated at a mean HbA_{1c} of 10.1% (87 mmol/mol) [64]. In African American and Hispanic individuals with diabetes, the delay in insulin initiation might be even longer than in non-Hispanic white individuals [65]. In contrast, prompt intensive insulin therapy at the time of initial type 2 diabetes diagnosis when HbA_{1c} levels are higher than 9.0% (75 mmol/mol) might even improve β-cell function [66].

Often as type 2 diabetes progresses, the transition from oral anti-diabetes agents to insulin can be a time of stress and anxiety for many people for various reasons, including [67]:

- A sense of personal failure about being unable to control blood glucose levels with lifestyle, diet, and oral therapy.
- A feeling that the diabetes is much more serious than previously because it now requires injections rather than tablets.
- Apprehensions, fears, and very occasionally real phobias over the need to self-inject a treatment.
- Worries of hypoglycaemia leading to coma and death.
- Concerns over weight gain.
- Concerns that insulin may severely affect the individual's occupation and certain lifestyle activities.

With the increasing use of GLP-1 RAs, many people are now acquainted with injection therapy before exogenous insulin is needed. The advantages of injectable GLP-1 therapy are low risk of hypoglycaemia and less frequent, often only once-weekly, injection, which allows the person to become accustomed to the idea and technique of self-injection in a less frightening way. Nonetheless, we remain aware of the many anxieties insulin injections can induce.

Selecting the most appropriate insulin regimen: towards a personalized approach

Most people who have had either type 1 diabetes or type 2 diabetes try a number of treatment regimens throughout their lives. There are many factors that influence the decision to opt for a specific regimen and ultimately the most important is individual choice built on evidence from clinical trials. As insulin preparations have evolved from the early animal insulins to both human and analogue insulins, we have also seen the development of more versatile and indeed flexible treatment regimens that enable the doctor and nurse to provide the person with diabetes requiring insulin with a bespoke treatment that fits in better with their individual needs and lifestyle (Figure 31.9).

Intensive insulin therapy, combining mealtime and basal insulin preparations or pump therapy, is the standard of care in people with type 1 diabetes [68]. While in some people with type 2 diabetes insulin requirements are similar to those with type 1 diabetes, for many with type 2 diabetes insulin initiation and intensification is a more gradual process. Views differ on the insulin of choice for initiation, particularly as an add-on to other anti-diabetes agents. Supported by clinical trials, once-daily long-acting basal insulins are now recommended in type 2 diabetes treatment guidelines and have found significant popularity, particularly in the community as a means of introducing the person with type 2 diabetes to insulin [54]. Choosing basal insulin analogues over NPH is a matter of debate, mainly because of the higher costs that use of basal analogue insulins entails, despite the fact that clinical trials demonstrated lower rates of hypoglycaemia with long-acting basal analogues as an add-on to existing oral therapy compared to NPH insulin [69]. However, while basal insulin is a popular way of starting insulin, many people with diabetes do not achieve satisfactory glycaemic targets with this regimen and will require a second insulin injection with a mealtime component within 6–12 months [70].

In areas of the world with high carbohydrate intakes, starting insulin therapy with a combination of a basal and prandial component (often as basal plus, or as premix insulins), or even a prandial

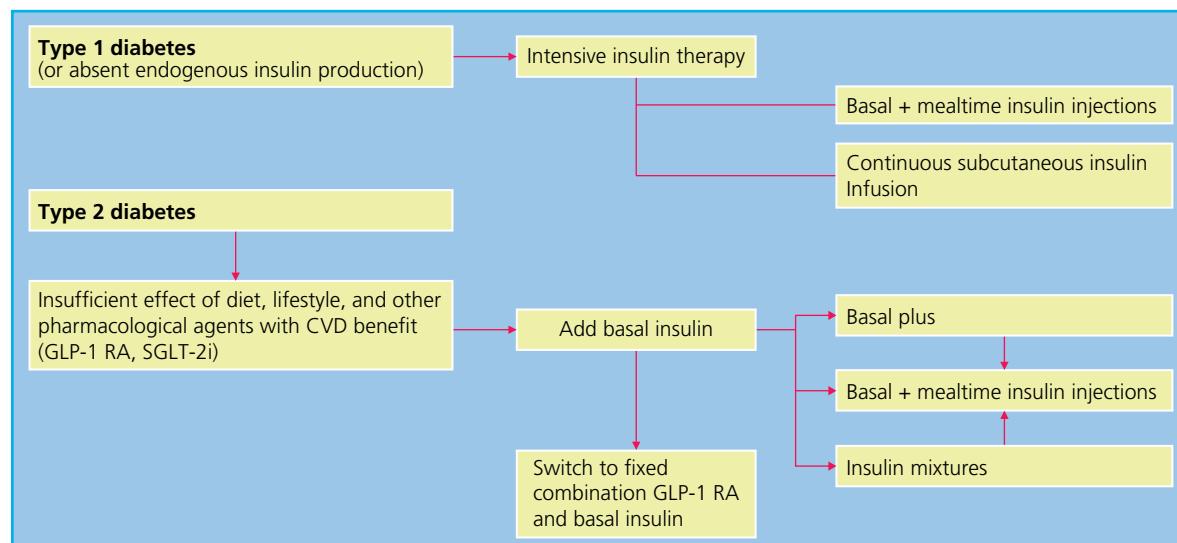

Figure 31.9 Suggested approach to selecting an insulin regimen in people with type 1 diabetes and 2 diabetes. CVD, cardiovascular disease; GLP-1 RA, glucagon-like peptide 1 receptor agonist; SGLT-2i, sodium glucose cotransporter 2 inhibitor.

insulin regimen only, is popular. The relative merits of basal only, prandial only, and premix insulin have been evaluated [70,71]. Clearly there are advantages and disadvantages associated with each approach.

A pragmatic response is to consider the person with diabetes and their lifestyle, social circumstances, and comorbidities and take account of their likely long-term insulin needs. If it seems likely that the person will remain on a basal insulin as a single injection or as part of a future basal-bolus regimen, the basal insulin may be the best option. However, if it seems probable that the individual will be switched to a premixed insulin if a long-acting bolus does not achieve target, then initiating with a premixed insulin is a sensible alternative.

Basal only

One way in which insulin injections can be introduced to people with type 2 diabetes who are no longer able to manage their blood glucose with diet, lifestyle, and non-insulin anti-diabetes pharmaceutical therapies is to start with only one injection of insulin a day. This is usually added on to existing agents such as metformin, sulfonylurea, dipeptidyl peptidase 4 (DPP-4) inhibitors, SGLT-2 inhibitors, or GLP-1 RAs rather than as a replacement therapy. National and international guidelines in the UK, Europe, and the USA as well as the recent ADA/EASD consensus on glucose-lowering therapies in type 2 diabetes also recommend the use of a basal insulin with oral therapy as a way of initiating insulin in people with type 2 diabetes [54]. The initiation of insulin therapy, whether in the hospital or now more commonly in the community, should only take place within a structured programme employing active insulin dose titration. The program should include appropriate education; ongoing telephone, text, or email support; the use of glucose monitoring to inform dose titration to an agreed target; an understanding of diet; avoidance and management of hypoglycaemia; and support from appropriately trained and experienced healthcare professionals. Use of structured diabetes self-management education and support systems has proven to be very effective [53].

Some guidelines continue to recommend initiation with a human NPH insulin taken once or twice a day according to need [72]. However, many healthcare professionals are opting for long-acting insulin analogues, considering the reduced risk of (nocturnal) hypoglycaemia with these analogues. Also practicalities drive the preference for using basal insulin analogues with longer action profiles, particularly in people who require assistance with injections from a carer or healthcare professional and where the use of an analogue would reduce the number of injections from twice to once a day [23]. Similarly, indications for switching from NPH insulin to a long-acting basal analogue include not reaching an agreed HbA_{1c} target because of hypoglycaemia regardless of HbA_{1c}.

Most basal insulins are best administered before bedtime to reach the maximal effect during the night, thus achieving the primary goal of basal insulin, which is suppression of nocturnal hepatic glucose output and maintaining fasting glycaemia in an optimal way. When using the ultra-long insulin analogues, like U300 glargine or degludec, the timing of insulin administration is less crucial. Starting insulin doses can be calculated based on body weight (e.g. 0.1 unit/kg) or be standard (e.g. 10 units).

Once a basal insulin is started, it is important to adjust insulin doses appropriately to achieve an agreed target. Whereas the goal is to improve overall glycaemia, as measured by HbA_{1c}, the target to be used by individuals with diabetes and healthcare professionals to

adapt the basal insulin dose is self-measured fasting glycaemia. Several algorithms have been developed to assist with this, almost all based on fasting blood glucose measured in the community and usually by the person with diabetes themselves [73–75]. Clinical inertia needs to be avoided and a reasonable, simple, but strict titration regimen should be agreed with the person with diabetes, in order to reach optimal glycaemic levels within an acceptable time-frame (e.g. titration twice a week). However, *over-basalization*, namely the blind up-titration of basal insulin doses without result, should be avoided. Indeed, once doses exceed 0.5 U/kg, the effects on glucose levels of increasing the insulin dose further are minimal, whereas their effect on weight gain continue. As a rule of thumb, when fasting glycaemia is within target but HbA_{1c} is not with basal insulin only, it is time to add mealtime insulin.

Basal plus

The addition of a fast-acting human insulin or rapid-acting insulin analogue prior to the main meal of the day can be a useful next step in intensification after starting a basal insulin in people with type 2 diabetes [76,77]. Increasingly healthcare professionals are prescribing rapid-acting insulin analogues over fast-acting human insulins [78,79]. The individual's dietary intake will determine which is the main meal and, therefore, with which meal the single injection of fast-/rapid-acting insulin will be given. Once again, it is important to titrate the prandial insulin to a glucose target. The ideal time to assess the impact of the prandial insulin, and certainly a rapid-acting insulin analogue, is 90–120 min after the meal. As with basal insulin adjustment, it is advisable not to change the insulin dose too frequently, ideally no less than twice a week. The person with diabetes may vary the amount of insulin administered based on the size of the meal, although as the insulin is given with the main meal of the day, the dose is usually fairly stable from one day to another. As glycaemic targets become more difficult to achieve, a second prandial insulin injection may be necessary, taken before the second main meal of the day using a similar dose titration procedure to that for the single prandial injection [80].

Insulin mixtures: premix insulins, combination insulins

As an alternative to the basal plus regimen, people with type 2 diabetes can change from a basal insulin to a mixed insulin formulation, which is given traditionally twice a day, with breakfast and the evening meal. This concept of premix insulins originated as a means of replacing the self-reconstituted combinations of regular insulin and NPH insulin and to cover the insulin needs for a typical Western diet with only two injections (30% regular insulin and 70% insulin NPH) [81]. However, such an approach does not mimic normal insulin physiology, and therefore increases the risk of hypoglycaemia [82]. Two types of pharmaceutical preparation have been developed to allow people with type 2 diabetes to harness the benefits of basal insulin action with other products, without increasing the risk of hypoglycaemia. The first is a combination of a basal and ultra-rapid insulin analogue (degludec and faster-acting insulin aspart, Rysodeg®, Novo Nordisk) and the second a combination of a basal insulin analogue and a GLP-1 RA (U100 glargin/lisixenatide, Suliqua®, Sanofi; degludec/liraglutide, Xultophy®, Novo Nordisk). In the case of the degludec/faster-acting insulin aspart combination, the advantage of the combination of a basal insulin and a mealtime insulin is maintained, with a lower risk of hypoglycaemia compared to standard premix insulins using NPH as the basal component. The combination of a basal insulin analogue and a GLP-1

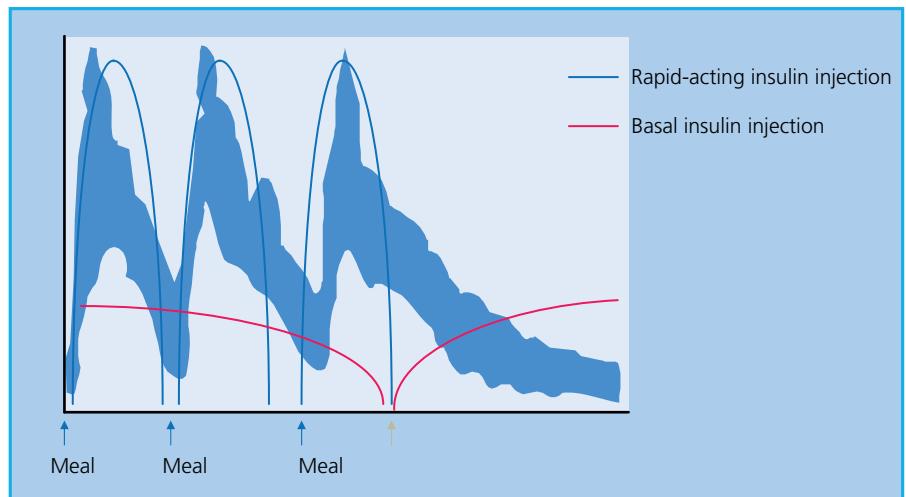

Figure 31.10 Schematic representation of the attempt to mimic physiological insulin release following three main meals using a basal-bolus regimen.

RA not only provides better overall glycaemic levels than basal-only insulins, but does so at a lower risk of hypoglycaemia and with less weight gain [83].

Basal bolus

Basal bolus is the most commonly used form of intensive insulin therapy in people with type 1 diabetes, but is also a popular regimen in people with type 2 diabetes where both mealtime and basal insulin components are needed.

The use of the basal bolus regimen in people with type 1 diabetes and type 2 diabetes attempts to mimic as closely as possible the normal physiological secretion of insulin by providing a background 24 h coverage of insulin by a basal insulin along with bolus injections at each meal (Figure 31.10). In most people with diabetes, with the development of long-acting analogue insulins the basal injection is administered once a day. However, based on the results of pre-meal self-monitored blood glucose values, some people may require two basal injections ~12 h apart to achieve satisfactory pre-meal glucose values without hypoglycaemia. Traditionally with NPH, basal injections are given in the evening, often before bed. However, this is less important with the basal insulin analogues and many people prefer to take their once-daily basal injection at the same time each morning. It is important that insulin doses are adequately titrated to achieve target glucose and HbA_{1c} values; for the basal bolus regimen the dose of the basal insulin is determined by measurement of fasting (pre-meal) glucose values, and the most appropriate fast human or rapid-acting analogue insulin dose is best determined by two-hour post-prandial glucose values.

More practical tips on starting and titrating insulin

In the past, particularly for people with type 1 diabetes, insulin initiation was conducted either as an inpatient or as a day case in a hospital diabetes centre. As confidence grew with the development of purer animal insulins and most recently with human and analogue insulins and the introduction of disposable syringes, pen injectors, and needles, more insulin starts are performed as an outpatient. Lately, with an increased emphasis on community-based diabetes care, insulin initiation, particularly in people with type 2

diabetes, is taking place in health centres and general practitioner surgeries [84]. While older algorithms for helping to decide when and where insulin should be initiated have been published, national and local guidelines now seem more appropriate as varying levels of expertise, infrastructure, and service delivery are present in different areas of the world.

In order to achieve a successful insulin initiation, it is vital that a good insulin initiation programme is in place, with a qualified and competent diabetes nurse specialist. Several programmes are available, most with appropriate training courses for healthcare professionals. Insulin initiation involves much more than teaching someone how to use a needle and syringe, and the process of starting and successfully stabilizing them on insulin will require several structured contacts with the nurse and also a 24 h emergency contact number for any urgent problems that may arise (Table 31.1).

For those presenting acutely ill with nausea and vomiting with or without ketosis, admission to hospital for insulin initiation and, where needed, intravenous fluids is a necessity.

Future perspectives: route, hepatoselectivity, glucose-dependent action

From the early days of insulin, alternatives to the classical parenteral route of insulin administration have been explored. Although inhaled insulin is available, the quest for oral insulin has never stopped. Structural modification and the use of innovative pharmaceutical formulations such as nanoparticles encapsulating the insulin to engender resistance to degradation have been investigated [85]. In 2019, a long-acting, basal insulin analogue formulated in a tablet with the absorption-enhancer sodium caprate, called oral insulin 338, was found to improve glycaemic levels in insulin-naïve individuals similar to subcutaneously administered insulin glargine [86]. Further development of this particular oral insulin project was discontinued because the doses were high, and therefore production for wide public use was deemed not commercially viable. Recent encouraging developments in oral peptide hormone administration in the GLP-1 RA arena (oral semaglutide using salcaprozate sodium [SNAC] technology) have boosted the research efforts towards

Table 31.1 An example of an outpatient/community pathway for people starting insulin for the first time.

Session 1

The need for insulin has already been discussed with the person with diabetes by a doctor or diabetes nurse specialist and the person with diabetes has been seen by a dietitian

A regimen has been agreed and the first prescription has been obtained by the person with diabetes

A review usually takes place of what diabetes is, including what insulin does and the need for insulin injections

A nurse demonstrates the basics and use of an insulin injection device and the person with diabetes gives the first injection

Further discussions including:

- sites for injection/site rotation
- timing of injections
- where and how to obtain equipment (insulin, pens, needles, self-monitoring equipment, sharps disposal equipment)
- recognition and management of hypoglycaemia and hyperglycaemia (in type 1 diabetes importance of ketones)
- self-blood glucose monitoring
- driving and legal issues surrounding insulin
- 24 h contact details provided

Session 2 (around 2 wk after insulin initiation)

Prior to session 2, the person with diabetes and the nurse will usually have had telephone contact over insulin injections and blood glucose readings

Review of information provided in session 1

Review of insulin injection technique

Session 3 (around 4 wk after insulin initiation)

Review of sessions 1 and 2

Further information provided about:

- insulin on holiday and when travelling
- insulin injections when travelling through time zones (e.g. transatlantic travel)
- insulin management during periods of acute sickness
- foot care, other diabetes-related complications, and, in women of child-bearing potential, pregnancy

Session 4 (around 10 wk after insulin initiation)

Review of previous sessions

Assessment of glycaemic control and need for further doctor/nurse follow-up

Book follow-up clinic/surgery appointment

the development of oral insulin preparations [87]. However, the hurdles remain numerous, such as low bioavailability, interference with food intake, and in particular the narrow dosing range of insulin.

Another unmet need in insulin therapy is the hepatoselectivity of the preparations. It is important to appreciate that in health, pancreatic-derived insulin acts directly on the liver via the portal circulation. In the fasting state, a major function of insulin is to suppress hepatic glucose production. Between 50% and 80% of the insulin is metabolized by the liver [88], such that much lower and tightly regulated insulin levels enter the systemic circulation. Peripheral tissues such as muscle also take up glucose at higher insulin concentrations, which tend to occur predominantly postprandially. The administration of insulin by subcutaneous injection delivers it to the systemic circulation, with relatively lower levels reaching the liver. Therefore, glucose uptake by muscle and adipose tissue is preferential to liver. The lower exposure of the liver to insulin also results in greater hepatic glucose production, making the management of blood glucose and body weight even more challenging.

An initial approach to targeting insulin action to the liver was through the development of hepatoselective insulins [89], including the technique of making the insulin molecule larger through PEGylation to favour its leaving the circulation at the hepatic sinusoids. The first trials with insulin peglispro resulted in a reduction of HbA_{1c} and body weight [90]. However, insulin peglispro also caused elevated transaminase and triglyceride levels, resulting in the early termination of its development [91]. Currently, other approaches such as an insulin analogue with a C20 fatty diacid attached at position A22K (NNC0123-0327) is under investigation; this insulin has a high affinity for serum albumin and reduced trans-endothelial transport from plasma to periphery, which could result in high clearance via the hepatic insulin receptors [92]. Safety will have to be proven, particularly regarding steatohepatitis and hypoglycaemia, before these products could gain market access.

Finally, the ultimate dream of insulin development is the realization of a glucose-dependent insulin action. Several paths are explored, ranging from glucose-responsive polymer encapsulation of insulin to molecule modifications [93].

Diabetes Center, Children's Hospital AUF DER BULT, Hannover Medical School, Hannover, Germany

Key points

- Continuous glucose monitoring (CGM) is becoming the gold standard for metabolic monitoring and is increasingly replacing blood glucose monitoring for everyday treatment decisions.
- Time in range and time below range complement glycated haemoglobin (HbA_{1c}) as measures of glycaemic regulation in type 1 diabetes.
- Standardized analysis of CGM values includes visualization of data with software solutions like the ambulatory glucose profile (AGP).
- Algorithms for automated insulin delivery combining glucose sensors and insulin pumps (hybrid closed loop) or smart pens, as well as artificial intelligence based on analysis of CGM values, are becoming commercially available.

Until recently, regular self-measurement of capillary blood glucose was an indispensable part of good metabolic management. Following the early days of urinary glucose determination for metabolic monitoring, the introduction of capillary blood glucose monitoring in the 1960s was instrumental in improving glycaemic management in people with diabetes (Figure 32.1). Blood glucose monitoring technology has improved considerably in recent years. Innovation in blood glucose monitoring devices and strip technology has brought significant advances in the reliability of measurement and operation of these systems. Comparable to the introduction of capillary blood glucose monitoring more than 50 years ago, continuous glucose monitoring (CGM) systems have significantly and positively influenced the glucose monitoring of people with diabetes in a short time and can contribute to a further improvement of metabolic management [1]. Modern programs and interfaces to computers and smartphone apps offer a wide range of display and analysis functions, including insulin dose calculation. Glucose monitoring is an essential part of the therapy of insulin-treated diabetes.

Glycated haemoglobin (HbA_{1c}) has become established as a target measurement for long-term glucose management [2] and is considered a surrogate for optimal glycaemic levels and treatment success in international diabetes guidelines [3]. However, because HbA_{1c} represents the average blood glucose concentration over the past 8–12 weeks [2], it does not capture *short-term* blood glucose fluctuations such as hypoglycaemia and post-prandial hyperglycaemia [4]. A primary goal of insulin therapy in diabetes has been to optimize glycaemic levels by reproducing the physiological insulin release that is seen in response to glucose and other stimuli when the pancreatic islets are functioning normally [5]. Recent developments in glucose measurement, insulin delivery, algorithms that relate these two processes, and data management software to demonstrate glycaemic patterns have shown the potential to improve the lives of people with diabetes. This chapter reviews the current status of these developments, and their use in the management of insulin-treated diabetes.

Self-monitoring of capillary blood glucose

Self-monitoring of capillary blood glucose has been considered an essential component in the treatment of type 1 diabetes since the Diabetes Control and Complications Trial (DCCT) [6]. Capillary blood glucose monitoring is also indicated for people with insulin-treated type 2 diabetes and may, when prescribed as part of a broader educational context, be helpful for other people with type 2 diabetes when used to guide treatment decisions or self-management [3]. The further development of the lancing devices and lancets on the market today has also made multiple daily blood glucose self-measurements tolerable and feasible. All lancing devices are based on the principle that the penetration depth of the respective lancets into the skin can be controlled. In addition, pain can be further reduced by choosing particularly thin lancets. Technical improvements in blood glucose meters in recent years include lower blood volume, higher measurement accuracy, lower susceptibility to interference, and better data display.

The preparatory steps for blood glucose monitoring, in particular obtaining a capillary blood drop, as well as correctly performing the actual measurement require theoretical and practical training. Ideally, this should be done using the system that the person with diabetes will later use. A one-off introduction is often not enough: the various steps should be repeatedly trained, discussed, and closely supervised. Since performing capillary blood glucose monitoring in public (school, workplace, restaurant, etc.) makes it visible that the person has diabetes, people often do not perform measurements in such situations. This can entail significant risks, as acute glucose derailments remain undetected. The understandable desire of the person with diabetes for discretion makes other glucose monitoring options attractive. However, not all people with diabetes want to wear a technical device permanently on their body or be disturbed by alarms.

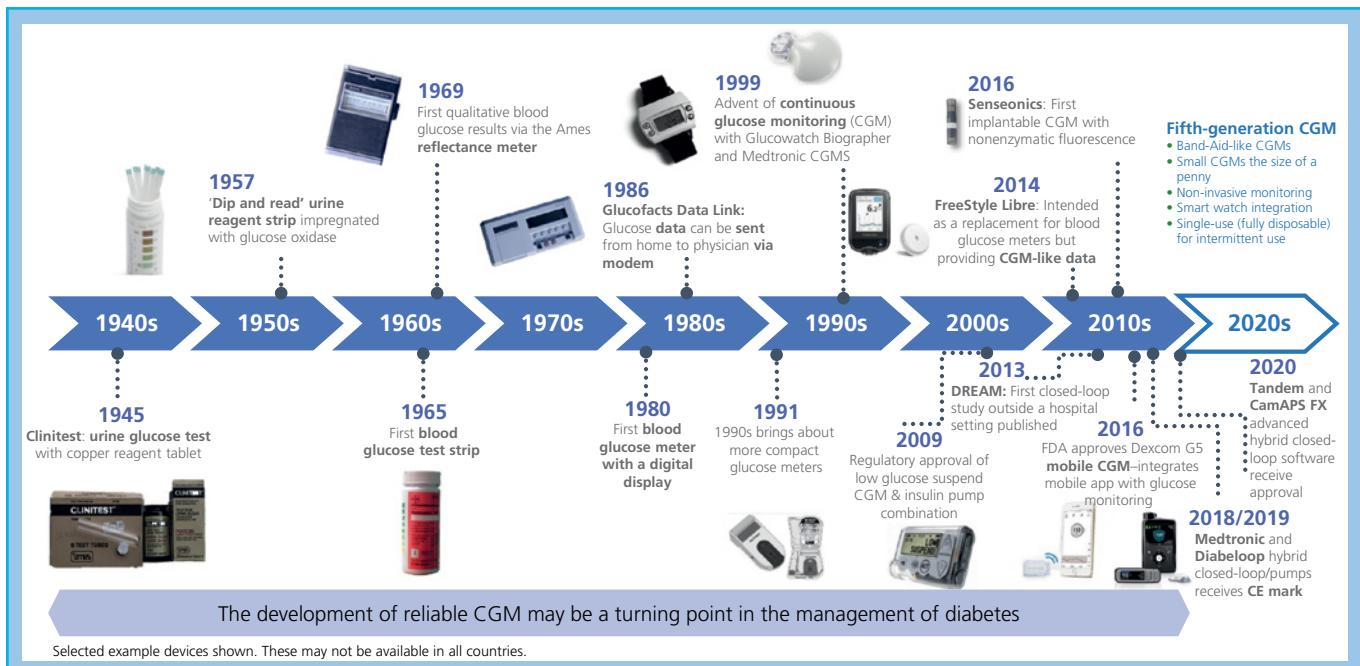

Figure 32.1 History and immediate future of glucose monitoring.

Measurement method and frequency

The enzyme used in capillary blood glucose monitoring systems is usually either glucose oxidase (GOD) or glucose hydrogenase (GDH). The glucose oxidase method is susceptible to substance and drug interferences (e.g. ascorbic acid, paracetamol, blood oxygen content) and these should be considered, especially in people with multimorbidities. For those with high or low haematocrit values, the manual or test strip package insert of the monitoring systems should be checked for compatibility.

People with type 1 diabetes using multiple daily injections or an insulin pump should measure the blood glucose concentration at least four times daily (before meals and at bedtime) and every 2–3 weeks during the night. In addition, measurements may be taken in special situations, for example to check the effects of meals, in suspected hypoglycaemia, during sport, illness, holidays, or when driving a car. People with type 2 diabetes using multiple daily injections should also determine pre-prandial and occasionally post-prandial glucose levels and measure before bedtime. People with type 2 diabetes treated with sulphonylurea require test strips to detect hypoglycaemia. There is a rationale to provide all people with type 2 diabetes and oral anti-diabetes therapy with at least 50 test strips per quarter in case of intercurrent illnesses, for training purposes, or if the treatment goals are not met. Women with gestational diabetes should always measure fasting blood glucose and post-prandial glucose 2–3 times per day.

Systems and measurement quality

There are many different capillary blood glucose monitoring systems currently available from various suppliers. Overviews of the properties of these systems are primarily based on the information provided by the manufacturers. Many modern capillary blood glucose monitoring systems have additional functions, such as data storage and read-out, marking of values as pre-prandial or post-prandial, colour coding of displayed values for immediate assessment, a light at the test strip slot, bolus calculators, calculation of an

Table 32.1 Comparison of ISO 15197:2013 and US Food and Drug Administration (FDA) blood glucose (BG) meter accuracy standards.

Setting	FDA	ISO 15197:2013
Home use	95% within 15% for all BG in the usable BG range ^a	95% within 15% for BG $\geq 100 \text{ mg/dl}$
	99% within 20% for all BG in the usable BG range ^a	95% within 15 mg/dl for BG $< 100 \text{ mg/dl}$
Hospital use	95% within 12% for BG $\geq 75 \text{ mg/dl}$	99% in A or B region of consensus error grid ^b
	95% within 12 mg/dl for BG $< 75 \text{ mg/dl}$	
	98% within 15% for BG $\geq 75 \text{ mg/dl}$	
	98% within 15 mg/dl for BG $< 75 \text{ mg/dl}$	

To convert mg/dl to mmol/l, divide by 18.018. BG, blood glucose.

^a The range of blood glucose values for which the meter has been proven accurate and will provide readings (other than low, high, or error).

^b Values outside of the 'clinically acceptable' A and B regions are considered 'outlier' readings and may be dangerous to use for therapeutic decisions.

estimated HbA_{1c} value, or the possibility of transmitting data to an app or internet cloud (connectivity).

Currently, all capillary blood glucose monitoring systems approved for commercial use in Europe must comply with ISO 15197:2013 in terms of measurement accuracy (Table 32.1) [7]. The new ISO 15197:2013 defines stricter quality standards for blood glucose measurement: for example, readings above 100 mg/dl (5.6 mmol/l) may only deviate by 15% compared to a laboratory reference method. For blood glucose values below 100 mg/dl (5.6 mmol/l), 95% of the measured values must lie within a range of $\pm 15 \text{ mg/dl}$ (0.83 mmol/l). The preface and annex of the DIN

standard have been revised and are now called DIN EN ISO 15197: 2015-12. For glucose meters used at home, the US Food and Drug Administration (FDA) guidance specifies the following accuracy standards [8]: 95% of all measured blood glucose meter values must be within 15% of the true value from a laboratory measurement; and 99% of meter values must be within 20% of the true value. Notably, these new FDA standards require greater hypoglycaemia accuracy than the 2013 ISO standard, which is used outside the USA.

Quality control for personal glucose measurement systems can be performed with a system-specific control solution. More than 90% of incorrect measurement results are due to operating errors: unclean hands, incorrectly stored or damaged test strips, and insufficient blood volumes. Therefore, careful training of people with diabetes and all other caregivers in the use of capillary blood glucose monitors is essential.

Continuous glucose monitoring

Systems for continuous measurement of interstitial glucose are offered in various technical designs (Tables 32.2 and 32.3). Continuous glucose monitoring in *real time* (rtCGM) provides contemporaneous subcutaneous glucose data [9, 10]; intermittently scanned CGM (*isCGM, flash glucose monitoring*) [11, 12] uses a comparable methodology to show continuous glucose measurements currently and retrospectively at the time of review (Figure 32.2). With isCGM, the current glucose level is displayed only with an active scan of the reader over the sensor, along with a trend arrow and an eight-hour history graph. It is difficult for people working outside the field of diabetes to differentiate between technologies, such as calibrations, alarms, practicalities of attaching and wearing sensors, or costs, which are device specific. Because these technological details are subject to constant change, the term CGM is used to refer to all aspects related to the device class unless otherwise noted [13].

rtCGM systems can be used either as stand-alone devices, for instance for people with diabetes with multiple daily injections, or in combination with an insulin pump. In sensor-augmented pump therapy, the rtCGM system can be programmed to communicate with the pump for automated insulin dosing (AID) to suspend

insulin at a certain glucose threshold or predictive low glucose suspension. The system can be used to prevent hyperglycaemia, by automated adaptation of the basal rate or automated correction boluses. Almost all rtCGM systems allow the measured values to be transferred to a cloud. From there, the data can be forwarded to family members or the diabetes team if so desired.

Continuous glucose monitoring measurement method

In most of the currently available transcutaneous needle sensors, glucose is measured using an enzymatic method, such as glucose oxidase, in the interstitial fluid of subcutaneous fatty tissue (Figure 32.3b). The measurement signal is an electrical current. That current is proportional to the glucose concentration at the measurement site, with a small background current, which can be accounted for as a signal offset if necessary. The transcutaneous rtCGM systems have a lifecycle of up to 10 days, after which the glucose sensor should be replaced according to the manufacturer's instructions. The sensors normally transmit an average value obtained every five minutes to the corresponding receiving device. As with blood glucose measuring systems, medication can result in interferences (e.g. paracetamol; see device operating instructions). Some systems are factory calibrated [14], while others need daily calibrations with capillary blood glucose measurement to account for sensor drift.

In addition, a long-term rtCGM system is available in which the sensor is inserted under the skin with minimal surgical intervention (Figure 32.3a). This implantable long-term CGM system comprises a wireless, subcutaneously implantable glucose sensor and a body-worn transmitter with on-body vibration alarm capability. The sensor is constructed of a fluorescent, boronic acid-based glucose-indicating polymer coated onto a miniaturized, polymer-encased optical detection system [15]. The external transmitter wirelessly communicates with and powers the sensor and contains Bluetooth capability for interfacing with a smartphone application. The sensor needs daily calibrations and is removed by a certified physician after its functional period of up to 180 days. The insertion and removal procedure from the subcutaneous location (upper arm) can be done in a brief outpatient procedure. As the glucose measurement is fluorescence based, it can lead to short-term measurement interruptions, especially at the beginning during bright sunlight.

Intermittently scanned continuous glucose monitoring

The use of isCGM incorporates trend displays of the currently scanned glucose value and the presentation of retrospective CGM data to help achieve therapy goals. Similar to capillary blood glucose monitoring, the success of isCGM depends on the user being active. With the second generation of devices, it has become possible to turn on threshold limit alarms (hypo- and hyperglycaemia alarms). The high and low alarms are distinguished by acoustically different alarm tones and scanning displays the current measured value. The third generation offers continuous Bluetooth connectivity to a smartphone app.

Like with all factory-calibrated devices, people with diabetes can largely do without capillary blood glucose monitoring. Blood monitoring is advised, however, if hypoglycaemia symptoms do not match the isCGM values and the glucose trend displayed, or very high glucose values or strong glucose fluctuations are present. Sensor artefacts can occur as a result of lying on the sensor while

Table 32.2 Types of continuous glucose monitoring (CGM) systems.

Type of CGM	Description
Real-time CGM (rtCGM)	CGM systems that measure and display glucose levels continuously
Intermittently scanned CGM (isCGM)	CGM systems that measure glucose levels continuously, but only display glucose values when swiped by a reader or a smartphone
Professional CGM	CGM devices that are placed on the person with diabetes in the healthcare professional's office (or with remote instruction) and worn for a discrete period of time (generally 7–14 d). Data may be blinded or visible to the person wearing the device. The data are used to assess glycaemic patterns and trends. These devices are a clinic-based device, as opposed to the patient-owned rtCGM/isCGM devices.

Table 32.3 Overview of commercially available continuous glucose monitoring (CGM) devices (available in Germany as of January 2023).

CGM model	Approved age group	Lifecycle per sensor	Connectivity, smartphone/wearable	Connectivity to automated insulin delivery	Calibration with blood glucose	Initialization phase	Recommended place of insertion	Glucose display	Glucose range	Low alarm	Replacement claim for blood glucose measurements
Abbott FreeStyle Libre	From 4 yr	Up to 14 d	Android and iOS app, Follower app	No	Factory calibrated	1 h	Upper arm	After scan, every min	40–500 mg/dl 2.2–27.7 mmol/l	No	Yes
Abbott FreeStyle Libre 2	From 4 yr	Up to 14 d	Android and iOS app, Follower app	No	Factory calibrated	1 h	Upper arm	After scan, every min	40–500 mg/dl 2.2–27.7 mmol/l	Yes	Yes
Abbott FreeStyle Libre 3	From 4 yr	Up to 14 d	Android and iOS app, Follower app	Yes (Ypsopump with CamAPS FX app)	Factory calibrated	1 h	Upper arm	No scanning, every min to smartphone app	40–500 mg/dl 2.2–27.7 mmol/l	Yes	Yes
DexCom G6	From 2 yr	Up to 10 d	Android and iOS app, Follower app, smartwatch app	Yes (Tandem T-slim with control IQ; Ypsopump with CamAPS FX app)	Factory calibrated, optional	2 h	Abdomen, (children, adolescents 2–17 yr: upper buttocks)	Every 5 min	40–400 mg/dl 2.2–22.2 mmol/l	Yes	Yes
DexCom G7	From 2 yr	Up to 10 d	Android and iOS app, Follower app, smartwatch app	Not yet	Factory calibrated, optional	30 min	Abdomen (children, adolescents 2–17 yr: upper buttocks)	Every 5 min	40–400 mg/dl 2.2–22.2 mmol/l	Yes	Yes
Medtronic Guardian 3	Without age limit	Up to 7 d	iOS app, Follower app	Yes (Medtronic 640G, 670G, 770G, 780G)	2 h, 8 h after insertion, then every 12 h	2 h	Abdomen, buttocks (upper arm)	Every 5 min	40–400 mg/dl 2.2–22.2 mmol	Yes	No
Medtronic G4	Age 7 (with 780G)	Up to 7 d	iOS app, Follower app	Yes (Medtronic 780G)	Factory calibrated, optional	2 h	Abdomen, buttocks (upper arm)	Every 5 min	40–400 mg/dl 2.2–22.2 mmol	Yes	Yes
Medtrum A6 touch Care	From 2 yr	Up to 7 d	Android and iOS app, smartwatch app	Yes, patch pump with low glucose suspend	Every 12 h	2 h	Upper arm, abdomen, buttocks, abdomen	Every 2 min	40–450 mg/dl 2.2–25 mmol/l	Yes	No
Menarini GlucoMen Day CGM	From 6 yr	Up to 14 d	Android and iOS app	No	Every 24 h	45 min	Abdomen	Every min	40–400 mg/dl 2.2–22.2 mmol/l	Yes	Yes
Senseonics Eversense	From 18 yr	Up to 180 d	Android and iOS app, Follower app, smartwatch app	No	4× every 2 h after insertion, then every 12 h	24 h	Implanted (upper arm)	Every 5 min	40–400 mg/dl 2.2–22.2 mmol/l	Yes	No

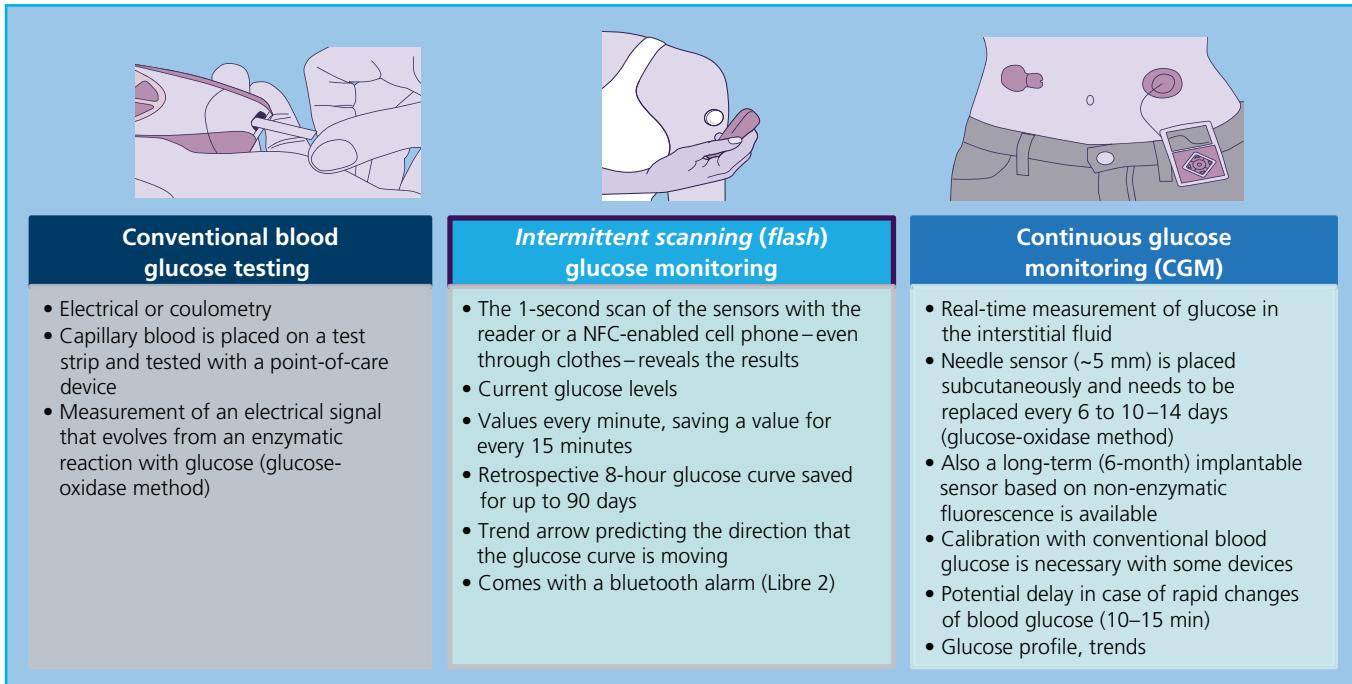

Figure 32.2 Overview of current technologies for measuring glucose in blood or the interstitial fluid. NFC, near-field communication.

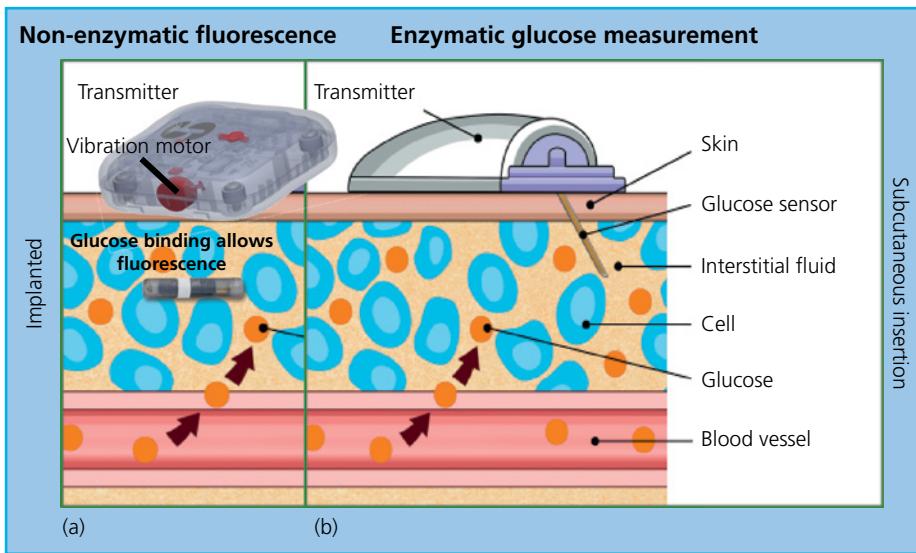

Figure 32.3 Principles of interstitial glucose monitoring. (a) Implantable long-term sensor (modelled from the Senseonics device) where glucose is measured with non-enzymatic fluorescence and an on-body transmitter that vibrates at threshold glucose levels. (b) Model of a subcutaneous electrochemical needle sensor that needs to be changed every 1–2 weeks with a transmitter corresponding to a dedicated scanning device (intermittently scanned continuous glucose monitoring, isCGM) or continuously to a receiver that could be a smartphone app, handheld, or pump (real-time continuous glucose monitoring, rtCGM).

sleeping; this also applies to rtCGM systems with needle sensors. This leads to apparent long hypoglycaemic episodes that have not actually occurred. isCGM systems require additional training similar to rtCGM systems.

Minimal requirements for continuous glucose monitoring performance

In contrast to factory-calibrated systems, the accuracy of systems that require user calibration is dependent on capillary blood glucose testing. Therefore, for these it is important to have an accurate glucose meter. Successful calibration also requires several conditions (Box 32.1).

The *mean absolute relative difference* (MARD) is currently the most common metric used to assess the performance of CGM [16]. MARD is the average of the absolute error between all CGM values and matched reference values. A small percentage indicates that the CGM readings are close to the reference glucose value, whereas a larger MARD percentage indicates greater discrepancies between the CGM and reference glucose values. This value determined in clinical studies is significantly influenced by the study protocol and the selection of the people with diabetes examined. The MARD value should therefore only be used as a guide [16]. Another parameter that deals with the measurement quality of a CGM system is the *precision absolute relative deviation* (PARD), calculated

Box 32.1 Teaching points for individuals with diabetes: calibration dos and don'ts.

- *Do* follow the manufacturer's instructions regarding the time and frequency of calibration to achieve the greatest possible accuracy.
- *Do* use only very recent blood glucose measurements for calibration.
- *Don't* calibrate when the blood glucose is changing at a significant rate, as indicated by trend arrows on the display. Times when rapid blood glucose change may occur include:
 - Within 3–4 hours of a meal or an insulin bolus.
 - During exercise.
 - When recovering from hypoglycaemia.

simultaneously for the same person from the direct comparison of an rtCGM system with a second sensor from the same system [16].

Although controversy exists regarding the exact cut point for accuracy, *in silico* testing has shown that a further lowering of MARD below 10% from reference values has little additional benefit for insulin dosing [17].

Clinical efficiency of continuous glucose monitoring

Numerous studies have shown that use of CGM improves glycaemic levels and quality of life in both children and adults with type 1 diabetes treated with pumps or multiple daily insulin injection therapy, improving HbA_{1c}, shortening the time spent in hypoglycaemia and hyperglycaemia, and reducing moderate to severe hypoglycaemia [9, 13, 18]. CGM use also benefits individuals with type 2 diabetes who are managed with or without intensive insulin treatment [4]. There are limited data regarding the benefit of rtCGM as an outcome measure for individuals with gestational diabetes (GDM) and type 2 diabetes, especially in those who do not use insulin [4]. The benefit of rtCGM is directly correlated to persistence and frequency of use. A meta-analysis by Pickup et al. found that every one day increase of sensor usage per week increased the effect of CGM; the effect on HbA_{1c} is more pronounced with higher initial HbA_{1c} (Figure 32.4). For retrospective analysis and counselling, a minimum of 14 consecutive days of data with approximately 70% of possible CGM readings appears to generate a report that enables optimal analysis and decision making. Standard reporting and visualization of CGM data are important [13, 19].

As the consequences of increased glycaemic variability adversely affect people with type 1 diabetes both physically and mentally [13, 20–23], people with diabetes report that the use of CGM leads to improved diabetes-specific quality of life through reduced variability of glucose values and additional subjective safety with regard to hypoglycaemia. Many individuals also experience improved general well-being and performance in many areas of life [24, 25] (Figure 32.5).

Practical issues with the use of continuous glucose monitoring

Calibrating the sensor

Some of the currently available CGM devices are calibrated using finger-stick capillary blood glucose measurements, while others are factory calibrated and no longer need calibration [14]. To optimize

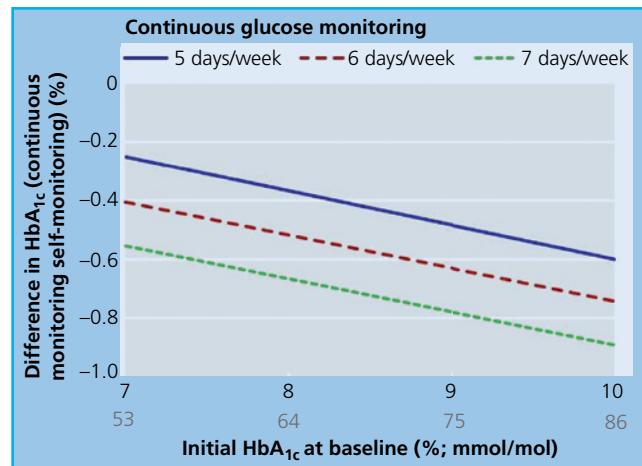

Figure 32.4 Device use is important for the success of continuous glucose monitoring (CGM). A model of the estimated relation between the difference in effect of CGM compared with capillary blood glucose monitoring and baseline glycated haemoglobin (HbA_{1c}) values for different sensor usages for an example 40-year-old with type 1 diabetes. Source: Modified from Pickup et al. 2011 [18].

sensor accuracy, it is important that the device is calibrated only when the glucose level is relatively stable, and there is steady-state equilibration between glucose concentrations in the blood and interstitial fluid. In practice, calibrations should be performed pre-prandially or at least three hours after a bolus (Box 32.1). Each manufacturer's instructions should be consulted to determine the timing and frequency of calibration for a specific CGM device.

Physiological lag between blood and interstitial glucose

The lag in the equilibration of glucose levels between the capillary blood and the interstitial fluid in the subcutaneous tissue (measured by the CGM device) has important practical implications. In general, increases or decreases in the glucose concentration will first be apparent in the blood followed by the interstitial fluid. This physiological lag has implications with regard to the detection and treatment of hypoglycaemia. Because of the lag of interstitial glucose behind blood glucose, when the glucose level is declining the interstitial (sensor) glucose can be in the normal range even though the actual blood glucose is low. This can occur with the newer generation of devices and is particularly pertinent during exercise [26]. Users should be instructed to perform a capillary blood glucose measurement before driving if the sensor glucose reading is normal and the trend graph or rate-of-change arrows on the sensor display indicate that the glucose level is declining (Box 32.2). The practical implication is that if the person feels hypoglycaemic or has reason to suspect that the glucose is declining, but this is not corroborated by the sensor, they should disregard the sensor data and carry out a capillary blood glucose measurement.

This lag phenomenon also has practical implications for the treatment of hypoglycaemia. During recovery from hypoglycaemia, the increase in the interstitial glucose will often lag behind the blood glucose [27], and when blood glucose has already normalized the sensor (interstitial) glucose may still be low. Individuals should be informed of the need to perform capillary blood glucose measurements to assess the response to treatment of hypoglycaemia accurately. Those who rely on the rtCGM to judge whether the glucose level is improving following ingestion

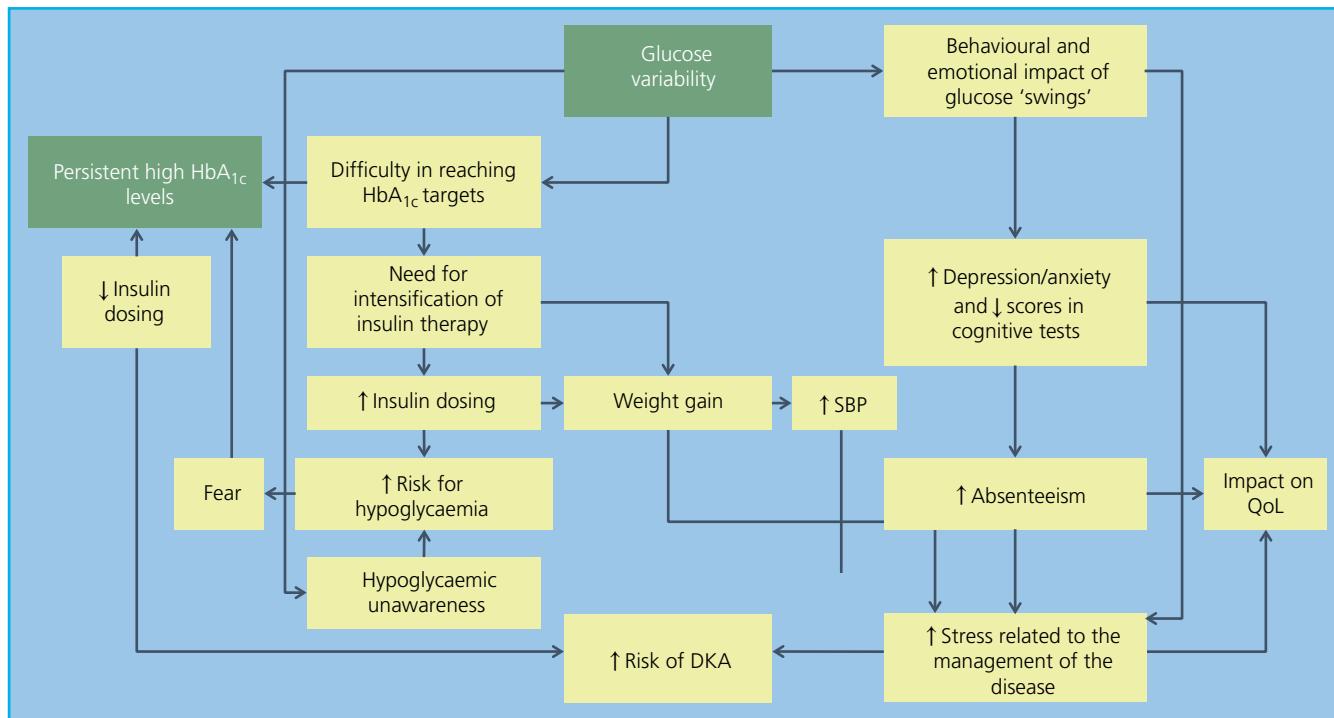

Figure 32.5 Consequences of increased glycaemic variability for people with diabetes. DKA, diabetic ketoacidosis; HbA_{1c}, glycated haemoglobin; QoL, quality of life; SBP, systolic blood pressure.

Box 32.2 Teaching points for individuals with diabetes: circumstances where capillary blood glucose must be checked

- If the sensor indicates that the glucose is elevated, the reading should be confirmed with a capillary blood glucose measurement before the person takes a corrective bolus.
- When subjective symptoms are not in keeping with the sensor reading, such as a low continuous glucose monitoring (CGM) reading in the absence of hypoglycaemic symptoms, a capillary blood glucose reading should be taken to confirm the glucose level.
- Before or during driving, if the sensor reading is normal but the CGM rate of change indicator or tracing indicates that the glucose level is falling, the person should measure capillary blood glucose.
- Following treatment of a low glucose level, if the sensor still shows a low reading, the person should check capillary blood glucose and use this measurement to decide whether to take in more carbohydrate. Reliance on the sensor reading to assess response can lead to overtreatment.

of carbohydrates may mistakenly assume that they need to consume more glucose than necessary.

Trend arrows

Trend arrows allow an estimation of the rate of change of glucose. With this information, a single glucose value can be correctly classified for the first time and a sensible therapy adjustment can be made, for instance percentage lowering or increasing of a basal rate, or eating carbohydrates, or insulin correction. The classifications of

the trend arrows vary according to the manufacturer. Although CGM measuring devices have a comparable graphical representation to inform the user about changes in glucose values, there is no uniform basic grid regarding the relationship between the rate of change and the positioning of the arrows [28]. General recommendations for therapy decisions need to consider both the trend arrows and the current prevailing glucose levels.

Ultimately the use of trend arrows for treatment decisions has to be adapted individually and various approaches have been suggested. The recommendation of the Juvenile Diabetes Research Foundation (JDRF) and the Diabetes Research in Children Network Study Group (DirecNet) suggest a percentage adjustment of the insulin dose according to the trend arrows to a maximum of 20%. According to their studies with different patient groups and therapeutic regimens, people with diabetes often make significantly higher insulin dose adjustments, well beyond these recommendations, based on the trend arrows. In these studies, which are based on self-completed questionnaires, people with diabetes reported that the insulin dose may be increased by more than 100% when the trend is rising, but the insulin dose is only reduced by a maximum of 50% when the trend is falling [29]. As a result, another approach recommends that a certain, absolute amount of glucose is added or subtracted from the current glucose value in accordance with the trend arrows for calculating the correction bolus. However, this approach requires a high degree of numeracy on the part of the person with diabetes and may lead to an additional burden [30].

A simpler model for using the rate-of-change information with trend arrows assumes that the glucose value, depending on the trend information, changes by 67 mg/dl (3.7 mmol/l), 112 mg/dl (6.2 mmol/l), or at least 135 mg/dl (7.5 mmol/l), rising or falling respectively within the next 45 minutes. An easily applicable addition or subtraction template for correcting the insulin bolus is suggested: 1, 1.5, or 2 insulin units depending on the trend arrow

information [31]. This simplifies the calculation of the insulin dose, but can only be used for a small group of people with diabetes, since it does not take into account individual insulin therapy, insulin sensitivity, or other clinical characteristics of the person with diabetes. Thus, other proposals recommend an adjustment based on insulin units depending on different levels of insulin sensitivity, and differentiates between children and adults [32, 33]. Ziegler et al. synthesized these recommendations in a clear, colour-coded, tabular format, aiming to provide CGM users with a personalized and simplified system of scorecards for daily use [28].

Setting of glucose alarms

The alarms for hypoglycaemia and hyperglycaemia are an important feature of CGM devices. There are trade-offs in the adjustment of alarm thresholds, and settings need to be individualized based on specific clinical considerations [34]. If the alarm thresholds are set at target or ideal glucose levels (e.g. low = 5 mmol/l [90 mg/dl]; high = 10 mmol/l [180 mg/dl]), there will be increased sensitivity for the detection of high and low glucose; however, the frequent false alarms can be a source of irritation and disrupt sleep, leading to *alarm fatigue* in some individuals, with a related tendency to ignore the alarms. There is also a risk of people sleeping through alarms. Buckingham et al. [35] found that people who were videotaped while sleeping awoke to only 29% of individual alarms and 66% of repeated alarms.

The adjustment of alarm thresholds is a stepwise process by first deciding on initial thresholds when initiating use of the sensor, and then optimizing alarm thresholds over time based on retrospective review of continuous glucose tracings. For those with hypoglycaemia unawareness or a history of severe hypoglycaemic reactions, where the overriding imperative is on reducing hypoglycaemia, the low glucose alarm threshold should be set at 4.5 mmol/l (80 mg/dl) or higher. However, the physiological lag between blood and interstitial glucose when the sensor alarm is triggered also depends on the device.

For individuals without a history of problematic hypoglycaemia, it is common practice to set the initial glucose thresholds at 3.0–3.5 mmol/l (55–60 mg/dl) and ≥ 14 mmol/l (250 mg/dl). This ensures that during the initial period after starting the use of CGM, while the individual is mastering the use of the technology, there will be fewer intrusive and irritating alarms, and less risk of alarm burnout. Over time, as the individual uses the information from the sensor to reduce glucose excursions, the alarm settings can be brought closer to target glucose levels, and this can assist with further improvement of glycaemic levels. Alarm messages and trend arrows of the CGM devices allow a near-normal, *tighter*, and safer adjustment and, through the trend arrows, targeted, forward-looking therapy adjustments.

Skin issues with continuous glucose monitoring

Wearing glucose sensors on the skin for 14 days and repeated use of the same skin site can lead to skin reactions in these areas. The reactions range from mild skin irritations to the development of contact allergies in some people with diabetes. Eczematous reactions to pump and CGM devices represent the most common skin complications [36]. This underscores the need for regular skin examination as an integral part of the diabetes consultation and for interdisciplinary collaboration on classification and treatment options. Currently, many papers are published showing allergic contact dermatitis to device patches [37]. The allergic reaction not only leads to immediate symptoms, but can make the further use of

this CGM system impossible and can lead to accompanying reactions to the plasters when using other technical systems (e.g. an insulin pump). Manufacturers of future medical devices will need to pay attention to the tolerability as well as durability of the patches. The substance isobornyl acrylate (IBOA) [38] has now been identified as a cause of contact dermatitis and is currently the subject of further investigation [39, 40]. The work from our clinic could show that despite device-associated skin reactions, the quality of life of the users is mostly not limited [36].

Skin care is of particular importance. For the removal of sensor, catheter, and patch residues, products that work on the basis of saturated hydrocarbons, alcohol, silicone, or oil can be used exactly according to instructions. If irritation is visible, skin protection products that leave a protective film or barrier between the skin and the adhesive of the patch can be used. For example, hydrocolloid-based plasters, which actually serve a different purpose and are used in ostomy care, can be helpful here [41]. They have very good skin compatibility and often maintain the protective skin barrier for the entire time the sensor is worn. In order to improve the adhesion properties, a protective film can be used. Most sensors can be simply taped over without pressure. A small piece of swab or tissue will prevent the foil from sticking to the transmitter or sensor. In particular, when bathing or visiting the swimming pool, a waterproof cover should be applied. Removing the waterproof foil is not necessary, but the adhesive quite often causes skin redness. In severe cases, even this may no longer be sufficient. Alternatives that do not contain IBOA are recommended, like the implantable Eversense system [42].

Use of capillary blood glucose monitoring and continuous glucose monitoring to guide management and assess outcomes

There are various ways beyond HbA_{1c} in which glucose data can be used for daily diabetes management decision making and during clinical trials. Over time these are evolving from seven-point capillary blood glucose monitoring [43] and the display of a typical CGM profile [44] to the ambulatory glucose profile (AGP) with trends [45] and glycaemic patterns [46] (Figure 32.6).

Visualization, analysis, and documentation of key capillary blood glucose monitoring metrics

In order to achieve therapy goals (e.g. an HbA_{1c} value set with the diabetes team, reduction of hypoglycaemia, improvement of pre-prandial or post-prandial glucose values), people with diabetes regularly measure the glucose concentration in capillary blood samples to monitor the glucose trend. Blood glucose measurements are also used to detect acute metabolic disorders (hypoglycaemia or hyperglycaemia). Capillary blood glucose data may be used in various ways. With multiple daily insulin therapy, individual values are used to determine the next dose of insulin and to teach people with diabetes the effects of specific foods, exercise, and other activities on blood glucose levels. For people with diabetes on all types of therapy, capillary blood glucose data may be used by the physician to guide treatment decisions based on the overall pattern of results.

Because of the large volume of data that may be generated, and the often haphazard record keeping, recognizing glycaemic patterns may be difficult. For this reason, there has been a move to incorporate new technology to simplify this task and make it more accurate.

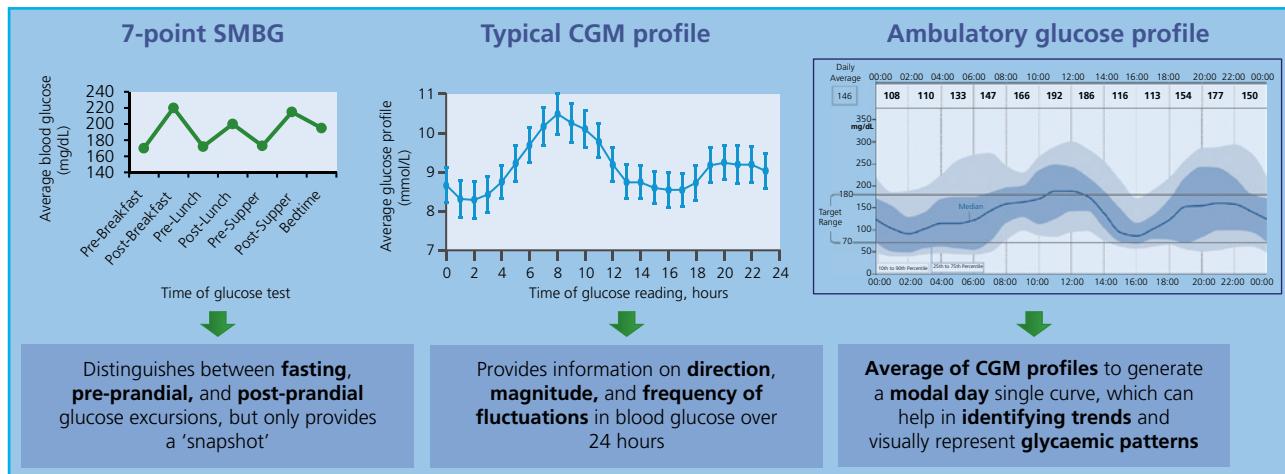

Figure 32.6 Comparison of data visualization with capillary blood glucose monitoring or continuous glucose monitoring (CGM) and the ambulatory glucose profile. SMBG, self-monitored blood glucose.

Such developments have come from manufacturers of glucose measuring systems, from suppliers of mobile phones and other telemedicine systems, and from various start-up companies. Systems have also been designed to produce graphical results of glucose patterns and have been shown to improve glycaemic management. The graphical output can be either on the meter itself [47] or using software that downloads capillary blood glucose data from the meter [48].

Assessment of glucose variability

A major limitation of HbA_{1c} is that it does not provide any information about the timing and magnitude of glucose variability, nor does it give data regarding the timing and frequency of hypoglycaemia [49]. However, from a clinical point of view, glycaemic variability is of relevance with respect to acute and long-term treatment of people with diabetes and is a consistent predictor of hypoglycaemia, both in prospective studies and within the setting of randomized clinical trials [50]. Relationships between increased glucose variability and many other outcomes, including microvascular and macrovascular outcomes, have been less consistent.

Standard deviation (SD) and coefficient of variation (CV) are widely used to quantify glucose variability [49]. The CV has the advantage of being a metric relative to the mean, which makes it more descriptive of hypoglycaemic excursions than the SD alone. In addition to these standard statistics, various diabetes-specific metrics of glucose variability have been introduced during the last half-century (reviewed in [49]), beginning with the M-value based on a logarithmic transformation of the glucose deviation from a pre-set value (e.g. 120 mg/dl [6.7 mmol/l]). Among these metrics, mean amplitude of glucose excursions (MAGE) has been one of the most widely used. The mean of daily differences (MODD) was introduced as a measure of inter-day variability, and the continuous overlapping net glycaemic action (CONGA) was presented as a composite index of the magnitude and the timing of glucose fluctuations captured over various time periods.

Several metrics based on this risk function of glucose variability have been introduced: the low glucose index (LGI) increases with the frequency and extent of hypoglycaemic excursions and, by design, ignores hyperglycaemia; the high glucose index (HGI) increases with the frequency and extent of hyperglycaemic excursions and ignores hypoglycaemia; and the average daily risk range

(ADRR) is equally sensitive to both low and high glucose excursions. The LGI is predictive of severe hypoglycaemia, the HGI is associated with HbA_{1c} and hyperglycaemic excursions, and the ADRR is a measure of overall glucose variability that captures the risk of both hypoglycaemia and hyperglycaemia. The lability index and the mean absolute glucose change (MAG) have been introduced and used in hospital settings to assess the effects of islet transplantation or increased risk for mortality in intensive care.

A more standard approach was used to define the threshold for excess glucose variability; here, the CV is preferred over the SD because it is independent of the mean glucose concentration. A % CV of 36% appears to be a suitable threshold [51] to distinguish between stable and unstable glycaemia in diabetes, because above this limit the frequency of hypoglycaemia is significantly increased, especially in people treated with insulin [51].

Statistical methods available for the analysis of CGM data include graphs, such as a Poincaré plot of system stability, and variability-grid analysis (VGA), used to visualize the glycaemic fluctuations captured by CGM. VGA was also used to depict the efficacy of closed-loop control algorithms [52]. Because the more comprehensive statistical assessments (e.g. Poincaré plot) would be reserved for in-depth scientific analysis of data, it is recommended that if the intent is to assess the effects independent of mean glucose, CV may be best and preferred over SD [13].

Time in range

Time in range (TIR), defined as the time during which glucose is within a predefined target corridor, was developed on the basis of data available from rtCGM or isCGM for both short- and longer-term glycaemic management. For the assessment of CGM results, the Advanced Technologies & Treatment for Diabetes (ATTD) Consensus defined a range of 70–180 mg/dl (3.9–10.0 mmol/l) as a target corridor [13], above which there is an increasing risk of hyperglycaemia and thus also of diabetic ketoacidosis, or below which there is an increased risk of hypoglycaemia [53]. The relative time within this target corridor (as a percentage or, alternatively, as hours per day) was defined in this context as TIR. As a general trend, the lower the TIR, the higher is the glucose variability and the higher the risk of hypo- and hyperglycaemic complications [54]. Furthermore, several studies show (not without exception [49]) an association between increased glucose variability (or low TIR) and

diabetes-associated complications such as retinopathy, microalbuminuria, and neuropathies [55–57]. TIR is now also used to evaluate new pharmacological diabetes therapies [58] and is considered by the FDA to be an appropriate endpoint to determine how successfully an artificial pancreas can maintain glucose within a predefined target range [58, 59]. In meta-analyses of different *closed-loop* approaches, TIR offers the possibility of comparison between individual studies and technical alternatives [56].

Practicalities for evaluating CGM data and targets for TIR have been agreed in three consensus meetings [4, 13, 58]. The *target range* for TIR is defined as 70–180 mg/dl (or 3.9–10.0 mmol/l) (Table 32.4). Hypoglycaemia values between 54 and 70 mg/dl (3.0–3.9 mmol/l) are classified as relevant hypoglycaemia (level 1) and those <54 mg/dl (<3.0 mmol/l) are classified as serious, clinically relevant hypoglycaemia (level 2). Respectively, for hyperglycaemia: values >250 mg/dl (>13.9 mmol/l) are defined as serious hyperglycaemia (level 2) and values between 181 and 250 mg/dl (10.1–13.9 mmol/l) as relevant hyperglycaemia (level 1). In the case of severe hyperglycaemia, additional ketone bodies should be

determined in the blood or urine under certain conditions to detect impending ketoacidosis in good time. Individual target values closer to the physiological normal range could be defined depending on the person's age, concomitant diseases, or engagement with self-management. Nocturnal glucose control is defined as the period between midnight and 6 a.m. For clinical trials, it is recommended that TIR and coefficients of variation be reported separately for night (midnight to 6 a.m.), day (6 a.m. to midnight), and 24-hour periods.

Establishing target *percentages* of time in the various glycaemic ranges with the ability to adjust the percentage cut points to address the specific needs of special diabetes populations (e.g. pregnancy, high risk) would facilitate safe and effective therapeutic decision making within the parameters of the established glycaemic goals (Table 32.4).

The composite metric includes three key CGM measurements: percentage of time per day within target glucose range (TIR), time below target glucose range (TBR), and time above target glucose range (TAR) (Figure 32.7). The primary goal for effective and safe

Table 32.4 Guidance on targets for assessment of glycaemic indices for those with type 1 diabetes or type 2 diabetes and older and high-risk individuals [5]

Diabetes group	Time in Range (TIR)		Time Below Range (TBR)		Time Above Range (TAR)	
	Target Range	% of readings time/day	Below Target Level	% of readings time/day	Above Target Level	% of readings time/day
Type 1 diabetes*/ type 2 diabetes	70–180 mg/dl 3.9–10.0 mmol/l	>70 % >16 h, 48 min	<70 mg/dl <3.9 mmol/l <54 mg/dl <3.0 mmol/l	<4 % <1 h <1 % <15 min	>180 mg/dl >10.0 mmol/l >250 mg/dl >13.9 mmol/l	<25 % <6 h <5 % <1 h, 12 min
Older/high-risk#						
Type 1 diabetes / type 2 diabetes	70–180 mg/dl 3.9–10 mmol/l	>50 % >12 h	<70 mg/dl <3.9 mmol/l	<1 % <15 min	>250 mg/dl >13.9 mmol/l	<10 % <2 h, 24 min

Each incremental 5 % increase in TIR is associated with clinically significant benefits

14 days with at least 70 % of data recommended for evaluation

* For age <25 years, if the HbA_{1c} goal is 7.5 % (58 mmol/mol) then set TIR target to approximately 60 %.

it is important to individualize and be conservative, with a strong focus on reducing the percentage of time spent <70 mg/dl (<3.9 mmol/l) and preventing excessive hyperglycaemia.

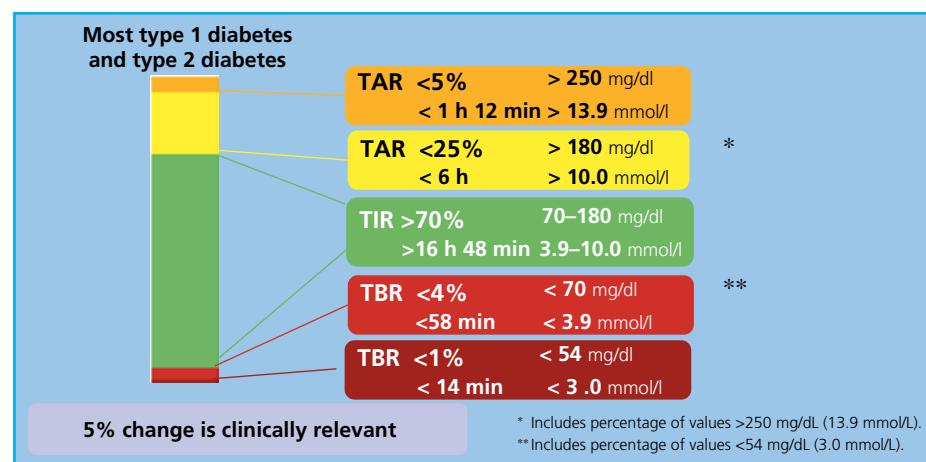

Figure 32.7 The 2019 Advanced Technologies & Treatment for Diabetes (ATTD) Consensus for continuous glucose monitoring time in range (TIR) targets for most individuals with type 1 diabetes and type 2 diabetes. TAR, time above target glucose range; TBR, time below target glucose range. Source: Modified from Battelino et al. 2019 [4].

glucose management is to increase the TIR while reducing the TBR. Expressing time in the various ranges can be done as the percentage (%) of CGM, average hours and minutes spent in each range, or both, depending on the circumstances (Table 32.4). Targets have been proposed for most individuals with type 1 diabetes and type 2 diabetes, including children and distinct targets for those at high risk (for example, hypoglycaemia unawareness) or frail and older people. Also, women with type 1 diabetes or type 2 diabetes during pregnancy and those with gestational diabetes should strive to achieve separate goals [4]. In any case, the first priority is to reduce TBR to target levels and then address TIR or TAR targets.

For people with type 1 diabetes, the targets are informed by the ability to reach the targets with hybrid closed-loop therapy [59–63]. Importantly, recent studies have shown the potential of reaching these targets with CGM in individuals using multiple daily injections [64]. In type 2 diabetes, there is generally less glycaemic variability and hypoglycaemia than in type 1 diabetes [65]. Thus, people with type 2 diabetes can often achieve more time in the target range while minimizing hypoglycaemia [66]. A novel single-number summary of the quality of glycaemia is the Glycemia Risk Index (GRI) [67].

Ambulatory glucose profile

To establish TIR as a clinical standard, Bergenstal et al. developed an ambulatory glucose profile (AGP) for interstitial glucose monitoring systems that indicates TIR itself, but also shows pattern recognition [68]. The more advanced rtCGM or isCGM devices have higher accuracy in glucose measurement and effective algorithms for converting the sensor measurement signal to the displayed glucose value compared with the past [69]. In addition, the values and the decision criteria relevant to the person with diabetes are now displayed in a more patient-friendly manner. An example of the practical implementation of this method is shown in Figure 32.8 and demonstrates clarity and good manageability in the daily routine of people with diabetes; it can also be used without extensive

laboratory diagnostics, in contrast to a measured HbA_{1c}. Visualization makes it easier for people with diabetes to use on a daily basis, and the effects of meals, exercise, medications, or changes in treatment regimen can be shown. This increases the understanding of phases of relative hypo- and hyperglycaemia and consequently these can be reduced.

Each manufacturer offers its own software for evaluating CGM data. The software programs can be complex and require an introduction. Current software usually offers a clear initial evaluation of CGM data using the AGP to calculate CGM-derived parameters such as mean glucose, glucose management indicator (GMI) [70], glycaemic variability, or time in, above, or below target range (TIR, TAR, TBR). The presentation as a clear graph also enables a quick overview. In the AGP, the median glucose progression is displayed from the measured values of several days. This shows the mean glucose curve at each point in time of the standard day. The graph identifies two other major glucose ranges. The blue area surrounding the median curve is the interquartile range (IQR), where 50% of all measured glucose values lie. The wider area is the interdecile range (IDR), which is bounded by the 10th and 90th percentiles. This is where 80% of the readings lie. The width of the IQR and IDR shows how much the measured values scatter; in other words, the glucose variability. The physician and diabetes team can therefore see at a glance the individual's median glucose over 24 hours and the glucose variability.

In addition, the AGP provides information on other important parameters, such as the median glucose value and areas of high and low glucose values. Hypoglycaemic events can be analysed accurately, as their number, duration, depth, and frequency in the selected period are determined with most of the current software solutions. It also provides the person with diabetes with an easy-to-understand picture of their glucose profile. Diabetes communities often discuss the AGP on social media to find therapeutic measures that help to achieve a flat, narrow, and in range (FNIR) day (Figure 32.9).

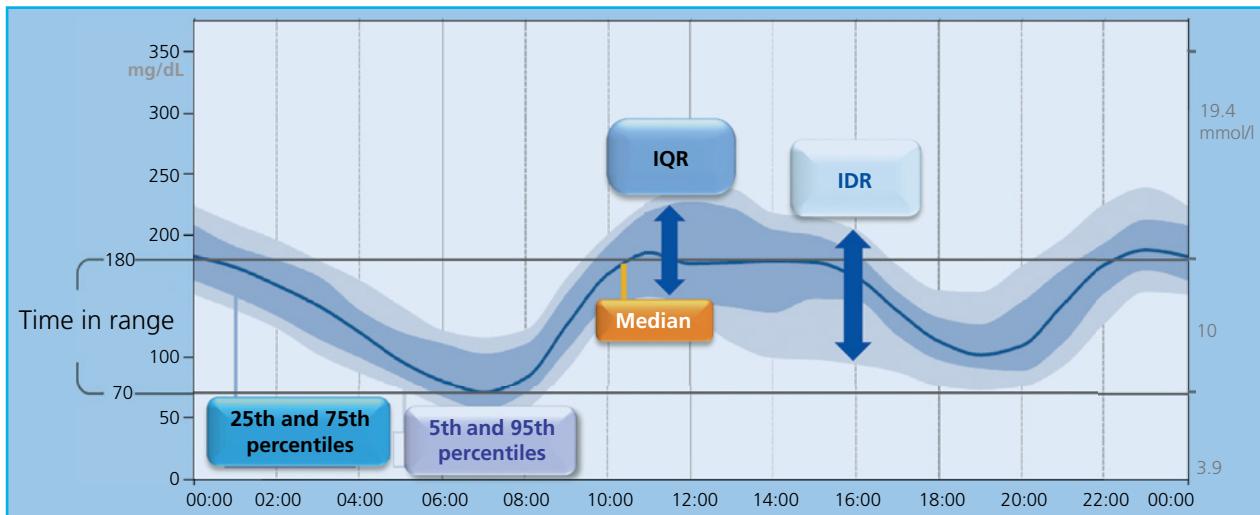

Figure 32.8 Interpreting glucose variability with the ambulatory glucose profile (AGP). If there is variability of glucose values in the interquartile range (IQR: blue area), then adjust the therapeutic regimen. If variability is predominantly in the interdecile range (IDR), then discuss potential lifestyle changes during the individual consultation. High glucose variability is associated with increased risk for hypoglycaemia.

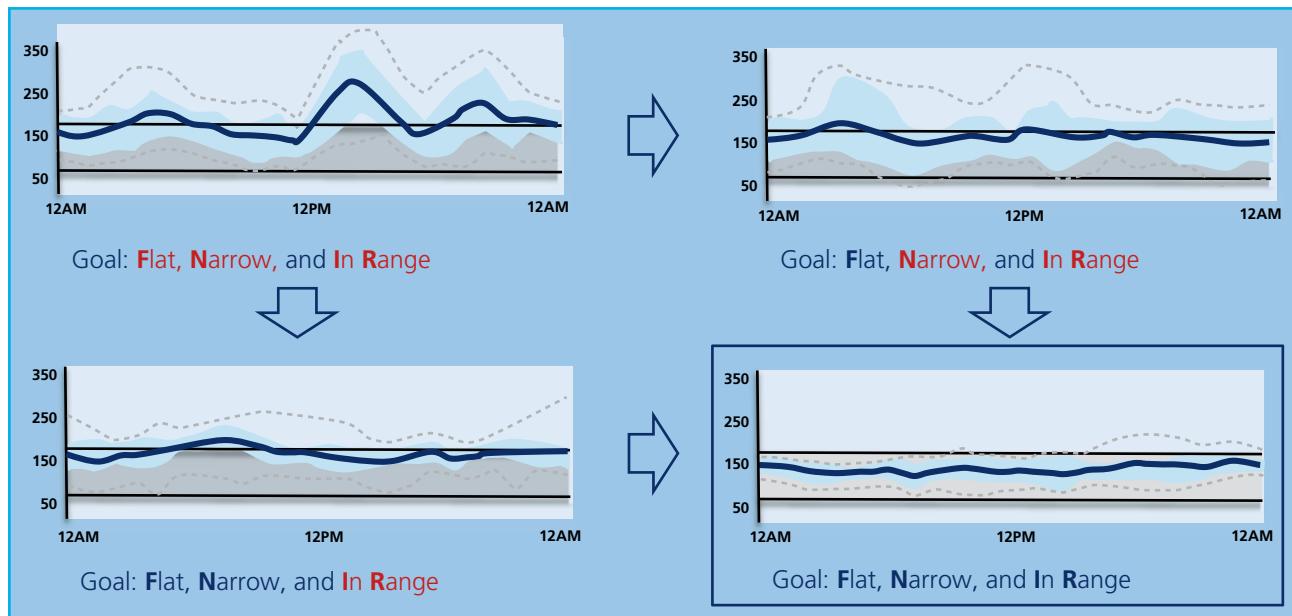

Figure 32.9 There are various ways in which continuous glucose data can be used to inform successful adjustments of the therapeutic regimen. Flat, narrow, and in range (FNIR) is one way to think about *ideal* blood glucose levels: high time in range and flat glucose levels with few ups and downs. People with type 1 diabetes or type 2 diabetes can strive for FNIR. On a day with FNIR levels, people should be encouraged to ask: What made that possible? How can I have more days like that? (See <https://diatribe.org> for details.)

The information displayed in the recommended AGP report can be used to analyse the AGP in a structured manner (Figure 32.10) [13, 66]. Experts recommend a five-step approach (Box 32.3) [71].

Future perspectives for continuous glucose monitoring

Transition from capillary blood glucose monitoring to continuous glucose monitoring

The performance of capillary blood glucose monitoring systems has improved in recent decades to such an extent that considerable further improvements are no longer expected in the foreseeable future. Capillary blood glucose monitoring still has the largest market share of glucose monitoring systems in the field of diabetes technology, partly due to the lower costs compared to rtCGM/isCGM systems. Continuous measurement systems such as rtCGM and isCGM are gaining in acceptance and importance, however. One important option for further development of all devices for glucose monitoring is their interoperability; that is, improved automatic availability of measurement results for evaluating data in programs or apps. As long as CGM is still costly and difficult to wear for individuals, these devices may be used intermittently and for a limited time, especially in cases of limited resources. From a global perspective, intermittent CGM use is more likely to occur than continuous use, primarily for economic reasons [72].

In the future, the merging of data, including those from the insulin dose (by using smart pens), carbohydrates (by an automated analysis of the carbohydrate content of meals), or exercise (by using data from fitness wristbands), will enable calculation of the optimal insulin dose thanks to the possibility of analysing data from many sources. Future bolus calculators will process such data and thus relieve people with diabetes of error-prone calculations.

Using continuous glucose monitoring in the virtual diabetes clinic

The virtual diabetes clinic has been a goal of healthcare systems and expert diabetes professionals for some time. Based around the growing number of diabetes-enabling technologies, telemedicine has been proposed as an important solution to the need to expand care for the benefit of people with diabetes, while improving efficiencies and rationalizing costs [73]. Telemedicine with CGM has been transformed from an aspirational goal to become the *de facto* standard of care for diabetes management during the Covid-19 public health emergency. Virtual consultation using continuous glucose data has been an invaluable tool in glycaemic management for a significant subset of those able to access this technology, most evidently for people with type 1 diabetes. Telemedicine is an acknowledged part of the post-Covid-19 world, but telemonitoring via CGM is still possible only for a subset of people with diabetes.

The diabetes services adapting most quickly to the needs of people with diabetes appear to be those with the most experience and confidence of working with diabetes health technologies and creating their own diabetes health ecosystems. These are often paediatric services. Given the mounting shortage of endocrinologists, especially in rural areas, the current paradigm of clinical care lacks the ability to provide the timely insulin adjustments needed to improve the management of type 1 diabetes. Digital decision support systems can address these issues by facilitating timely and more frequent insulin dose adjustments, either in person or remotely. Frequent insulin dose adjustments guided by an automated, artificial intelligence-based decision support system were as effective and safe as those guided by physicians in controlling glucose levels. In a six-month, multicentre, multinational, parallel, randomized controlled non-inferiority trial of 108 participants with type 1 diabetes, aged 10–21 years and using insulin pump therapy, use of an automated decision support tool for optimizing insulin pump settings was

TIME IN RANGES

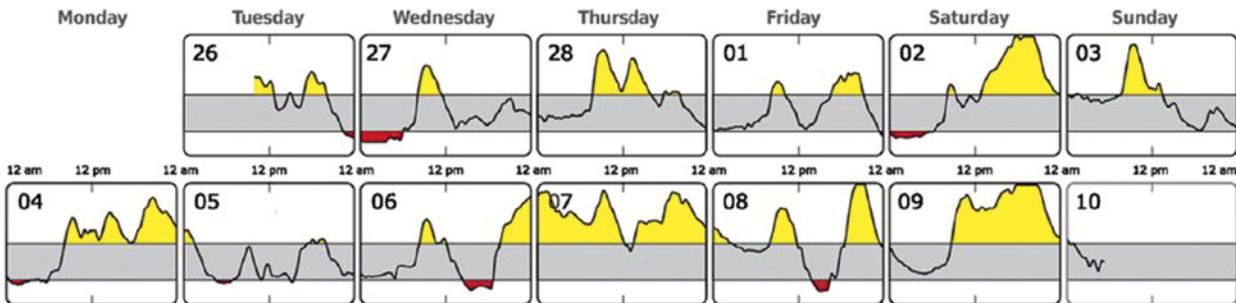

AMBULATORY GLUCOSE PROFILE (AGP)

AGP is a summary of glucose values from the report period, with median (50%) and other percentiles shown as if occurring in a single day.

DAILY GLUCOSE PROFILES

Each daily profile represents a midnight-to-midnight period.

Figure 32.10 The structured ambulatory glucose profile (AGP) report as suggested by the consensus group. Source: Modified from Battelino et al. 2019 [4].

Box 32.3 Stepwise structured analysis of the ambulatory glucose profile

1. What are the data quality and quantity?

The quality and quantity of the data are essential to the interpretation of the ambulatory glucose profile (AGP). An evaluation period of at least 14, but not more than 28, days is optimal to make a relevant statement about patterns. A period with standard conditions should be selected to inform therapeutic decisions. Vacations and illness, for example, are exceptions to the daily routine, during which glucose values may be different despite the same insulin dose. Using the measurement sensor for more than 70% of the evaluation time is considered sufficient. Data gaps can reduce the significance of the analysis.

2. What are the target range and time in the target range?

Usually a target range of 70–180 mg/dl (3.9–10.0 mmol/l) is recommended. A tighter range (70–140 mg/dl; 3.9–7.8 mmol/l) can be used in those striving for normoglycaemia.

3. Does the person with diabetes have hypoglycaemia?

In general, preventing hypoglycaemia, and especially severe hypoglycaemia, is one of the primary goals of therapy adjustment. To analyse hypoglycaemia, it is advisable to check individual days in addition to pattern recognition in the AGP.

4. What is the glucose variability?

The fourth step of the analysis is to evaluate glucose variability. This will reveal variations typical of the time of day and allow specific therapy adjustments. Glucose variability can be differentiated using interquartile range (IQR) and interdecile range (IDR). A broadened IQR usually indicates that changes in the therapeutic regimen are needed. In contrast, issues related to a wide IDR are more likely to be caused by lifestyle issues of the individual, such as an irregular daily routine or skipping or reducing a mealtime bolus. However, irregular daily routines eventually contribute to both a wider IDR and a wider IQR. For an in-depth analysis, additional information such as the amount and time of intake of carbohydrates and insulin, as well as information on exercise or illness, should be recorded.

5. What about the stability of the glucose profile?

This refers to the example of being flat, narrow, and in range (FNIR) described in Figure 32.9. Steep rises and falls indicate a need for optimization. Possibly the coefficient of variation (CV) can be used in addition. A CV >36% signifies instability with an increased probability of hypoglycaemia. As a general rule, if the analysis shows that therapy adjustments are needed, do not address too many issues at once.

non-inferior to intensive insulin titration provided by physicians from specialized academic diabetes centres [74].

Using continuous glucose monitoring for automated insulin dosing

A sophisticated artificial pancreas would be a device that mimics the glucose-regulating functions of a healthy pancreas, automatically controls blood glucose levels without patient intervention, and delivers insulin. Previous attempts to perform fully automatic

insulin therapy (e.g. without meal announcement) using a control algorithm have not been successful.

Post-prandial hyperglycaemia is a particular problem here, since a fully automated system based on a glucose sensor alone can only respond to increases in glucose. However, this response first needs a certain glucose gradient for a rise to be detected as a meal [75]. The subsequent insulin release thus follows an already incipient hyperglycaemia, which is further intensified because even with new, ultra-short-acting insulins, the pharmacodynamic onset of action occurs after ~10 minutes.

However, it can be assumed that the current treatment standard of intensified insulin therapy with syringes, pens, or insulin pumps will increasingly be supplemented by systems for automatic insulin dosing based on CGM using smart pens or so-called hybrid closed-loop systems. As can be seen in other technologies like mobile phones, more diverse and advanced hybrid close-loop systems will continually come onto the market. They are characterized by automatic corrections of bolus delivery and basal rate, but a meal input remains necessary. However, they differ considerably both in the underlying algorithm and in the target values, sports, or sleep settings. This form of therapy requires trust in the system, as its use is associated with a transfer of tasks and responsibility. Since the people with diabetes and parents of children with diabetes have to modify the learned principles of diabetes therapy, good, detailed, and repetitive structured training of people with diabetes is still necessary. A life that should differ as little as possible from that of those without diabetes is the goal.

It is likely that only a few diabetes teams will fully master the advantages and disadvantages of the different systems for AID to provide informed advice to people with diabetes and to identify the most suitable system for each individual during the consultation. One of the challenges of the future will be to find a basis for adequate system selection, training, and reimbursement of the next generation of diabetes therapy.

New Technologies for Insulin Administration

Hannah Forde and Pratik Choudhary

Leicester Diabetes Centre, Leicester, UK

Key points

- The emergence of new technologies for insulin delivery as well as glucose monitoring has led to significant improvements in the care of type 1 diabetes.
- Insulin pen technology has significantly advanced since the first pen was launched by Novo Nordisk in 1985 and now 'smart' connected pens are available, which can record the timing and dose of insulin administration and communicate with blood glucose monitoring and continuous glucose monitoring (CGM) systems.
- Several 'smart' insulin pen products (caps and attachments) are also in production that will integrate with various insulin pens to track insulin dosage and timing.
- Newer insulin pumps are smaller, more portable, and user friendly and have greater technological capabilities, including temporary basal rates/patterns, advanced bolus options, bolus advisors, and the ability to integrate with CGM.
- There is conflicting evidence on whether continuous subcutaneous insulin infusion (CSII) therapy is superior to multiple daily injections

for achieving optimum glycaemic levels and reducing hypoglycaemia. However, people with elevated glycated haemoglobin (HbA_{1c}) or a high burden of hypoglycaemia seem to gain the most benefit from pump therapy.

- Data from both randomized controlled trials and observational studies confirm a positive effect of CSII on the quality of life of people with type 1 diabetes.
- Tubeless 'patch' pumps are now available and these may have some advantages over conventional 'tubed' pumps, though there are limited data comparing the two types of device.
- The most common insulin pump-associated adverse effects are related to problems with infusion sets.
- Intraperitoneal pumps remain a valuable option for those in whom subcutaneous insulin therapy fails.
- Glucose-responsive smart insulin delivery systems are currently in development and represent a promising area of research.

Insulin therapy has evolved since its discovery 100 years ago, and insulin analogues have more or less replaced the traditional basal-bolus regimens of human insulins and neutral protamine Hagedorn (NPH). Insulin analogues are associated with improved glycaemic levels, less day-to-day variability, and reduced hypoglycaemia in people with type 1 diabetes, compared to human insulin preparations whose pharmacodynamic properties result in large fluctuations in the glycaemic profile [1]. Although basal-bolus regimens with newer insulins have significantly improved type 1 diabetes care, the quest for more physiological insulin delivery is ongoing.

As the insulins themselves have progressed, so too have their delivery systems. Conventional insulin administration involved subcutaneous injections with syringes marked in insulin units. Depending on the manufacturer, traditional syringes differed in gauge, capacity, and needle length [2]. This was the only mode of insulin delivery available for decades and made the process of giving an insulin injection impractical, time-consuming, and socially unacceptable for many people living with diabetes. Syringes have now been superseded by insulin pen devices, which

are recognized as being easier to use, more convenient, and less painful, while providing greater dose accuracy and increased life flexibility [3, 4].

Another mode of insulin delivery is the insulin pump or continuous subcutaneous insulin infusion (CSII). CSII uses a portable, battery-operated programmable pump to continuously infuse rapid-acting insulin at a slow and variable basal rate over 24 hours, with additional bolus insulin administration directed by the user when food is eaten or to correct hyperglycaemia [5]. CSII offers increased flexibility for people with type 1 diabetes and may be considered superior to multiple daily injection (MDI) for some individuals with diabetes.

The emergence of new technologies for insulin delivery as well as glucose monitoring has led to significant improvements in type 1 diabetes care. Efforts are ongoing to identify new minimally invasive methods of insulin administration that are safe, effective, and will further reduce the burden of living with diabetes. In this chapter, we discuss a range of new technologies for insulin delivery and review the available evidence investigating their use in clinical practice.

Insulin pens

The first insulin pen, NovoPen[®], was manufactured in 1985 by Novo Nordisk (Bagsværd, Denmark) [6]. Insulin pens were designed to alleviate many of the limitations of vials and syringes. Indeed, the advantages of insulin pens over syringes have been proven in many studies [7–10]. Since then several disposable or reusable, pre-filled or refillable insulin pen devices have been developed, which can deliver long-acting, rapid-acting, and mixed insulins. More recently, insulin pen devices have been further refined and many now include advanced ‘smart’ features to address problems such as hypoglycaemia, medication taking, insulin initiation, and titration and dosing errors [11].

In 2017, the first US Food and Drug Administration (FDA)-approved insulin smart pen was released [12]. The InPen[®] system, manufactured by Companion Medical (San Diego, CA, USA), records the amount and timing of the insulin dose and transmits the information via Bluetooth to a smartphone app. It can be used with either insulin aspart (NovoLog[®]/NovoRapid[®], Novo Nordisk) or insulin lispro (Humalog[®], Eli Lilly, Indianapolis, IN, USA) [13]. The dedicated smartphone app includes a bolus calculator, which adjusts the insulin dose recommendation for insulin on board (IOB). The app can also prepare reports that can be shared with healthcare professionals, to assist in identifying trends to inform treatment decisions. There are numerous other smart insulin pens, which can precisely track insulin delivery and wirelessly transmit the data to a smartphone app, but these do not have the additional advantage of a bolus calculator.

Novo Nordisk has also contributed to the smart pen market. The NovoPen[®] 5 and NovoPen[®] Echo devices were its first smart pens for adults and children, respectively. These devices, compatible with insulin aspart, have a built-in memory function that records the last dose in units as well as the time elapsed since the last injection. The information is displayed electronically on the pen and there is an additional safety feature that clicks when the full dose of insulin has been administered [14]. Novo Nordisk has also recently launched *smart connected pens*, the Novopen[®] 6 and NovoPen Echo[®] Plus. These pens communicate with continuous glucose monitoring (CGM) systems and blood glucose meters, and Novo Nordisk has established partnerships with several glucose monitoring companies to allow integration of glucose monitoring and insulin dosing data. The effect of a smart connected insulin pen on glycaemic management was investigated in a non-interventional study in a Swedish cohort of almost 100 adults with type 1 diabetes [15]. In this study, the participants received the Novopen[®] 6 device and CGM was utilized to monitor *time in range* (TIR) and hyper- and hypoglycaemia [15]. The device was associated with a significant increase in TIR and a significant reduction in hyper- and mild hypoglycaemia (3.0–3.9 mmol/l) [15]. It is worth noting, however, that there was no control arm in this study and the individuals with diabetes had frequent visits with healthcare professionals (>5 visits in a period of six months), which may have accounted for some of the improvement in glycaemic levels [15].

Several insulin pen products, including smart caps and attachments that can integrate with different insulin pens, are in various stages of development and commercialization, offering the ability to passively track insulin doses and timing and allowing varying degrees of integration with electronic health records and glucose monitoring platforms [16]. Some attachments interface with a smartphone app and have alert features to avoid missed or extra doses of insulin. Unintentional omission of insulin is common; in

a telephone survey of more than 500 persons with diabetes, 7.4% of respondents chose *forgot* when selecting their top three reasons for omitting insulin [17]. Forgetting, or questioning an insulin dose, affects insulin-taking behaviour and increases worry and concern for individuals with type 1 diabetes [18]. Smart caps and attachments are novel strategies that can assist people with type 1 diabetes in the management of memory-related dosing issues. The efficacy of the InsulClock[®] (InsulCloud, Madrid, Spain) was assessed in a single-centre pilot study in 16 people with suboptimally managed type 1 diabetes [19]. The device shows type, time, and quantity of insulin administered and interfaces with an app that provides dose reminders and allows food/glucose data input [14]. In this small study, InsulClock use was associated with increased TIR and reduced hyperglycaemia, coupled with improved insulin administration and treatment satisfaction [19].

These devices are also useful research tools. The Gocap (Common Sensing, Cambridge, MA, USA), which interfaces with an app and displays the type and time of insulin administration and allows for relevant data entry, has been used to objectively evaluate insulin administration in 75 individuals using an MDI regimen [20]. With the use of this Bluetooth-enabled pen cap, the study identified that 24% of bolus doses and 36% of basal doses were dosed or timed inaccurately [20]. Additionally, the Gocap has been used in conjunction with CGM to illustrate the effect of insulin dose and timing on post-prandial glucose readings [21]. Access to these data could facilitate healthcare professionals and people with type 1 diabetes to make effective changes to their bolus insulin regimen.

i-Port

Injection ports are a viable alternative to subcutaneous insulin injections [22]. The i-Port Advance[™] (Medtronic, Minneapolis, MN, USA; Figure 33.1) is a small injection port that allows the person with diabetes to take multiple daily subcutaneous injections without having to puncture the skin each time [22]. It can be worn for up to three days during all normal daily activities. Khan and Alswat assessed the impact of the i-Port Advance on satisfaction, insulin administration, and treatment outcomes in 55 people with insulin-treated diabetes (92.7% type 1 diabetes) [23]. They reported

Figure 33.1 The i-Port Advance[™] system. Source: With permission from Medtronic.

improved insulin administration and reduced frequency of hypoglycaemia and hospitalizations with the i-Port, but there was no significant difference in glycaemic levels or treatment satisfaction among regular and irregular users of the system [23]. Gregory et al. described another potential use of the i-Port system when it was used effectively to desensitize an individual with type 1 diabetes complicated by insulin allergy to subcutaneous insulin [24]. While i-Ports may be useful for those with severe needle phobias, their use has not been widely adopted in clinical practice. This is likely due to the availability of newer and smaller needles, which make insulin injections almost painless [23].

Continuous subcutaneous insulin infusion

The first use of CSII with an insulin pump was described in 1978 by Pickup et al. in 12 individuals with ‘insulin-dependent’ diabetes [25]. Though there was initial excitement surrounding CSII therapy, pumps soon fell out of favour as concerns grew over their size, safety, and efficacy [26]. A strong resurgence occurred following the publication of the Diabetes Control and Complications Trial (DCCT) in the 1990s, as individuals treated with CSII in the DCCT had slightly better glycaemic indices than those treated with MDI [27]. This renewed interest in pump therapy coincided with technological advances resulting in improved blood glucose monitoring devices and insulin delivery systems [28]. Since then, CSII has been shown to reduce glycated haemoglobin (HbA_{1c}) as well as the frequency of hypoglycaemia, and it has been incorporated into our management pathways for selected people with type 1 diabetes [29]. However, access to CSII therapy varies greatly depending on location. It is estimated that 11.7% of people with type 1 diabetes in England are using CSII currently, compared to 40% of people with type 1 diabetes in the USA [30].

CSII therapy has significantly progressed since it was first developed (Figure 33.2). Newer models are smaller, more portable and user friendly, and have greater technological capabilities including bolus calculators, advanced bolus delivery options, and the ability to integrate with CGM. *Sensor-augmented pump therapy* refers to CSII systems that integrate with CGM systems, and most systems now feature varying degrees of automation where the system alters insulin delivery in response to sensor glucose readings without input from the user. Artificial pancreas or closed-loop systems represent the most advanced forms of these systems [31].

Features of continuous subcutaneous insulin infusion

Variable basal insulin delivery

The main advantages of CSII are the ability to vary basal rates and the ease of delivery of multiple and more frequent boluses. Basal insulin requirements vary throughout the day, owing to circadian changes in counter-regulatory hormones and insulin sensitivity, behavioural factors (activity, alcohol), and emotional changes (stress) [32–36]. CSII facilitates flexible modulation of basal insulin requirements, depending on demand, to a far greater extent than traditional long-acting insulin taken once (insulin glargine, insulin degludec) or twice daily (insulin detemir). King and Armstrong used CGM data to compare the effect of insulin glargine on nocturnal glycaemia with pre-programmed rates of insulin lispro delivery in individuals using CSII [37]. They reported that those treated with glargine spent more time in hypoglycaemia, and twice the amount of time in the hyperglycaemic range [37]. Their findings were corroborated in a similar study by Braggd et al., who used blinded CGM to compare CSII with basal insulin substitution with insulin glargine in a non-blinded, randomized crossover trial of 15 experienced pump users with type 1 diabetes [38]. They demonstrated improved glycaemic levels with CSII compared to insulin glargine, with a lower mean glucose reading and a greater TIR [38].

There are numerous options for basal rate settings when initiating CSII. The simplest approach is to start with a flat basal rate; that is, 50% of total daily dose (TDD), divided equally over 24 h (Figure 33.3). A flat basal rate will not account for the fluctuating insulin requirements throughout the day, but additional basal rates can then be added according to glucose readings and diurnal variations [40]. Most people with type 1 diabetes will require multiple basal rates throughout the day [41]. Chico et al. assessed insulin requirements in 74 individuals with type 1 diabetes transitioning from MDI to CSII, and found that hourly basal rates were highest late in the evening (dusk phenomenon) and in the early hours of the morning (dawn phenomenon) [41]. Hence, many expert groups recommend the use of a modified circadian basal profile when initiating CSII [42] (Figure 33.3). This usually includes 4–5 basal rate profiles throughout the day, with increased insulin delivery in the early morning and late evening, and reduced insulin delivered in the late night and early afternoon [43].

In children and young adults, studies have reported large variations in basal insulin requirements and circadian insulin profiles between different age groups [39, 44]. As such, some experts have

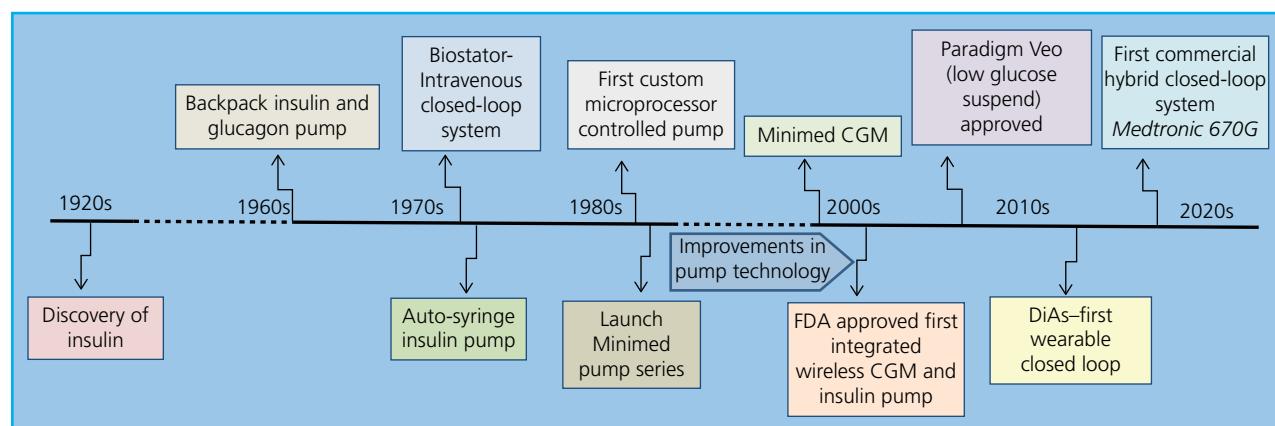

Figure 33.2 Timeline of history of insulin pump technology. CGM, continuous glucose monitoring; DiAs, Diabetes Assistant; FDA, Food and Drug Administration.

Figure 33.3 (a) Options for basal insulin profile. Broken line represents a flat basal rate over 24 hours. Continuous line represents a modified basal profile. TDD, total daily dose. (b) Options for basal insulin profile based on circadian rhythm, as described by Bachran et al. [39]. The graph depicts requirements for age group 18–24 years.

been advocating a *circadian rhythm*-based basal rate profile when initiating CSII (Figure 33.3b). This involves a double-peaked basal rate profile that mirrors circadian insulin requirements [45]. Much of the research in this area, however, has been conducted in paediatric populations, and there are no clear data of the benefits of a circadian-based profile over a flat basal rate in adults. Although more physiological, there does not appear to be an association between number of basal rates and glycaemic indices such as HbA_{1c} [46]. Laimer et al. also described some concerning associations between high basal rate variability and poor outcomes [45]. In this study of approximately 5000 adults with type 1 diabetes, increased basal rate variability correlated with increased severe hypoglycaemia and diabetic ketoacidosis (DKA) [45]. Recent data from closed-loop studies suggest that overnight basal insulin requirements may vary as much as 200% from day to day, which may explain why it is often difficult to find a basal pattern that offers stability.

Dawn phenomenon

The dawn phenomenon was first described by Schmidt et al. in 1981, when they observed a rise in early-morning fasting blood glucose in 10 of 11 individuals with type 1 diabetes [47]. The dawn phenomenon has been attributed to reduced hepatic and peripheral insulin

sensitivity secondary to nocturnal growth hormone spikes [48]. In older studies the magnitude of the dawn phenomenon was greatly exaggerated, as plasma insulin concentrations would fall by dawn, following a nocturnal dose of NPH or lente insulin [49]. The dawn phenomenon is less pronounced with CSII or long-acting insulin analogues, but remains highly variable among individuals [50]. It occurs in approximately 50% of people with type 1 diabetes and is a common indication for CSII therapy [50].

To counteract the dawn phenomenon, insulin pump users often program the pump to deliver increased insulin doses in the early hours of the morning. Though theoretically sensible, the safety and efficacy of this approach were challenged in an eight-month longitudinal study by Bouchonville et al., who used CGM to investigate early-morning CSII programming to manage the dawn phenomenon [51]. In a cohort of 40 people with type 1 diabetes, they reported the occurrence of the dawn phenomenon to a variable extent in all individuals, but a fixed increase in early-morning insulin delivery was found to be ineffective at managing the early-morning hyperglycaemia and increased the risk of hypoglycaemia [51]. In contrast, Lindmeyer et al. recently observed a lower probability of hypoglycaemia (<4.4 mmol/l) and a higher probability of hyperglycaemia (>7.2 mmol/l) in pump users with the most marked dawn

phenomenon, despite increased insulin infusion rates [52]. Although the benefit of CSII for management of the dawn phenomenon may not be as well defined as previously thought, it is likely that it can be mitigated with the judicious use of CGM and an increase in morning insulin delivery.

Temporary basal rates

One of the advanced features of insulin pump therapy is the ability to set short-term temporary basal rates. It is also possible to manually suspend all insulin delivery, including the current basal and any bolus deliveries in progress. The ability to increase or decrease basal insulin delivery by 10–100% is particularly advantageous for managing glucose levels during periods of both increased or decreased activity or during illness. Approximately 60% of pump users utilize this temporary basal function, and there is an association between the habitual use of temporary basal rates and better glycaemic management [53, 54]. People using CSII with CGM are more likely to use temporary basal rates, indicating more active self-adjustment of insulin therapy [55].

Temporary basal rate reduction is most frequently used for managing periods of exercise. In people without diabetes, insulin secretion is significantly reduced during exercise [56]. It is not possible to simulate this physiological reduction in insulin in people with diabetes who have received a basal insulin analogue. However, CSII allows temporary reduction in basal insulin delivery or indeed insulin suspension to compensate for the increased risk of exercise-induced hypoglycaemia. As rapid-acting insulin peaks at 90–100 minutes, it is necessary to adjust the basal rate pre-exercise. A 50–80% reduction in basal insulin delivery 90 minutes before moderate-intensity aerobic exercise reduces the risk of immediate hypoglycaemia [57]. This approach is superior to complete insulin suspension at onset of exercise for both minimizing hypoglycaemia risk without compromising post-exercise glucose levels [57]. CGM studies have demonstrated the risk of delayed hypoglycaemia, which can occur many hours after the activity due to enhanced insulin sensitivity [58]. Hence, a temporary basal rate may be required post activity or during the night after exercise, but this requires individual assessment [59].

Increased temporary basal rates are particularly useful during periods of acute illness or stress or prolonged periods of inactivity (e.g. a long car journey). Increasing basal insulin delivery in these situations can be more effective at managing hyperglycaemia than administering multiple extra correction boluses [58].

A variety of basal rates can be stored in the pump as distinct basal patterns. This feature is particularly useful for people whose daily activities, and thus insulin requirements, vary on a day-to-day basis, such as shift workers. Some women utilize this function to manage their glucose levels during the pre- or peri-menstrual period, though advice in this regard should be individualized.

Bolus advisors

Bolus advisors are provided by most modern pumps and recommend bolus doses of insulin based on target glucose values, insulin sensitivity factor (ISF), predicted carbohydrate intake, insulin-to-carbohydrate ratio (ICR), and current glucose values, while compensating for the IOB from prior boluses. The formula utilized by bolus advisors to recommend an accurate bolus is as follows:

$$\text{Bolus Dose (units)} = [\text{Carbohydrate (g)} \div \text{ICR}] + [(\text{Current glucose} - \text{Target glucose}) \div \text{ISF}] - \text{IOB}$$

Bolus advisors are useful for several reasons. Whatever the mode of insulin delivery, people on intensive insulin therapy must be adept at handling numbers to calculate safe and appropriate insulin doses. National and international surveys have shown that many people lack the basic numerical skills that are essential to maintain their health and make informed medical decisions [60]. Poor numeracy skills are common in people with diabetes and are associated with fewer self-management behaviours and suboptimal glycaemic management [61, 62]. Manual calculation of bolus insulin doses by people with type 1 diabetes is erroneous >60% of the time [63]. Bolus advisors may help overcome the issue of low numeracy in people with type 1 diabetes. Their efficacy was demonstrated by Hommel et al. in a randomized controlled trial (RCT) of people with type 1 diabetes treated with MDI, initiating carbohydrate counting with or without the guidance of an automated bolus calculator [64]. They reported greater reductions in HbA_{1c} in individuals using the bolus calculator compared to those using mental calculations [64]. In other studies, improvements in HbA_{1c} were not seen, but glucose variability was reduced and post-prandial glycaemic excursions were ameliorated [65, 66]. People using bolus advisors also report better treatment satisfaction due to the ease of calculation as well as increased confidence in the accuracy of the dosage and reduced fear of hypoglycaemia [67].

Although user experience with bolus advisors is generally positive, the Relative Effectiveness of Pumps Over MDI and Structured Education (REPOSE) study identified some unintended consequences from offering people this technology [68]. Some people became deskilled and dependent on their advisors as they were no longer calculating their doses [68]. There was also a misconception that pre-programmed bolus advisor parameters did not require review and this, in turn, could negatively impact glycaemic management [68].

One of the benefits of automated bolus advisors is their ability to calculate more precise insulin doses. Precision dosing is an important factor in ensuring the efficacy and safety of insulin treatment, particularly for insulin-sensitive individuals and children and older adults with type 1 diabetes [69]. When used in combination with CSII, insulin doses can be delivered in increments as low as 0.025 units, facilitating greater accuracy in insulin administration, which may lead to improved diabetes management.

After the first bolus of the day, automated bolus advisors account for any residual insulin activity (IOB), so that subsequent boluses are reduced to avoid insulin stacking. This is important, as clamp studies have shown that 40% of insulin aspart (0.2 unit/kg) glucose-lowering activity is still present three hours post subcutaneous injection [70]. Data from paediatric pump users suggest an average daily bolus frequency of 6–7 per day in this cohort [71, 72]. If these boluses are given over an 18-hour waking period, average time intervals between boluses would range from 2.5 to 3 hours. If residual insulin activity is not accounted for, there is a risk of hypoglycaemia due to inevitable insulin stacking.

Bolus advisor users can only reap the benefit of this technology if their parameters are programmed correctly. The correct ICR and ISF should be established prior to setting up the bolus calculator. Residual insulin activity is calculated based on a unique algorithm incorporating the insulin action time (IAT). Currently there is no widely accepted consensus on the IAT for insulin analogues [73]. However, Heinemann and Woodworth demonstrated the variable pharmacodynamics of insulin lispro with different doses, suggesting the need for a shorter IAT (2–3 h) for people with smaller average doses (2–5 units/dose), and a longer IAT (4–5 h) for those with

larger regular doses (>10 units/dose) [74]. The Diabetes Technology Network-UK recommends using an IAT <4 h when the TDD is >30 units/d, and >4 h when the TDD is >60 units/d [42].

Advanced bolus options

Most modern pumps offer a range of bolus options (Figure 33.4). The advanced bolus option offers the chance to tailor the delivery of the bolus dose, according to the composition of the meal and the expected effects on glycaemia; however, this is not widely used in clinical practice. An extended or square-wave bolus of insulin is delivered over a set period of time as opposed to an upfront standard bolus of insulin. It can be given over several minutes up to a number of hours and can be useful to manage high-fat and high-protein meals. The dual-wave or multiwave bolus involves an instant bolus followed by an extended bolus, and it is effective at controlling post-prandial glucose levels after high-carbohydrate, high-fat meals [75]. Indeed, use of dual-wave boluses has been associated with better glycaemic levels in some small studies [76, 77]. However, these results are somewhat compounded by the fact that people using advanced bolus options may have an improved understanding of diabetes and more confidence in self-management of their insulin therapy.

Sensor-augmented pump therapy

The augmentation of pump therapy with integrated real-time CGM creates the opportunity to automate insulin delivery based on sensor values and has been shown to improve glucose levels and reduce hypoglycaemia [78, 79]. Threshold-suspend systems suspend basal insulin delivery once a low glucose value is reached,

while predictive-suspend systems suspend basal insulin delivery in response to predicted hypoglycaemia. These systems have been shown in large-scale RCTs to reduce the duration of and frequency of hypoglycaemia, respectively [80, 81]. In particular, the predictive low glucose suspend feature demonstrated an 87% reduction in rates of severe hypoglycaemia in a high-risk population with impaired awareness and was associated with a high degree of satisfaction and a feeling of increased security, particularly at night [82, 83].

Hybrid closed-loop technology is currently the most advanced form of insulin delivery available. It utilizes a control algorithm, which automatically adjusts basal insulin delivery every few minutes based on sensor glucose levels, but requires the user to calculate and deliver meal-related boluses. These hybrid closed-loop systems significantly improve glycaemic indices with real-world experience demonstrating TIR >70% [84]. As hybrid closed-loop systems do not fully automate diabetes management, users must be educated and motivated to derive the maximum benefit from the system [85], with some studies showing that up to 30% of users stop using them over time. More advanced systems, with reduced need for sensor calibrations, more aggressive algorithms, and simpler or absent requirements for food-related boluses are in development.

Do-it-yourself artificial pancreas system

The term do-it-yourself artificial pancreas system (DIY-APS) describes the automated closed-loop insulin delivery system developed by members of the diabetes community that uses CGM, an algorithm to calculate insulin doses, a communication device, and an insulin pump [86]. As the algorithm is unauthorized, these devices are not approved, commercialized, or regulated [11]. Driven predominantly by the #WeAreNotWaiting community, there has been rapid growth in the use of DIY closed-loop systems worldwide over the last number of years [87]. There are currently three forms of DIY-APS in use: OpenAPS, AndroidAPS, and Loop [86]. In general, DIY-APS work similarly to commercially available closed-loop systems, but DIY systems may offer users improved interoperability and customizable settings [88]. In contrast to commercially available closed-loop systems, advances have been made in DIY algorithms such that the second-generation DIY-APS are fully automated and meal/carbohydrate announcements are not required [89].

Real-world evidence for DIY-APS has been overwhelmingly positive, though these studies are limited not only by the small self-selecting population of tech-savvy people with diabetes who are highly engaged in the management of their diabetes, but also by the subjectively reported outcomes. Melmer et al. analysed data from 80 OpenAPS users and found that mean TIR achieved by this cohort was 77.5%, with just 4.3% time below 3.9 mmol/l [90]. Quality-of-life outcomes have also been reported by DIY system users. In a qualitative analysis of more than 3000 tweets from 328 people with type 1 diabetes or caregivers, the overarching sentiment emerging from the data was that OpenAPS reduced diabetes-related burden and distress [91]. The main disadvantages of DIY-APS relate to the technical and hardware limitations of old or out-of-warranty pumps or potential problems that may arise with an unregulated, unapproved algorithm [86]. Furthermore, healthcare professionals often feel uncomfortable supporting people with diabetes who use these systems because of a lack of knowledge of the system or because of fears of indemnity. However, in a recent survey of UK practitioners, 97% of respondents reported that healthcare professionals should learn more about DIY-APS to improve their ability to support users of these systems [92].

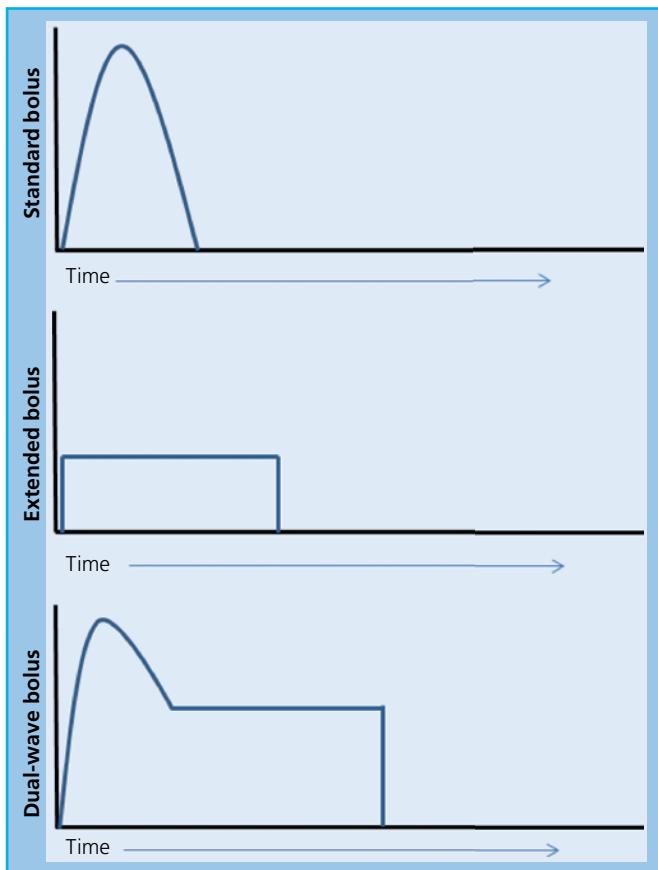

Figure 33.4 Standard, extended, and dual-wave bolus insulin delivery options.

Evidence base for pumps

The evidence base for pumps is derived from both RCTs and real-world evidence. RCTs of pumps are often limited by short study duration, a carefully selected population, and the fact that they are conducted under specific, tightly controlled conditions. Furthermore, as early studies of CSII versus MDI were conducted using older basal insulins, many RCTs are not typically representative of routine current clinical practice. Real-world evidence has advantages over RCTs, including lower costs, fewer restrictions in population inclusion, and longer timeframes [93]. In this context, large population-based cohort studies complement the evidence generated from RCTs. The following sections will explore the available evidence for CSII under a number of subheadings.

Glycaemic management

Numerous older studies demonstrated the superiority of CSII over MDI in improving glycaemic levels and reducing glucose variability, but these benefits were less pronounced in studies using more modern basal insulin analogues. In a meta-analysis published in 2008, Pickup et al. evaluated three RCTs and one before/after study that compared glycaemic levels achieved using insulin glargine-based MDI with CSII [94]. Although the studies were of short duration (1.25–6 months), the mean HbA_{1c} difference between glargine-based MDI and CSII was 0.63% (7 mmol/mol) in favour of CSII [94]. In a more recent meta-analysis conducted by Pala et al., the evidence comparing CSII with modern MDI regimens was again reviewed [95]. In trials where rapid-acting analogues were used, the advantage of CSII was significantly smaller than in trials with regular human insulin and CSII (-0.29% vs -1.93%; -3 mmol/mol vs 21 mmol/mol) [95]. A similar modest reduction in HbA_{1c} (-0.37%, 4 mmol/mol) was demonstrated by Benkhadra et al. in their analysis of 25 RCTs comparing CSII with MDI in both adults and children with type 1 diabetes [96], echoing the previous findings of a Cochrane review in 2010 [97].

There is little information on the comparative effectiveness of CSII and MDI over longer periods. Real-world evidence suggests minor sustained improvements in HbA_{1c} with pump therapy. In a Swedish observational study of almost 300 individuals with type 1 diabetes using CSII therapy, Carlsson et al. demonstrated that the improvements in HbA_{1c} persisted at five-year follow-up, but the effect of CSII on glycaemic management diminished over time [98]. Similar findings were reported by an Australian group that had up to eight years of follow-up data for some of its pump users [99]. In this study, greater HbA_{1c} reductions occurred in those with higher HbA_{1c} levels at CSII commencement, a common theme in pump studies, and the greatest reduction in HbA_{1c} occurred at one year [99]. Beato-Vibora et al. reported greater benefits in HbA_{1c} with a mean reduction of 1.1% (12 mmol/mol) sustained over five years, in more than 300 pump users in a single-centre UK study [100]. Overall, it seems that there are variations in long-term efficacy of CSII. In another UK study, Nixon et al. categorized 35 adults with type 1 diabetes into subgroups according to their response to pump therapy [101]. They reported that 57% of people had an initial improvement in HbA_{1c}, followed by a deterioration, 31% had sustained glycaemic improvement over four years, and 12% were non-responders [101].

When comparing CSII with MDI, it is very difficult to control for the confounding effect of the intensive diabetes self-management education and increased healthcare access associated with the commencement of CSII therapy. The REPOSE study tried to address this issue and is the longest and largest RCT of CSII in type 1

diabetes [102]. In this study, the efficacy and cost-effectiveness of CSII therapy were compared to an MDI regimen in 317 adults with type 1 diabetes, when both groups received equivalent structured training in flexible insulin therapy [102]. It is noteworthy that the participants in this study had no preference for either MDI or pump therapy, and individuals with a strong desire for pump therapy were excluded. In addition, the individuals had no clinical indication for pump therapy. The trial participants had longstanding diabetes (approx. 18 years) and suboptimal glycaemic levels at baseline (mean HbA_{1c} 9.1%; 76 mmol/mol) [102]. The individuals were followed for two years and the primary outcomes were change in HbA_{1c} from baseline and the proportion of individuals achieving HbA_{1c}<7.5% (58 mmol/mol) [102]. Both groups achieved clinically significant improvements in both glycaemic levels and rates of severe hypoglycaemia [102]. Although the improvement was slightly greater in the pump group, this did not reach statistical significance in the primary analysis [102]. The treatment difference was significantly greater in the per protocol analysis in favour of CSII ($p = 0.02$) [102]. The number of episodes of DKA was greater in the CSII group compared to those on MDI [102]. In this study, CSII was only superior to MDI in relation to treatment satisfaction and some quality-of-life domains [102]. This benefit of CSII therapy on quality of life has been shown previously and will be discussed later in this chapter.

The effect of CSII therapy on glycaemic measures has also been studied in other populations, with varying success. In a recent RCT conducted in the UK, the efficacy, safety, and cost utility of CSII were compared with MDI in children between 7 and 15 years, during the first year following diagnosis of type 1 diabetes [103]. Again, all participants in this trial completed a structured education programme and there was no clinical benefit of CSII over MDI in this cohort [103]. Furthermore, neither regimen was successful in achieving optimum glycaemic targets [103]. Interestingly, observational studies investigating CSII use in paediatric populations with longer duration of diabetes have reported better outcomes. Korkmaz et al. compared long term glycaemic outcomes in 52 individuals with type 1 diabetes treated with CSII to 38 age- and sex-matched MDI-treated controls [104]. The mean duration of diabetes in the study cohort was 10.7 years, and in this study CSII was associated with better glycaemic levels in all ages and at all times over a five-year period, compared to MDI [104]. In another retrospective multicentre study of pump use in children and adolescents with type 1 diabetes for an average of 6.3 years, CSII was associated with significant improvement in HbA_{1c} during follow-up, but the major benefit was in boys only [105].

A higher number of capillary blood glucose measurements and a higher daily number of boluses are associated with better glycaemic levels in children and adults [106, 107]. Hence, it is unsurprising that the use of real-time CGM, in addition to pump therapy, results in improved HbA_{1c}, as demonstrated in the Sensor-augmented pump Therapy for A1C Reduction (STAR-3) study. In this large one-year, multicentre RCT comparing sensor-augmented pumps to MDI in almost 500 people with type 1 diabetes, mean HbA_{1c} dropped by 0.8% (9 mmol/mol) in the sensor-augmented pump group compared to 0.2% (2 mmol/mol) in the MDI group [108]. It is noteworthy that participants in the sensor-augmented pump group had more clinical contacts than the MDI group in the first five weeks of the study [108]. The additional training and education received by this group may well have contributed to the favourable outcomes. The real-world Comparison of Sensor-Augmented Insulin Regimens (COMISAIR) study suggests that the benefit of sensor-augmented pumps is derived mostly from real-time CGM.

In their non-randomized, prospective clinical trial, Šoupal et al. found that after three years' follow-up, CGM with MDI performed as well as CGM with CSII at improving glycaemic levels, increasing TIR and reducing hypoglycaemia [109].

CSII may be advantageous in pre-pregnancy and pregnancy. Women with pre-gestational type 1 diabetes have an increased risk of adverse outcomes, including spontaneous abortions, congenital malformation, macrosomia, pre-eclampsia, need for operative delivery, and progression of diabetes complications [90]. In a study of women with type 1 diabetes attending a clinic for pre-pregnancy care, individuals using CSII had lower HbA_{1c} levels at booking compared to those on MDI [110]. In another observational study of 128 pregnant women with pre-gestational type 1 diabetes, CSII compared favourably with MDI in reducing HbA_{1c} and glycaemic variability during the pre-conception period and during each trimester of pregnancy [111]. Rys et al. published a systematic review and meta-analysis of 47 studies, including 43 non-RCTs, with data on almost 8000 pregnancies in women with type 1 diabetes, evaluating CSII versus MDI in pregnancy [112]. HbA_{1c} was lower in pump users compared to MDI in the first trimester, but the difference in HbA_{1c} between the two groups decreased in subsequent trimesters [112]. They postulated that the better glycaemic management observed in the CSII group in the first trimester could be attributed to greater participation in pre-conception care by this cohort [112]. The difference in glycaemic levels between the two groups diminished as the pregnancy progressed, suggesting that good glycaemic management is possible with either method of insulin delivery when the woman is highly motivated to self-manage her diabetes. In terms of materno-fetal outcomes, this review demonstrated increased maternal gestational weight gain and increased large for gestational age babies in the CSII group [112]. This observation was also reported by Hauffe et al., and emphasizes the importance of education on gestational weight gain for women with type 1 diabetes who are planning pregnancy [113].

The use of CSII for the treatment of type 1 diabetes in older adults is becoming increasingly popular. A recent report from the Diabetes Prospective Follow-up Registry compared diabetes-related outcomes in older adults with type 1 diabetes using CSII versus MDI [114]. CSII was associated with slightly better glycaemic levels and lower rates of severe hypoglycaemia and DKA, suggesting that older age itself should not be considered a contraindication to insulin pump therapy [114]. Although not routinely used in clinical practice, there is also evidence that people with type 2 diabetes may benefit from CSII. The OpT2mise Glucose Control in Type 2 Diabetes Mellitus with Insulin Pump Therapy study was a multicentre randomized open-label trial of CSII versus MDI in individuals with suboptimally managed type 2 diabetes [115]. At six months, there was a significantly greater reduction in HbA_{1c} in the CSII group compared to the MDI group [115]. A meta-analysis of five RCTs comparing CSII to MDI in the treatment of type 2 diabetes concluded that CSII is superior to MDI in individuals with suboptimally managed type 2 diabetes and is associated with a reduction in insulin requirements and no weight gain [116]. The individuals with the highest HbA_{1c} at baseline and the highest insulin requirements seemed to benefit most from CSII [116].

Healthcare professionals find it difficult to predict who gains the most benefit from insulin pump therapy. Though multiple guidelines recommend the use of CSII for those with problematic hypoglycaemia, pump therapy can confer additional benefits outside of this setting, particularly in the form of improved glycaemic

management [117]. Unfortunately, clinicians are inherently biased when it comes to determining suitability for CSII, as many are concerned that the technology may be too complex or advanced for some individuals [118]. Staff involved in the REPOSE study reported being surprised by how well some individuals, for whom CSII would not have been recommended in routine clinical practice, managed their insulin pump regimen [118]. This further supports the need for healthcare professionals to challenge their personal beliefs and views regarding suitability for this therapy.

Hypoglycaemia

The greatest risk of intensive insulin treatment is hypoglycaemia. Tight glycaemic management in the intensive arm of the DCCT was associated with a threefold increased risk of severe hypoglycaemia [27]. CSII is often recommended for people with type 1 diabetes whose attempts to achieve target HbA_{1c} on MDI are hampered by disabling hypoglycaemia despite dose optimization and adequate healthcare provider support. Although this cohort of people with type 1 diabetes are difficult to study, as people with impaired awareness of hypoglycaemia or a history of severe hypoglycaemia are often excluded from clinical trials, there is both RCT and real-world evidence to support the use of CSII in this cohort.

In a large study of 75 adolescents and young adults, aged 12–20 years, receiving intensive insulin treatment, CSII reduced the rate of severe hypoglycaemic events by 50% compared to MDI without adversely affecting glycaemic levels [119]. Although this was a prospective study, it is limited by its non-randomized nature. The participants in this study who received CSII therapy chose CSII as their preferred mode of treatment, which may reflect higher levels of motivation or a greater understanding of diabetes self-management compared to the MDI group [119]. Similar large reductions in severe hypoglycaemia rates were reported in the 2008 meta-analysis by Pickup and Sutton [94]. This meta-analysis of studies comparing the frequency of severe hypoglycaemia during CSII and MDI therapy only included studies published during or after 1996, where duration of CSII treatment was >6 months, and rate of severe hypoglycaemia on MDI was >10 episodes per 100 person-years [94]. Although this showed that severe hypoglycaemia was reduced with CSII compared to MDI (rate ratio 4.19 for all studies), all MDI regimens in these studies were based on isophane- or lente-type intermediate-acting insulin in combination with regular or monomeric mealtime insulin. Hence, these results cannot be extrapolated to a population using newer long-acting insulin analogues, as is the current practice. Interestingly, in a small randomized pilot study of 21 individuals with type 1 diabetes complicated by severe hypoglycaemia, optimizing analogue therapy had similar efficacy to CSII in restoring hypoglycaemia awareness and preventing further episodes of severe hypoglycaemia [120].

The Hypo-compass trial was a 2×2 factorial RCT comparing CSII and MDI with or without CGM in 96 individuals with type 1 diabetes and impaired awareness of hypoglycaemia [121]. The aim of the intervention was rigorous avoidance of biochemical hypoglycaemia without relaxing overall glycaemic management [121]. All individuals received comparable education in the form of a 1–2-hour hypoglycaemia psycho-education session, and intense clinical support for the six-month trial. At 24 weeks, there were similar reductions in severe hypoglycaemia (over 10-fold) and improvements in hypoglycaemia awareness between groups, though treatment satisfaction was higher in the CSII group [121]. Although the individuals returned to routine care after 24 weeks, these improvements were sustained at 24-month follow-up [122]. It was

surprising that this study did not show any differences in outcomes between CSII and MDI groups, but it is notable that the MDI group in the Hypo-compass trial were managed with a twice-daily basal analogue regimen, utilized a bolus calculator, and received weekly phone calls and monthly visits for the first six months. This was not the case in the studies included in the meta-analysis by Pickup and Sutton [94]. Significant improvement in the control arms due to these factors may partly explain the apparent lack of benefit from CGM or CSII in this study.

Real-world evidence demonstrates that CSII reduces the burden of hypoglycaemia. In a large retrospective analysis of more than 300 adult CSII users, the percentage of individuals with >5 mild or moderate hypoglycaemic events per week reduced from 29% to 12% [100]. In addition, the frequency of severe hypoglycaemic episodes halved from 0.6 to 0.3 per year [100]. This reduction in hypoglycaemia was sustained over a mean follow-up of 4.3 years [100]. These findings have been corroborated in other retrospective observational studies evaluating the efficacy of CSII in children, adolescents, and adults with type 1 diabetes, and reductions in both mild, moderate, and severe hypoglycaemia have been reported [123–125]. In general, people with a high burden of hypoglycaemia at baseline tend to derive the most benefit from CSII therapy [126].

Late complications

Few studies have examined the effect of CSII on long-term complications in people with type 1 diabetes. Zabeen et al. compared rates of microvascular complications in adolescents and young adults with type 1 diabetes treated with either CSII or MDI for at least 12 months [127]. In this cohort of almost 1000 individuals, glycaemic levels were equivalent between groups, but CSII use was associated with lower rates of retinopathy and peripheral nerve abnormalities compared to MDI [127]. The potential beneficial effect of CSII on glycaemic variability may be responsible for the findings [127]. Similarly, Downie et al. demonstrated in a subgroup analysis of their study that, despite similar HbA_{1c} levels, there was reduced risk of retinopathy in people with type 1 diabetes who were treated with CSII compared to MDI [128]. In another study assessing the effect of CSII on the development of microalbuminuric nephropathy, Lepore et al. compared the albumin excretion rate in 110 individuals using CSII to 110 people using MDI. Although albumin excretion rate at baseline was similar in both groups, albumin excretion rate was significantly lower in the CSII group at two- and three-year follow-up [129]. The results of this study are confounded, however, by the improved glycaemic levels in the CSII group compared to the MDI group at follow-up (HbA_{1c} 8.1% vs 8.4%; 65 mmol/mol vs 68 mmol/mol) [129].

In 2015, Steineck et al. published a large nationwide observational study investigating the relationship between insulin pump treatment and cardiovascular mortality [130]. Data were obtained from the Swedish national diabetes register on more than 18 000 people with type 1 diabetes, of whom almost 2500 were using insulin pumps [130]. After a mean follow-up of 6.8 years, CSII was associated with significantly reduced fatal coronary heart disease (45%), fatal cardiovascular disease (42%), and all-cause mortality (27%) [130]. It is unclear if the improved cardiovascular outcomes seen in the CSII group were related to direct treatment effect, or if they were attributable to potential increased education, monitoring, and self-management skills in this group. It is also plausible that reduced hypoglycaemia and less glucose variability in pump users contributed to the beneficial effects on cardiovascular disease. Further prospective studies, with long-term microvascular and

macrovascular outcome data, are required before we can infer a true cause–effect relationship between CSII and diabetes-related complications.

Quality of life

Many RCTs comparing the efficacy of CSII with MDI also reported quality-of-life outcomes. As mentioned, pump users in the REPOSE trial reported greater improvement in treatment satisfaction and in some quality-of-life domains (dietary freedom and daily hassle of functions) compared to the MDI group [102]. The Pumps for Kids, Infants, and Neonates (PumpKIN) trial was a multicentre RCT of children (aged 6–16 years) with type 1 diabetes randomized to commence CSII or remain on MDI for six months [131]. In this study, CSII therapy was associated with significant improvements in diabetes health-related quality of life in younger children, and the caregivers of the CSII group also reported a significant decline in overall diabetes burden compared to the MDI group [131].

Most of the evidence for quality-of-life benefits with pump therapy comes from real-world evidence. In a study comparing health-related quality of life in more than 200 youths with type 1 diabetes treated with either CSII or MDI, pump users reported significantly better quality of life compared to those on an MDI regimen [132]. Although there were no differences in glycaemic levels or physical fitness between the two groups, CSII use was associated with better physical, emotional, and school-related functioning and reduced diabetes-related worry [132]. Other studies have reported consistent findings when parents were used for proxy reporting on their child's quality of life [133, 134]. An Italian study of more than 500 adolescents between 10 and 17 years of age also indicated that CSII was associated with better health-related quality of life than MDI [135]. CSII users reported improved treatment satisfaction and perceived clinical efficacy, and reduced interference with daily activities [135]. Interestingly, in this study, CSII performed better in those with lower quality-of-life scores, suggesting that those with perceived low quality of life may gain benefit from pump therapy [135].

Adults have also reported improved quality of life on CSII. In a small qualitative study of Kuwaiti adults with type 1 diabetes recruited from pump clinics, CSII had positive impacts on the quality of life of participants, primarily by enhancing lifestyle flexibility [136]. Quirós et al. found the user experience of adults CSII users to be very positive, with 93% of participants reporting that they would not return to their previous insulin treatment [137]. These results are discordant with those reported by Reddy et al., who investigated the effect of glycaemic variability on quality of life in adults with type 1 diabetes [138]. Almost two-thirds of participants were on CSII and although glycaemic variability was lower in this group, there were no significant differences in diabetes-related quality of life between CSII and MDI groups [138]. Although this study and few others suggest that quality of life in CSII users is equivalent or even inferior to those on MDI, comparison between studies is difficult as inconsistent assessment and poor trial methodology often cloud the issue [139].

Cost-effectiveness

With the rapid evolution of technologies for treatment of type 1 diabetes, economic evaluations are required to guide policy making. Although CSII has benefits in terms of glycaemic management, hypoglycaemia, complications, and quality of life, these must be weighed against the cost of standard care with MDI. A recent systematic review of 35 studies investigating the cost-effectiveness

of diabetes technologies concluded that insulin pumps were cost-effective, particularly for those with suboptimal glycaemic management or high levels of hypoglycaemia [140]. In this meta-analysis, CSII in conjunction with self-monitoring blood glucose was cost-effective compared to MDI with self-monitoring blood glucose in 56% of studies reviewed [140]. Incremental cost-effective ratios (ICERs) below willingness-to-pay thresholds ranged from \$21 000 to \$57 000 per quality-adjusted life year (QALY) gained in the USA [141, 142]. In contrast, a health economics analysis of the REPOSE study, which compared pumps with MDI with equivalent structured education in both groups, indicated that the ICER was unlikely to fall below a threshold of £30 000 per QALY gained, and therefore was not considered cost-effective in those without an immediate clinical need [30].

Determinants of cost-effectiveness of diabetes therapies are largely based on changes in HbA_{1c} and rates of hypoglycaemia. HbA_{1c} is used to predict long-term complications and hypoglycaemia contributes to costs incurred from lost productivity, ambulance call-outs, emergency department attendances, and so on [140]. Therefore, cost-utility analyses of CSII compared to MDI are influenced by the predetermined modelled treatment effects in favour of a specific therapy. Older studies conducting economic evaluations on CSII versus MDI modelled HbA_{1c} reductions of 0.6–1.2% (7–13 mmol/mol) in favour of pump therapy based on meta-analyses by Weissberg-Benchell et al. and Pickup et al. [28, 143]. This may have led to the long-term benefits of CSII therapy being overestimated, considering that recent data suggest more modest reductions in HbA_{1c} [95, 96, 144]. However, any positive bias towards CSII may be offset by the conservative assumption that hypoglycaemia rates were equivalent in both CSII and MDI groups in many studies. When the treatment effect for hypoglycaemia prevention is increased, ICER is reduced significantly [140]. Many trials are not adequately powered to draw definitive conclusions about treatment effects on severe hypoglycaemia, and the short duration of RCTs suggests that they may not be suitable for long-term modelling of hypoglycaemia risk [140]. In summary, although ICERs vary widely, the current economic literature suggests cost-effectiveness of CSII, especially in populations with the most to gain.

Types of pumps

Conventional pumps comprise a small digital device that continuously delivers rapid-acting insulin through a catheter inserted into the subcutaneous tissue, which is fixed in place with an adhesive. Most infusion catheters are connected to the pump by plastic tubing. In contrast, tubeless pumps (also called patch pumps) do not use plastic tubing and adhere directly to the skin. Insulin is delivered through the infusion catheter. Insulin delivery is controlled by a remote device through wireless technology [145]. Patch pumps can deliver basal insulin, bolus insulin, or both and are used by about 5% of people utilizing insulin pumps [146].

There are both simplified and advanced patch pumps available, with the more simplified versions geared towards type 2 diabetes management. These are primarily used as pen replacements, are fully disposable, and are changed daily [146]. The advanced patch pumps are flexible devices, which have all the features to manage a complex insulin regimen [146]. There are some advantages of patch pumps over conventional tubed pumps. Firstly, upfront costs are lower, and as patch pumps are disposable, a four-year commitment to CSII therapy is not necessarily required and new pump users can be transitioned back to MDI if they are struggling on their new regimen. Secondly, patch pumps are smaller and

more discreet than conventional pumps, and since they attach directly to the skin, there are no issues with insulin infusion sets. Insulin infusion sets are problematic as they require priming and are prone to clogging, kinking of tubing, and obstruction of insulin delivery by air bubbles [147]. In a survey of people with type 1 diabetes using conventional pumps, kinking and blockage were the commonest infusion set problems and were reported in more than 50% of respondents [148]. Another advantage of the patch pump is that it can be attached to many different parts of the body, which is useful for individuals with abdominal lipohypertrophy. Finally, many are water resistant and can be used while showering or swimming [147]. There are also some limitations of the patch pump. If the device is removed for any reason, it must be disposed of and a fresh patch pump reinserted. This can lead to increased waste in plastic, materials, and batteries. The requirement for an additional device to control the infusion of insulin is also a disadvantage of patch pumps. If the pump user misplaced or forgot to carry the device, bolus insulin delivery would not be possible in its absence.

Currently, there is a paucity of RCT data and limited real-world evidence comparing tubed and tubeless pumps. Leelarathna et al. conducted a retrospective observational study comparing glycaemic outcomes with different types of insulin pumps in a large cohort of more than 500 adults with type 1 diabetes [149]. They observed no difference in HbA_{1c} lowering between patch pumps and conventional tubed pumps [149]. Data on quality of life were not collected, which is a limitation of this study, as patch pump users are widely satisfied with this treatment [150]. Although patch pumps are an exciting new tool in the diabetes armour, there is a need for more robust evidence to guide their use prior to widespread adoption into clinical practice.

Types of cannulas

Insulin pumps are manufactured with either steel or Teflon (polytetrafluoroethylene) cannulas. Teflon catheters are preferentially used in the USA and in Europe, with the exception of Germany, where approximately 40% of the cannulas are steel [151]. There are advantages and disadvantages to both. Steel catheters are easier to insert and are less prone to kinking and dislodgement [151]. They may cause more discomfort, however, particularly during exercise, and may be associated with more bleeding [152]. Auto-insertion devices are not used with steel cannulas, which may be problematic for individuals with needle phobias or issues with dexterity. Furthermore, steel sets need to be changed every two days, whereas Teflon sets require changing every three days [151].

There is a dearth of evidence comparing insulin infusion sets. Patel et al. conducted a randomized open-label crossover study, comparing steel to Teflon catheters in insulin pump therapy in people with type 1 diabetes. In this extended-wear study, where infusion sets were worn until failure or up to one week, there was no difference in their function over seven days, but there was a 15% initial failure rate with the Teflon sets due to kinking [153]. At seven days, both types of infusion sets had a 64% failure rate, with the commonest causes of failure being hyperglycaemia and pain [153]. In an *in vivo* study of the inflammatory tissue response to steel and Teflon cannulas in swine, there was no superiority of one material over another in terms of inflammation [152]. This is important, as Eisler et al. previously demonstrated that tissue inflammatory response directly affects bolus shape and tubing pressure in large swine receiving continuous insulin delivery via Teflon infusion sets [154].

Although Teflon cannulas appear to be more popular than steel at the moment, the evidence is equivocal in favour of or against either material. As steel cannulas are cheaper and associated with fewer set failures, people should be offered a choice of cannula, unless there is a clear predisposing reason to opt for one over the other [151].

Insulin pump-associated adverse events

The most common insulin pump-associated adverse events include pump malfunction, infusion set blockage, site issues, and cutaneous problems. These adverse events predispose the person with diabetes to developing hyperglycaemia and ketosis [155]. Adverse events occur in 40% of pump users per year and a small proportion require hospital admission as a result [155]. There are no clear predictors of pump-associated adverse events, although longer duration of pumping may be protective [156]. There does not appear to be any relationship between pump-associated adverse events and glycaemic levels, socioeconomic status, pump manufacturer, or infusion set type [156, 157].

Pump malfunction or pump failure is common. In a prospective observational study, Guenego et al. analysed all insulin pump defects in a cohort of 350 pump users and found that malfunctions occurred in 68% of pumps [158]. The majority of these (44%) were minor defects, 35% were mechanical defects, but 12% represented complete failures, although hyperglycaemia only occurred in 2.9% of cases [158]. These rates of pump failure are consistent with other studies. In a large Italian cohort of more than 11 000 children and adolescent pump users, 11.8% of pump replacements were due to pump failure [159]. In cases of pump failure or malfunction, the device is often returned to the manufacturer for analysis and replaced with a new pump.

Insulin infusion sets are sometimes referred to as the Achilles' heel of CSII therapy. There are numerous types of insulin infusion sets, which vary depending on the angle of insertion into the skin, the length of the cannula, the tubing material, and the length of the tubing [147]. Technical issues arising from insulin infusion sets may be related to kinking or bending of the cannula, displacement of the attachment on the skin, or occlusion of or leakage from the infusion set. All of these can result in DKA. Using an auto-inserter, ensuring the adhesive is attached correctly, and using additional tape if required can minimize these complications [147]. The presence of subcutaneous lipohypertrophy and the use of insulin infusion sets for longer than the recommended period of time predispose to the development of infusion set-related adverse events [160, 161].

The absence of long-acting basal insulin in pump users contributes to the rapid development of DKA in the event of insulin infusion set failures. The theoretical increased risk of DKA means that CSII therapy was often considered a dangerous treatment regimen for people with type 1 diabetes. However, recent data suggest that DKA rates in pump users are no higher than in those on MDI [162, 163]. In fact, in clinics managing large numbers of people on CSII (>250 individuals), DKA rates were actually lower among CSII users [163]. This is likely due to improved diabetes self-management education. Practical guidance to avoid ketosis is given at initiation of pump therapy, and most individuals are advised to change infusion sets in the case of two consecutive high glucose readings that have not responded to a correction bolus.

Skin reactions in response to CSII are often reported in both paediatric and adult populations with type 1 diabetes. In one study of 111 adults, 64% reported skin problems related to pump therapy,

with itching being the most common complaint. This also led to increased disease burden and emotional distress [164]. High rates of skin irritation by the adhesive tapes contained in the insulin infusion sets have consistently been reported in many other studies [165, 166]. Erythema, pruritus, pain, scars, or lipohypertrophy are some of the other cutaneous complications that have been reported by users of CSII therapy [147]. Inadequate disinfection of the insertion site or infrequent changing of insulin infusion set may predispose to dermatological complications [147].

Intraperitoneal pumps

Continuous intraperitoneal insulin infusion (CIPII) refers to continuous insulin delivery directly into the peritoneal cavity [167]. This mode of insulin delivery more closely mimics physiological insulin secretion, as insulin rapidly enters the portal venous system and therefore the onset of insulin action is faster than with subcutaneous insulin [168]. Intraperitoneal pumps are a valuable option for people with diabetes in whom subcutaneous insulin therapy fails, and can be offered to those with severe subcutaneous insulin resistance, suboptimal glycaemic levels, marked glucose fluctuations, or recurrent severe hypoglycaemia, despite intensive education and follow-up on a subcutaneous insulin regimen [169].

For CIPII, a catheter is placed within the peritoneal cavity and attached to either an insulin pump implanted in the abdominal wall or a percutaneous port that is connected to an external insulin pump. To date, most clinical experience of CIPII has been with implantable pumps and evidence suggests that implantable intraperitoneal pumps significantly reduce glycaemic fluctuations and improve quality of life in people with both type 1 diabetes and type 2 diabetes [169]. Percutaneous port systems such as the Accu-Chek® DiaPort (Roche Diabetes Care, Indianapolis, IN, USA; Figure 33.5) improve quality of life and reduce hypoglycaemia compared to CSII [170]. Infections, insulin underdelivery, and abdominal pain are the most commonly reported complications of CIPII [169, 170]. The increased complication rates, the invasiveness of CIPII, as well as the need to permanently wear an implanted device will likely continue to limit the widespread use of CIPII in the future, particularly as insulin pump and CGM technology continues to improve.

Future prospects

Although huge progress has been made in improving delivery systems for insulin administration over the last 20 years, the future looks bright, with exciting new technologies on the horizon. Glucose-responsive smart insulin systems aim to provide insulin action commensurate to the glycaemic state of the person [171]. Algorithm-based glucose-responsive insulin systems already exist in the form of closed-loop systems with CGM and CSII. Another glucose-responsive insulin is the polymer-based system, in which insulin is encapsulated within a glucose-responsive matrix suitable for subcutaneous injection, which senses ambient glucose concentrations and releases a proportional amount of insulin for systemic absorption [171]. Thus, these matrices are impermeable to insulin in normo- or hypoglycaemic conditions, and the permeability of the polymer increases in response to a rise in interstitial glucose concentrations [171]. Insulin or its formulation can also be manipulated at a molecular level, to confer glucose-dependent activity, and this is another avenue for glucose-responsive insulin design [171, 172].

Transdermal insulin delivery via microneedles can effectively lower glucose levels [173]. The smart insulin patch is made up of glucose-responsive vesicles, consisting of hypoxia-sensitive hyaluronic acid, loaded with insulin and glucose oxidase enzyme [174]. Hypoxia caused by the oxidation of glucose in the hyperglycaemic state promotes the reduction of hyaluronic acid that triggers the dissociation of vesicles and the release of insulin [174]. This patch

has been shown to be effective at regulating glycaemia *in vivo* [174]. Other similar patches, bearing microneedles loaded with insulin and a non-degradable glucose-responsive polymeric matrix, have also proven to function well in mice and swine [175]. Although these glucose-responsive insulin systems are in their infancy in terms of development, they represent promising areas of research towards the functional replacement of the pancreatic β cell.

Conclusion

It is clear that technologies for insulin administration have significantly progressed since the first insulin pen was released over 35 years ago. The development of new technologies facilitates the move towards a more personalized care paradigm, as healthcare professionals can now tailor treatment options to suit the individual needs of the person with type 1 diabetes. Although not without their limitations, insulin pumps reduce hypoglycaemia, modestly improve glycaemic levels, and have positive impacts on quality of life in a number of groups of people with type 1 diabetes. As insulin pump technology continues to evolve, the benefits in these domains are expected to increase, thereby easing the day-to-day burden of diabetes self-management. Identifying which cohorts of people with type 1 diabetes derive the most benefit from advanced diabetes technologies is critical to ensure optimum utilization of healthcare resources. However, if long-term cost-effectiveness can be established, integrated automated insulin delivery systems may well become the standard of care for type 1 diabetes over time.

Whole Pancreas and Islet Cell Transplantation

Braulio A. Marfil-Garza¹, Peter A. Senior^{2,3}, and A.M. James Shapiro²

¹ Department of Surgery, University of Alberta, Edmonton, Alberta, Canada

² Department of Medicine, University of Alberta, Edmonton, Alberta, Canada

³ Clinical Islet Transplant Program, University of Alberta, Edmonton, Alberta, Canada

Key points

- Whole pancreas and islet cell transplantation are robust and safe options for people with type 1 diabetes and persistent problematic hypoglycaemia.
- Whole pancreas and islet cell transplantation improve patient survival and have positive impacts on diabetes-related complications by stabilizing the progression of macro- and microvascular complications.
- Whole pancreas transplantation is associated with higher rates and longer duration of insulin independence compared to islet cell transplantation.
- Whole pancreas and islet cell transplantation provide optimal glycaemic management post-transplant and near complete abrogation of severe hypoglycaemia.
- In islet cell transplantation, graft function is preserved for several years beyond the loss of insulin independence, which results in better glycaemic levels over time.
- Despite improving success with current β -cell replacement therapies, many issues remain, including limited organ/tissue source, challenges with peri-procedural care, and the need for lifelong immunosuppression.

What is the problem?

Diabetes care has undergone one of the most notable revolutions in the history of medicine. Over the last 100 years since the discovery of insulin, our paradigm has evolved from saving lives to optimizing treatment for people with diabetes. Realization that intensive glycaemic management ameliorates the progression of diabetes-related complications in people with both type 1 diabetes (Diabetes Control and Complications Trial and Epidemiology of Diabetes Interventions and Complications cohorts) [1,2] and type 2 diabetes (UK Prospective Diabetes Study) [3] prompted efforts to establish rigorous glycaemic targets (glycated haemoglobin [HbA_{1c}] levels $\leq 7\%$; 53 mmol/mol), which are now advocated for most non-pregnant adults with diabetes [4,5]. While the implications of these targets have been debated, particularly in relation to important patient-related outcomes (e.g. end-stage renal disease, ESRD) [6], optimal glycaemic management remains one of the maxims in diabetes care. This fact has changed the natural history of diabetes and transformed its epidemiological picture. Chronic manifestations of the disease such as nephropathy, neuropathy, or vascular disease have become more common and now occupy a more prominent space in clinical guidelines.

Unfortunately, striving for optimal glycaemic levels is challenging, particularly in type 1 diabetes. Iatrogenic hypoglycaemia is particularly relevant and one of the most consistently reported adverse effects with intensive insulin treatment. Early clinical trials reported a 2–6-fold increase in the incidence of severe

hypoglycaemic episodes [2,3,7], with more than half of these occurring during sleep [7]. An incidence of ~50% in individuals with type 1 diabetes [8] supports the generalized perception that severe hypoglycaemia is limited to type 1 diabetes. However, a meta-analysis reporting a prevalence of severe hypoglycaemic episodes of 23% in individuals with type 2 diabetes treated with insulin [9] highlights the relevance of this issue in both populations. The global burden of hypoglycaemia-related mortality is equally worrisome. While catastrophic scenarios such as *death-in-bed syndrome* remain uncommon [10], a study using the World Health Organization (WHO) mortality database reports a standardized overall proportion of 4.49 deaths due to hypoglycaemia per 1000 total diabetes deaths (range 0.11–283.1) [11]. This makes hypoglycaemia a key barrier for optimal glycaemic management [12].

Despite these numbers, hypoglycaemia remains a relatively neglected complication [13]. It is noteworthy that the 2021 American Diabetes Association's Standards of Care now include a time in range of >70% and below range of <4% when using ambulatory glucose profiles as a key glycaemic goal [5]. This will raise awareness of the importance of addressing glycaemic variability. However, problematic hypoglycaemia (defined as ≥ 2 episodes of severe hypoglycaemia per year or 1 episode + hypoglycaemia unawareness, extreme glycaemic lability, or maladaptive behaviour) demands more individualized management. Current recommendations propose a four-stage tiered algorithm:

1. Structured or hypoglycaemic-specific education programmes.
2. Continuous subcutaneous insulin infusion or continuous glucose monitoring.

3. Sensor-augmented insulin pumps and/or very frequent contact with a specialized hypoglycaemia service.

4. β -cell replacement therapies with either whole pancreas or islet cell transplantation [14].

While β -cell replacement therapies are the last resource, they effectively address the problem; both forms abrogate problematic hypoglycaemia in nearly all individuals while providing optimal glycaemic levels. In this chapter, we will describe whole pancreas and islet cell transplantation, dissect the current clinical evidence, explore the main challenges ahead, and present some potential solutions.

β -cell replacement therapies: a potential solution for diabetes

β -cell replacement therapies are robust alternatives to treat difficult-to-manage diabetes and problematic hypoglycaemia that persists despite conventional therapies. They have undergone significant refinements, and outcomes have improved substantially since their inception. Figure 34.1 depicts the growth of research in the field and provides historical context. Before the discovery of insulin, a relationship between the pancreas and diabetes, which was first identified by Von Mering and Minkowski in 1892, had already driven several attempts to reverse diabetes through pancreatic tissue transplantation [15]. British surgeons Watson-Williams and Harsant performed the first transplant of fragmented sheep pancreatic tissue to a 13-year-old child with diabetic ketoacidosis in 1894; James Allan followed with xenografts composed of feline pancreatic fragments in another person with diabetes [16]. Charles Pybus was the first to transplant human cadaveric fragmented pancreatic tissue into the subcutaneous space of two male individuals with diabetes in 1916 [17]. Repeated failure to achieve normoglycaemia, likely due to prompt immune rejection (the basis of transplantation immunology was not established until the 1950s), coupled with success with contemporary insulin therapies, led to abandonment of β -cell replacement therapies for a few decades. It was not until the 1960s, when the use of steroids and new immunosuppressants allowed successful renal transplantation, that the interest in both whole pancreas and islet cell transplantation was reinvigorated.

Whole pancreas transplantation

History

Whole pancreas transplantation was first conceived as a complementary procedure to improve the clinical success of kidney transplantation in individuals with ESRD secondary to diabetes. In 1966, Drs Kelly and Lillehei performed the first simultaneous segmental pancreas-kidney transplant on a person with type 1 diabetes at the University of Minnesota. This first attempt allowed complete insulin independence for six days before insulin resistance (probably due to high doses of steroids) and graft pancreatitis (probably due to pancreatic duct ligation) ensued. The patient died two weeks after pancreatectomy from a pulmonary embolism [18]. The second simultaneous pancreas-kidney (SPK) transplant, performed by Dr Lillehei, comprised a pancreaticoduodenal transplant (whole pancreas) with a cutaneous duodenostomy to manage exocrine drainage [19]. Subsequently, iterations of the surgical technique by Drs Lillehei, Lárgiader, and Idezuki, such as enteric drainage

through a Roux-en-Y duodenal jejunostomy, enabled graft survival for up to one year post-transplant [19]. Other attempts at whole pancreas transplantation, mostly SPK, were done in the USA, Europe, and South America; however, success was minimal. Only one individual from Dr Lillehei's series of 25 cases reported up to 1970s maintained function for one year post-transplant [20]. Ureteral exocrine drainage, pioneered by Gliedman and colleagues in the early 1970s, improved graft survival (up to 50 months); however, this was ultimately abandoned due to anastomotic leakage [21].

In the 1970s-1980s, segmental pancreatic transplantation was revisited, with two techniques to manage exocrine drainage showing improved outcomes, the open drainage (into the peritoneal cavity) and duct polymer injection. The former, as reported by Dr Sutherland et al. from the University of Minnesota, allowed insulin independence for 18 years; however, some transplant recipients suffered from peritonitis and/or pancreatic ascites [22]. Segmental pancreatic transplantation was later coupled with bladder drainage, pioneered by Dr Sollinger from the University of Wisconsin, which became a very common technique during the 1980s due to the low incidence of complications and the added benefit of offering a non-invasive method to monitor for rejection [23]. Later modifications of this technique, such as duodeno-cystostomy, implemented as part of a whole pancreatic transplantation procedure, became popular in the late 1980s; nearly 90% of pancreatic transplantation had bladder drainage during that period. However, a high incidence of urinary tract infections, reflux pancreatitis, and metabolic abnormalities (e.g. acidosis) demanded surgical conversion to enteric drainage in many cases, which led to a relative abandonment of this technique [20].

Enteric drainage is now the preferred approach, with as many as 90% of whole pancreatic transplants having enteric exocrine drainage [24]. Venous drainage is an interesting issue. To replicate physiology, portal drainage was initially explored. However, it was not widely adopted, and because of technical complexity and no clear metabolic benefits, only ~8–20% of transplant are managed with this approach currently [24]; most individuals undergo systemic venous drainage to the common and/or external iliac vessels or the distal vena cava.

Following relative standardization of the surgical techniques, the issue of immunosuppression became central for long-term clinical success. Professor Sir Roy Calne and colleagues first reported the use of cyclosporine A as a successful agent for immunosuppression following whole pancreatic transplantation. He was also the first to describe portal vein drainage in pancreatic transplantation. Combination with steroids was advocated by Dr Starzl's group to reduce cyclosporine A-induced nephrotoxicity; triple therapy with cyclosporine A, steroids, and azathioprine was later introduced by Dr Sutherland's group [20]. Successful clinical trials with tacrolimus by Dr Starzl led to its widespread use as maintenance immunosuppression [20]. In the mid-1990s, mycophenolate mofetil (MMF) was then introduced [24]. Induction immunosuppression regimens involving T-cell depletion, such as anti-thymocyte globulin (ATG), and steroids were introduced in the late 1990s to prevent early rejection.

Procedural considerations

Today, the typical whole pancreas transplant occurs in a person with type 1 diabetes (~90%), older than 30 years (~90%), with ESRD, and comprises an SPK (~84%) with enteric exocrine (91–92%) and systemic venous (~80%) drainage [24]. Whole pancreas transplantation is a major surgery demanding expertise in

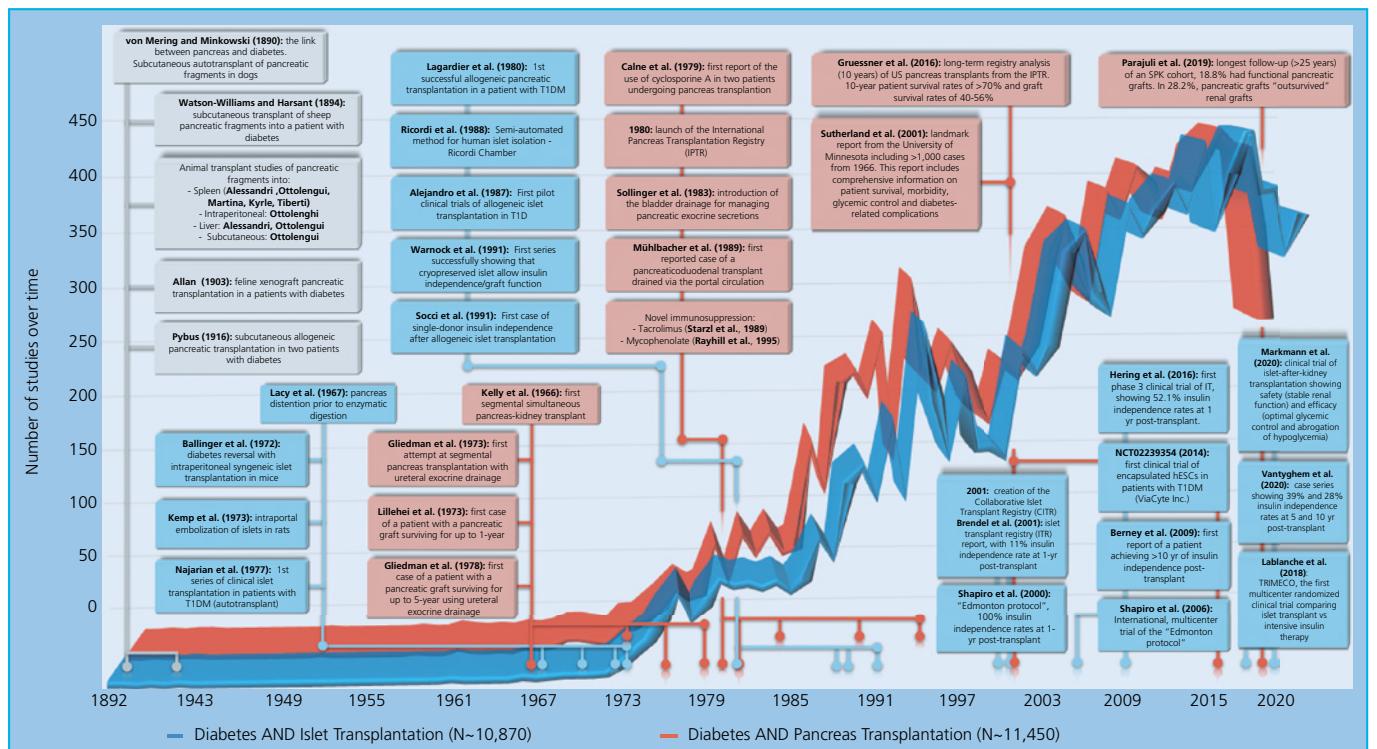

Figure 34.1 Growth of the field and timeline to clinical success. A non-systematic search in PubMed for publications using the terms (islet transplant* OR pancreas transplant*) AND diabet* up to 1 January 2021. Additionally, we included several key historical studies, despite their not appearing in the original search, due to their relevance.

perioperative management, thus >70% of the transplants are done in high-volume centres. Donor selection is a key consideration for a successful whole pancreas transplantation. The *ideal* pancreatic graft would come from a young (<50 years old) and lean (normal body mass index, BMI) donor.

A detailed description of the surgical technique is beyond the scope of this chapter, but several considerations are worth highlighting. Whole pancreas transplantation carries the greatest risk of graft thrombosis among abdominal transplants, which is the most common cause of early graft loss (5–10%). Thus, careful consideration of surgical aspects such as optimal vessel mobilization (i.e. use ofatraumatic vascular clamps, proper length venotomy and arteriotomy, proper suture technique) and flexibility to choose the optimal site of vascular anastomosis are all important details. Importantly, while systemic anastomosis is the preferred method for venous drainage (largely due to less complex dissection being required), the jury is still out on the superior metabolic and potential immunological benefits of the portal venous drainage approach [25].

A final comment concerns immunosuppression. Compared to islet cell transplantation, T-cell-depleting agents (i.e. ATG) are the most commonly used agents for induction immunosuppression in whole pancreas transplantation (68% of cases) [24]. Stronger, more specific, and more expensive immunosuppressants, such as basiliximab or alemtuzumab, have not consistently shown clinical benefit when compared (even in a randomized fashion) with ATG [26]. For maintenance immunosuppression, the preferred regimen comprises tacrolimus, MMF, and prednisone (\pm tapering/withdrawal); however, a shift towards steroid-free immunosuppression has been advocated recently, particularly by high-volume centres [24]. This practice remains controversial, as a consistent clinical benefit has not been observed [27].

Indications

Most whole pancreas recipients have type 1 diabetes, but this procedure has also been undertaken in individuals with type 2 diabetes. There are three main types of whole pancreas transplantation: simultaneous pancreas-kidney (SPK), pancreas-after-kidney (PAK), and pancreas-alone (PTA) transplants. Hence, some of the indications, although overlapping, may differ with each of these procedures (Table 34.1). In broad terms, SPK is recommended for individuals with severe diabetes and ESRD (estimated glomerular filtration rate [eGFR] <20 ml/min/1.73 m²); PAK is usually recommended as a sequential procedure when recipients of a kidney transplant have a viable living kidney donor identified, but a deceased pancreas has not been identified; PTA is recommended for individuals that have frequent, acute, and severe complications of diabetes, such as ketoacidosis and hypoglycaemia with or without hypoglycaemia unawareness [28].

Islet cell transplantation

History

In the early 1960s, Dr Paul Lacy and his team at the Washington University School of Medicine inaugurated the modern era of islet transplant research by championing a paradigm shift in the field: separation of the endocrine and exocrine components of the pancreas and islet purification. Building on early ideas from Leonid W. Sobolew and the pioneering works of Drs Helleström and

Table 34.1 Indications and contraindications for β -cell replacement therapies.

Indications

- People with type 1 diabetes (typically with duration >5 yr)
- People with type 2 diabetes may be candidates for a whole pancreas transplantation if they have the following conditions:
 - Low exogenous insulin requirement
 - BMI <30 kg/m²
 - HbA_{1c}>7.5–8.0% (58–64 mmol/mol) despite expert diabetes management (including endocrinologist/diabetologist and diabetes educators)
 - Problematic hypoglycaemia (≥ 2 episodes/yr of severe hypoglycaemia) despite optimal diabetes management with insulin pump and adequate monitoring by an endocrinologist/diabetologist and diabetes educators
 - At least one episode of severe hypoglycaemia in the past year, defined as blood glucose <54 mg/dl (3 mmol/l) plus one of the following symptoms: memory loss, confusion, behavioural changes, impaired consciousness, seizure, or visual symptoms, in which the person was unable to treat themselves and which resolved after carbohydrate intake or glucagon administration.
 - Evidence of impaired awareness of hypoglycaemia and/or extreme glycaemic lability using objective scores, such as the Clarke score (≥ 4), HYPO score (≥ 1000), or lability index (≥ 400), among others.
 - A composite of Clarke score ≥ 4 + HYPO score ≥ 75 th percentile (≥ 423) + lability index ≥ 75 th percentile (≥ 329) may also be used
 - Major fear of maladaptive behaviour related to hypoglycaemia may also be considered
 - Recurrent episodes of diabetic ketoacidosis and/or severe, rapidly progressing complications of diabetes may also be considered
 - Candidates for either a simultaneous pancreas–kidney or islet–kidney transplant should meet criteria for a kidney transplant alone

Contraindications

- Age >60 yr
- This is an absolute contraindication for whole pancreas transplantation and a relative contraindication for islet cell transplantation
- BMI >30 kg/m² (28 kg/m² may be preferred for whole pancreas transplantation)
- Insulin requirements >1.0 U/kg/d or HbA_{1c}>10.0% (86 mmol/mol)
- High insulin requirements and/or HbA_{1c} levels are not a contraindication for whole pancreas transplantation
- Untreated proliferative retinopathy
- High cardiovascular risk (threshold for a prohibitive cardiovascular risk may be lower for whole pancreas transplantation)
 - Uncontrolled hypertension
 - Myocardial infarction within 6 mo
 - Evidence of ischaemia on functional cardiac testing in the previous year
 - Left ventricular ejection fraction <30%
- History of malignancy
 - Completely resected squamous or basal cell carcinoma of the skin is not a contraindication
- Untreated infection (including viral infections, such as hepatitis B or C and HIV)
 - History of opportunistic infections such as aspergillus, histoplasmosis, or coccidioidomycosis in the previous year
- Inability to comply with immunosuppression and proper follow-up
- Any medical (including psychiatric) condition that could interfere with safe participation and follow-up post-transplant

BMI, body mass index; HbA_{1c}, glycated haemoglobin.

Moskalewski using manual pancreatic dissection [32] and the use of collagenase [33], respectively. Dr Lacy's team introduced the two-step islet isolation process using intraductal pancreatic distension to dissociate the tissue and islet purification using discontinuous density gradients (e.g. Ficoll®, Pharmacia & Upjohn, Kalamazoo,

MI, USA) [16]. This became the gold standard for rodent islet isolation. Having access to pure and functional islets led to successful transplantation studies and diabetes reversal in murine models [34]. The conditions for the first clinical trials were met when Drs Kemp and Lacy established the superiority of intraportal (compared to intraperitoneal) infusion for islet cell transplantation [35]; this remains the gold standard in the clinic [36].

In the late 1970s, Dr John Najarian and colleagues at the University of Minnesota were the first to demonstrate that insulin independence could be achieved with intraportal islet infusion (auto-transplantation) [37,38]. In 1980, Drs Largiadèr, Kolb, and Binswanger at Zurich University reported the first case of insulin independence (~10 months) in an individual with diabetes following allotransplantation of pancreatic microfragments (~200 000 islets) into the spleen [39]. Subsequent clinical success was hampered by impure islet preparations and suboptimal immunosuppression, which led to infusion of low islet masses and complications (e.g. thrombosis) and prompt immune rejection [40]. Thus, islet isolation techniques were revisited. Intraductal collagenase perfusion of the pancreas, coupled with gentle mechanical dissociation and density gradient purification, was introduced by Drs Warnock, Rajotte, and colleagues at the University of Alberta [41,42]. This approach yielded high-purity islet preparations (>90%) and enabled high rates of post-transplant normoglycaemia after a single-donor islet transplant in dogs [41]. Shortly thereafter, these researchers reported on a 36-year-old person with type 1 diabetes who achieved sustained (at least five months) insulin independence after receiving an islet graft composed of both fresh and cryopreserved islets with 75% purity; such purity enabled high doses (>10 000 islets/kg) without any complications [43,44].

The biggest breakthrough came with the introduction of the *automated* method for islet isolation, designed and implemented by Dr Camillo Ricordi while working in Dr Lacy's laboratory. As stated in his 1988 paper [45], the automated method met the following requirements:

1. Minimal traumatic action on the islets.
2. Continuous digestion in which the islets that are progressively liberated can be saved from further enzymatic action.
3. Minimal human intervention in the digestion process.
4. High yield and purity of the isolated islets.

This method swiftly became the standard for human islet isolation all over the world. A few years later, Dr Scharp and colleagues reported on the first person with type 1 diabetes achieving transient insulin independence using the automated method [46]. The same year, a case series of six individuals with type 1 diabetes treated with islet cell transplantation using the automated method for islet isolation was reported by Dr Socci and colleagues from the San Raffaele Institute of Milan, Italy. Notably, this series included the first person to achieve transient insulin independence after islet cell transplantation from a single donor [47]. Further additions to islet isolation protocols included semi-automated density gradient separation using the Cobe® IBM 2991 cell separator (IBM Systems Development Division, Endicott, NY, USA) by Lake et al. [48], cold preservation solutions by Olack et al. [49], and techniques for islet staining by Latif et al. [50], which ultimately led to standardization of reporting on islet preparations (i.e. numbers, mass, viability, etc.), which was greatly required to allow meaningful comparisons of results between centres [51]. While optimization of the islet isolation process remains an ongoing effort in the field, advances up to now have enabled infusion of pure and large islet masses (up to

1 000 000 islets). However, the lack of long-term clinical success in the late 1990s shifted the focus towards improving immunosuppression and peri-transplant care.

In 1997, Secchi et al. reported that induction immunosuppression with steroids and ATG, coupled with maintenance immunosuppression using azathioprine, cyclosporine A, and steroids, as well as peri-transplant use of insulin, allowed insulin independence rates of 35% after intraportal islet cell transplantation in individuals with 'insulin-dependent diabetes mellitus' [52]. Researchers at the University of Miami, using OKT3 (anti-CD3) as induction agent (instead of ATG), reported graft survival rates of up to six years post-transplant in two of six individuals [53]. Unfortunately, by the end of the 1990s, the global clinical experience was not encouraging. By 2000, the Islet Transplant Registry, which included information on 237 allotransplants, reported a one-year insulin independence rate of 11% [54]. Importantly, a milestone in the field was achieved that year with the Edmonton Protocol, carried forward by a team led by James Shapiro at the University of Alberta. By using large numbers of fresh islets (>11 000 islet equivalents [IEQ]/kg) and a steroid-free immunosuppression regimen based on daclizumab (anti-interleukin [IL]-2 antibody), sirolimus, and tacrolimus, this protocol was the first to achieve 100% one-year insulin independence rates in seven consecutive non-uraemic individuals with type 1 diabetes [55]. The Edmonton Protocol reinvigorated research in the field, inaugurated the new era of islet cell transplantation, and motivated many countries to start islet cell transplantation programmes. Clinical outcomes after the Edmonton Protocol will be discussed later.

Procedural considerations

The pathway towards a successful islet cell transplantation differs when compared to whole pancreas transplantation and other organs. In addition to obtaining a viable organ, islet cell transplantation requires pancreas processing and islet isolation. This process is done by tissue specialists at dedicated facilities, following good manufacturing practices (Figure 34.2) [57]. Importantly, the efficiency and success of islet isolation (adequate number, quality, purity, viability) are variable and heavily dependent on the skills of the isolation team. Following islet isolation, suitable preparations are infused into the intraportal circulation of the recipient through percutaneous transhepatic access. This procedure is typically done using procedural sedation and through fluoroscopic guidance by interventional radiologists. After confirming proper positioning of the catheter with a portal venogram, the islets are infused using a closed gravity-fed bag [58]. The use of heparin to prevent the instant blood-mediated inflammatory response and portal vein thrombosis together with a peri-transplant insulin infusion to maintain euglycaemia and promote β -cell rest following transplantation is a key component of most islet cell transplantation protocols [59]. These interventions are modified to subcutaneous low molecular-weight heparin and aspirin, as well as subcutaneous insulin, 48 hours after transplant.

In terms of immunosuppression, the original Edmonton Protocol has been modified in many centres around the world, including the Edmonton site itself. Current induction immunosuppression either uses agents to prevent activation of lymphocytes – anti-CD25 (IL-2 receptor α -chain) blockers such as daclizumab, basiliximab – or lymphodepletion agents – ATG (horse or rabbit derived), anti-CD52 blockers (alemtuzumab) – or anti-CD3 blockers (OKT3, teplizumab); some centres include steroids in their induction immunosuppression regimens. These are usually combined with

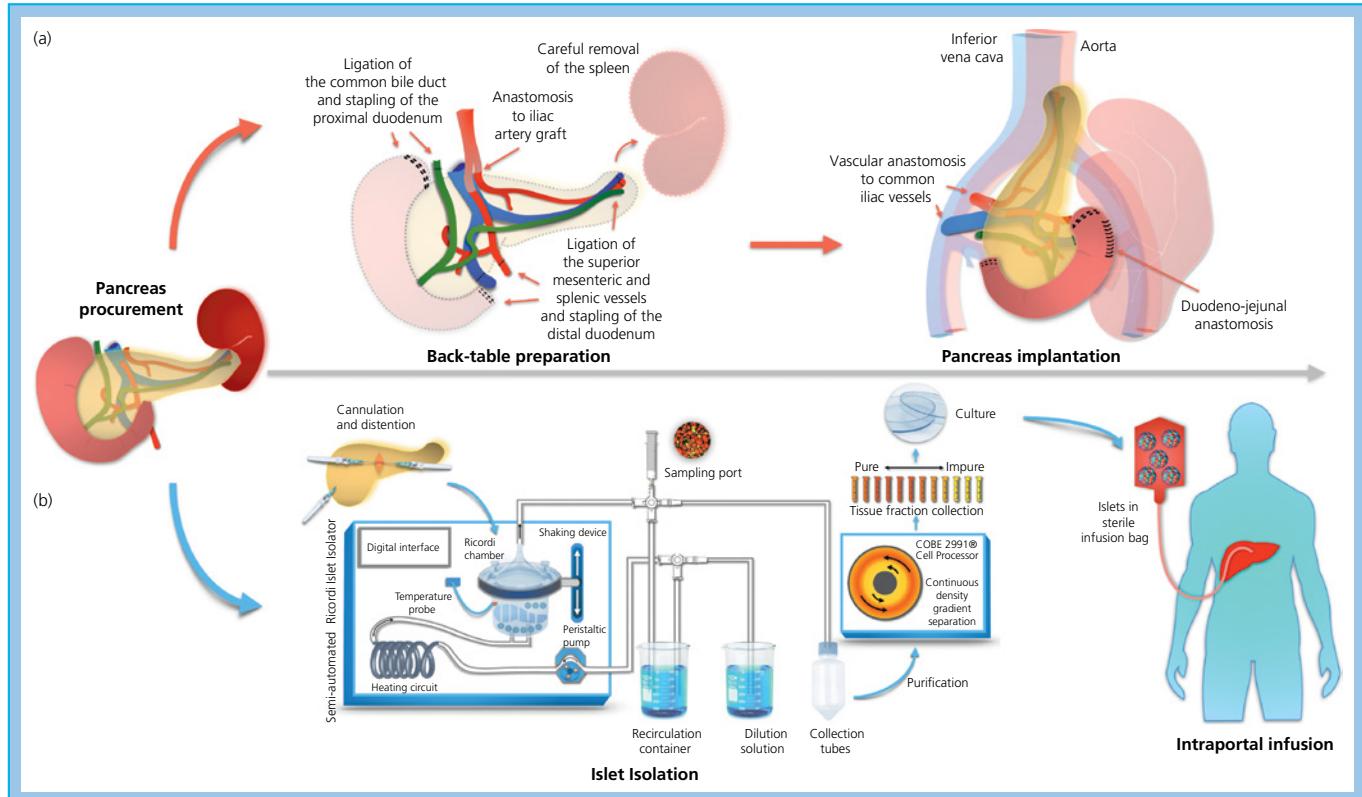

Figure 34.2 Pancreas and islet cell transplantation procedures. (a) Pancreas transplantation. The pancreas graft is removed *en bloc* with the duodenum and spleen to prevent injury to the proximal and distal pancreas. During cold-phase dissection, the portal and superior mesenteric veins, as well as the gastroduodenal, splenic, and superior mesenteric arteries, are carefully identified, ligated, and divided individually. During back-table preparation, the spleen, peri-pancreatic tissue, and fat are removed carefully to avoid parenchymal injury to the pancreas. The duodenal segment is shortened by stapling proximally and distally. The splenic and superior mesenteric vessels are ligated, as well as the common bile duct. Vascular reconstruction is performed with the donor iliac artery bifurcation as a Y-graft to provide single inflow to the splenic and superior mesenteric arteries. No extension graft is used for the portal vein due to a higher risk of thrombosis. Integrity of the vascular arcade is tested with fluid flush. The prepared graft is implanted in the right iliac fossa. The diagram shows vascular anastomosis to the common iliac vessels and a duodeno-jejunal anastomosis for exocrine drainage, but these may vary by centre. (b) Islet cell transplantation. Islet isolation starts with processing of the resected pancreas (i.e.

resection of the spleen, duodenum, and peri-pancreatic fat). Following exposure through an incision of the pancreas mid-body, the main pancreatic duct is cannulated with two catheters, directed at the head and tail of the pancreas; flow through the major papilla is blocked with a third catheter. Distension of the pancreas is achieved by infusing cold collagenase through the catheters using a perfusion machine. After distension, the pancreas is sliced and introduced in the Ricordi chamber for enzymatic and mechanical digestion. Enzymatic digestion is achieved by activating the collagenase (warming to ~36 °C); mechanical digestion occurs by introducing silicon nitride/metal marbles inside the chamber and shaking of the chamber. The solution is recirculated until the pancreas is appropriately digested, which is assessed by taking samples at different time points and staining them with the zinc-binding dye dithizone. When deemed appropriate, the solution is diluted to stop enzymatic activity and the tissue is then purified using a cell processor and continuous density gradient centrifugation. The purest tissue fractions are harvested for culture and, subsequently, transplantation. Source: The islet isolation diagram is modified from Marfil-Garza et al., 2021 [56].

anti-inflammatory agents such as tumour necrosis factor (TNF)- α (etanercept, infliximab) and/or IL-1 (anakinra) inhibitors [60]. Current maintenance immunosuppression regimens include combinations of calcineurin inhibitors (tacrolimus, cyclosporine A), mammalian target of rapamycin (mTOR) inhibitors (sirolimus, everolimus), and/or MMF. Strategies to improve islet survival, engraftment, and avoid immune rejection will be discussed later.

Indications

Lifelong immunosuppression post-transplant has been associated with toxicity and adverse effects, such as opportunistic infections and neoplasms. Arguably, this issue represents the major limitation for the generalized use of islet cell transplantation in every person with diabetes. Thus, in its current state, islet cell transplantation is limited to individuals with type 1 diabetes suffering from refractory problematic hypoglycaemia and/or impaired awareness of hypoglycaemia [14], in which the perceived benefits for quality of life [61] and survival [62], compared to no transplant, outweigh the risks related to the procedure and lifelong immunosuppression. For those with functioning renal transplants, already committed to lifelong immunosuppression, the risk–benefit ratio is simpler. Regarding selection of the individual, recent recommendations by the TREPID working group and the International Pancreas and Islet Transplant Association (IPITA)/European Pancreas and Islet Transplant Association (EPITA) opinion leader workshop include accounting for physiological age, weight, cardiovascular risk, the presence of diabetes-related chronic complications, previous organ transplantation (and sensitization state), current use of immunosuppression, and, importantly, the person's capacity to deal with hypoglycaemia [29,30].

A synthesis of current indications and contraindications for islet cell transplantation is presented in Table 34.1. It should be emphasized that specific instruments to assess severity of hypoglycaemia, glycaemic lability, and impaired awareness of hypoglycaemia, such as the HYPO score [63], lability index, glucose coefficient of variation, and Clarke and Gold scores [64], may help to complement clinical assessment and decide on eligibility for islet cell or whole pancreas transplantation and to define appropriate patient-centred outcomes and realistic expectations [30]. However, they should not represent the main and only strategy for selection of individuals.

Clinical outcomes: state of the art

Whole pancreas transplantation

Survival and morbidity

Advances in surgical techniques, peri-transplant care, and immunosuppression have improved patient survival and decreased morbidity following whole pancreas transplantation. Currently, the three-year survival rate of SPK, PAK, and PTA is 95%, 93%, and 96%, respectively [24]. Reports with longer follow-up show a 10-year survival rate of ~76%, ~72%, and ~82% for SPK, PAK, and PTA, respectively [65]. Interestingly, while it is clear that SPK confers a survival benefit when compared to remaining on the waiting list [66–69] or to kidney transplant alone (living or deceased donor) [70], there is controversy over PAK and PTA.

Studies looking at the United Network for Organ Sharing (UNOS) and the International Pancreas Transplant Registry (IPTR) databases found no overall survival benefit following PAK compared to remaining on the waiting list; however, restricting the

analysis to follow-up beyond one year showed a benefit for survival (hazard ratio [HR] 0.18, 95% confidence interval [CI] 0.13–0.25) [68]. In contrast, a more recent study found that PAK conferred no survival benefit at 5–10 years (HR 1.07, 95% CI 0.84–1.37) [67]. For PTA, the same report with UNOS/IPTR data found no overall benefit for survival, however, restricting the analysis to follow-up beyond one year showed a survival benefit (mortality HR 0.15, 95% CI 0.08–0.29) [68]. One study showed that PTA added 2.4 life-years compared to remaining on the waiting list [69]. Conversely, more recent studies have shown no survival benefit with PTA [71]. Importantly, specific analysis considering pancreatic graft status in both PAK and PTA populations was not done with these studies and is needed, as there is evidence from the SPK population that benefits for survival seem to be conditional on pancreatic and kidney graft survival [24,70]; naturally, kidney graft survival may be more strongly associated with survival rate [24,72].

Studies showing improvement in average life-years saved and quality-adjusted life-years using probabilistic simulation models [73] strengthen the case for SPK in individuals with severe diabetes and ESRD as a more cost-effective strategy compared to kidney transplant alone. Finally, the decision to move forward with whole pancreas transplantation should be weighed against the higher 90-day post-transplant mortality rates for all pancreas transplantation categories, compared to individuals on the waiting list [67].

Glycaemic management and graft survival

Currently, the three-year pancreatic graft survival rates are 86.9%, 78.8%, and 74.0% for SPK, PAK, and PAT, respectively [24]. Reports with longer follow-up show a 10-year pancreatic graft survival of ~55%, ~38%, and ~35% for SPK, PAK, and PTA, respectively [65]. These numbers are somewhat representative of the rates of insulin independence post-transplant, given that one of the definitions for graft failure in whole pancreas transplantation includes a return to insulin. Thus, considering that individuals are insulin independent, optimal glycaemic levels as well as complete abrogation of severe hypoglycaemic episodes are expected as long as the pancreatic graft is surviving. Indeed, people with a failed pancreatic graft seem to lose all benefit in terms of glycaemic indices and incidence of symptomatic hypoglycaemia [74]. Interestingly, impaired glucose tolerance may be observed after 10 years of follow-up in ~50% of cases, even when only evaluating *functional* pancreatic grafts [75]; the clinical impact of these findings (i.e. diabetes-related complications) remains unknown.

Several risk factors may correlate with graft failure, such as low-volume centre, older age, BMI >30 kg/m², use of dialysis pre-transplant, enteric drainage, immunological status pre-transplant (panel reactive antibodies [PRA] >20%), non-depleting induction immunosuppression, and the use of maintenance immunosuppression regimens other than tacrolimus + MMF + steroids [24,76]. The duration of diabetes is also a determinant of graft survival, with slightly better rates of graft survival reported for those with long-standing (>20 years) type 1 diabetes, particularly for persons undergoing SPK [76]. Interestingly, rates of graft survival, as well as glycaemic levels, are similar between people with type 1 diabetes and type 2 diabetes [77]. This, coupled with the fact that whole pancreas transplantation seems to be associated with a low rate of type 1 diabetes recurrence (~7%) [78], suggests that alloimmunity is the predominant determinant of graft survival. However, conversion from a negative to a positive autoantibody status possibly confers a

lower probability of graft survival over time [79]. Currently, the benefits of monitoring either allo- and autoantibody status post-transplant are not clearly established.

Diabetes-related complications

Retinopathy

Early reports comparing successful to failed whole pancreas transplants showed no difference in progression of retinopathy, for both PTA [80] and SPK [81, 82]. Importantly, most individuals had previous laser photocoagulation and their degree of retinopathy remained stable. Later, a study comparing successful SPK to failed SPK or kidney transplant alone showed improvement in visual acuity and stabilization of retinopathy in the former group for up to three years of follow-up [83]. Although ~80% of the individuals had laser photocoagulation before transplant, the need for further laser therapy was decreased in the successful SPK group versus the failed SPK or kidney transplant alone group [83]. When compared to conventional insulin therapy, PTA seems to ameliorate progression and/or improve retinopathy in people with non-proliferative retinopathy and stabilize progression in those with proliferative retinopathy [84]; however, the benefits on stabilization of proliferative retinopathy seem to be more pronounced in the SPK population [85].

A recent large study looking at retinopathy after whole pancreas transplantation (mean follow-up of 4.2 years) suggests that, in almost 80% of cases, retinopathy remains stable. Interestingly, 92% of those who progressed did so within one year post-transplant (early worsening) [86]. These authors identified baseline degree of retinopathy, recent (<1 year) treatment with photocoagulation, and PTA as risk factors for early worsening [86]. Another recent study looking at individuals who underwent SPK and had a surviving graft for >25 years reported stabilization of retinopathy in 90 of the individuals, but there was comparative analysis with individuals with a failed graft [87]. Importantly, most individuals undergo whole pancreas transplantation late in the course of their disease have some degree of retinopathy at the time of transplant (~90–100%) and the majority have laser-treated and/or proliferative retinopathy [84, 86]. Initially close and then ongoing monitoring of retinopathy after transplant seems prudent, since the benefit of whole pancreas transplantation may be more related to stabilization rather than improvement or reversal of retinopathy, particularly for individuals with proliferative retinopathy.

Neuropathy

Up to 80–100% of people undergoing whole pancreas transplantation have signs of peripheral neuropathy [22, 88, 89]. However, neuropathy after whole pancreas transplantation has been relatively understudied and, overall, there is a lack of recent reports [22]. A study comparing people with successful versus failed SPK showed rapid and longlasting recovery of neurophysiological measurements such as nerve conduction velocity and amplitude; however, no significant differences were observed compared to control individuals [88]. The classic reports from the University of Minnesota group, which compared successful whole pancreas transplantation with control groups (including failed whole pancreas transplantation and individuals on the waiting list), showed improvement and/or stabilization in nerve conduction studies in the whole pancreas transplantation group. More importantly, these findings also translated into a *clinical benefit*, which was mainly driven by a lack of deterioration in neurological examination scores compared to

controls [89, 90]. Studies including people undergoing PTA also showed improvement in neurophysiological measurements and neurological examination scores [91]. Correlation of this latter outcome with patient-important outcomes, such as decreased pain, numbness, or complete sensory loss, remains undetermined and should be explored in the future.

Autonomic neuropathy, which has significant impacts on quality of life, has also been understudied. Several measurements of autonomic neuropathy, such as vasomotor function (e.g. capillary vasoconstriction responses), cardiac function (e.g. heart rate variability), and gastric function (e.g. gastric emptying), have been reported to improve after whole pancreas transplantation compared to kidney transplant alone [92, 93]. A recent study on SPK long-term survivors reported improvement or stabilization of gastroparesis in 75% of the individuals [87]. Importantly, improvements in autonomic neuropathy have been correlated with improvement in quality of life [93] and hypoglycaemia symptom recognition [94], albeit more studies would strengthen these notions.

Nephropathy

The combined percentages of SPK (84%) and PAK (8%) somewhat reflect the prevalence of kidney disease in candidates for whole pancreas transplantation [24]. As such, two potential *renal* outcomes post-transplant emerge: kidney graft survival/function and native kidney function. For the first outcome, studies have shown that in individuals undergoing SPK, a surviving pancreatic graft confers a survival benefit for the kidney graft [95]; however, this is only observed when compared to individuals receiving a deceased-donor kidney graft [96]. For those undergoing PAK, a surviving pancreatic graft confers a survival benefit for the kidney graft, even when compared to people receiving a living-donor kidney graft. Interestingly, a living-donor kidney graft also improved the rates of pancreatic graft survival compared to a deceased-donor kidney graft [67].

As for the second outcome, early studies showed that normoglycaemia after successful PTA could reverse histological lesions in established diabetic nephropathy after 10 years of follow-up [97]. Later, studies comparing PTA with intensive insulin therapy showed improvement of proteinuria and no significant changes in creatinine clearance [98], which in the context of immunosuppression constitutes a favourable outcome. A large case series by Boggi et al. confirmed that proteinuria improved after PTA, with 54% of persons with macroalbuminuria at baseline reversing to either microalbuminuria (18%) or normal (36%) [92]. These authors reported that those with an eGFR >90 ml/min had a faster and more pronounced deterioration in renal function (~4.9 ml/min/yr vs ~2 ml/min/yr in those with <90 ml/min at baseline, p<0.05), possibly due to correction of hyperfiltration [99]. Regarding onset of ESRD after PTA (i.e. need for dialysis or kidney transplantation), large studies have shown a five-year cumulative incidence of 3.5%, 12.2%, and 26.0% and a 10-year cumulative incidence of 21.8%, 29.9%, and 52.2% in individuals with a baseline eGFR of >90, 89–60, and <60 ml/min/1.73 m², respectively [100].

A recent report assessing different cohorts (Joslin Clinic, Finnish Diabetic Nephropathy Study, Steno Diabetes Center Copenhagen, and Institut national de la santé et de la recherche médicale [Inserm]) shows a similar 10-year cumulative incidence of ESRD in non-transplanted people with type 1 diabetes and earlier stages of chronic kidney disease (16.5–31.1%); higher incidence rates with more advanced disease were also observed [101]. However, the effects of PTA on renal function are still debated, and

nephrotoxicity secondary to immunosuppression should be considered. Diabetes is also a risk factor for ESRD post-transplant [102], thus the combination of immunosuppression and diabetes may be particularly harmful. Nevertheless, this remains controversial, as large studies in non-renal solid organ transplants have shown an overall five-year cumulative incidence rate of ESRD as high as 18.1% and 21.3% for liver and intestine transplantation, respectively [102], which compares similarly to PTA. Overall, the decision to proceed with PTA should be weighed against the adverse effects of lifelong immunosuppression, among which nephrotoxicity is central, particularly with calcineurin inhibitors.

Cardiovascular disease

Cardiovascular disease and risk factors are highly prevalent in candidates for a whole pancreas transplant. In a large study, 51.8–79.5% had hypertension, 4.1–4.9% had peripheral vascular disease, 1.9–4.1% had a prior coronary bypass, 3.8–5.4% had a prior coronary intervention, 1.8–2.1% had valvular disease, and 0.8–1.1% had a pulmonary circulation disorder at baseline [103]. SPK has the highest prevalence, followed by PAK and PTA [22]. The prevalence of coronary artery disease observed with coronary angiography is substantially higher (~50–70%) [104–107]. The presence of cardiovascular disease at baseline confers a worse prognosis in terms of person and graft survival [22]; however, studies have shown that whole pancreas transplantation stabilizes and/or improves disease markers such as carotid intima-media thickness [108, 109], left ventricular function [110, 111], low-density lipoprotein (LDL) cholesterol [91, 99], triglycerides [109, 111], inflammatory and pro-thrombotic factors (i.e. homocysteine, von Willebrand factor, D-dimer, etc.) [109], and endothelial dysfunction [109]. More importantly, the incidence of person-centred outcomes, such as cardiovascular death and/or major adverse cardiovascular events (i.e. fatal or non-fatal myocardial infarction or stroke), is lower in those undergoing whole pancreas transplantation when compared to kidney transplant alone, both deceased donor [111–113] and living donor [114], as well as individuals on the waiting list [111, 113]. The benefit seems to be mostly observed for SPK, and somewhat dependent on pancreatic graft survival [114]. In contrast, the evidence for PAK and PTA in terms of important cardiovascular outcomes is inconclusive [22, 114]. Analyses including graft status in these two latter populations could shed more light on these important matters.

Islet cell transplantation

Survival and morbidity

Islet cell transplantation is one of the safest transplants in terms of person survival. The latest report from the Collaborative Islet Transplant Registry (CITR), which gathers clinical data from allogeneic islet cell transplantation from centres all over the world, reports a five-year survival rate of 98.4% [115]. Single-centre studies have reported a mortality rate of 0.3–1.0% per 100 person-years [116, 117]. While morbidity and transplant-related adverse effects are fairly common, a substantial decrease in serious events related to infusion or immunosuppression has been observed, from ~20.0% in the early eras (1999–2002) to ~7% in most recent eras (2011–2014) [115]. Similar to SPK, studies suggest that a simultaneous islet–kidney transplant (SIK) confers a survival benefit compared to both individuals having a kidney transplant alone and those on the waiting list [62]. Importantly, islet cell transplantation substantially improves health-related

quality of life [61, 118]. However, samples have been typically small and more studies including appropriate control groups and sufficient follow-up are needed.

Glycaemic management and graft survival

Initial excitement following the publication of the Edmonton Protocol was subsequently tempered by reports showing that insulin independence was not usually sustainable over time, with only ~10% of individuals maintaining insulin independence beyond five years [119]. Later, an international, multicentre trial of the Edmonton Protocol reported one-year insulin independence rates of only 44% [120], which highlighted the importance of centre experience in islet isolation and peri-transplant care. However, over the last two decades a steady improvement in outcomes related to insulin independence and graft survival has been observed [121]. The most recent CITR report shows five-year insulin independence rates of ~30% [115], and single-centre studies have recently reported 10-year insulin independence rates of 18–28% [116, 122]. More consistent has been the change in insulin use following islet cell transplantation, with a decrease of ~70% at 5 years and ~50% at 10 years [115, 117].

While insulin independence and reductions in insulin use are highly desirable, evaluating the success of islet cell transplantation around this outcome may underestimate clinical benefit, since the primary goal of islet cell transplantation is to address problematic and recurrent hypoglycaemia. Hence, an appropriate measure of its success would be abrogation or minimization of severe hypoglycaemic episodes. This view coincides with a person-centred approach, and recent position statements and workshops have advocated for this outcome to take an equally central place when evaluating the success of islet cell transplantation [29, 30]. In this regard, >90% of individuals have complete abrogation of severe hypoglycaemic episodes at 5 years post-transplant [115], but rates of 80–100% at 10 years post-transplant have also been reported [117, 123]. Similarly, restoration of awareness of hypoglycaemia is an important outcome after islet cell transplantation. This is a key phenomenon occurring in candidates for islet cell transplantation. Unfortunately, there is controversy regarding the extent of recovery in terms of the counter-regulatory hormonal responses and symptom recognition during hypoglycaemia following islet cell transplantation. Early experience showed no improvement in either measure [124]; however, more recent studies have shown significantly improved awareness of hypoglycaemia after islet cell transplantation [125–128]. This should be further studied in the future. Finally, abrogation of hypoglycaemia cannot occur at the expense of glycaemic levels. In this regard, islet cell transplantation is also effective, with composite outcomes, such as absence of severe hypoglycaemic episodes and $\text{HbA}_{1c} < 6.5\%$ (48 mmol/mol) or 7.0% (53 mmol/mol), depending on the study, being reported in 62.5–87.5%, 58.3–71.0%, 35–55%, and 21.9–36.3% at 1, 2, 5, and 10 years, respectively [115, 123, 128–130]. Finally, most studies show a substantial and sustained improvement in glycaemic management [131, 132].

Diabetes-related complications

Retinopathy

Retinopathy is common in individuals undergoing islet cell transplantation, with ~60% having some degree of retinopathy [115]. Most studies report stabilization and/or improvement of retinopathy after transplant. Two studies comparing islet cell transplantation

to intensive insulin therapy have reported no progression of retinopathy, with those with more severe retinopathy being more protected [133,134]. A case series reports similar outcomes, with one person demonstrating improvement of retinopathy one year post-transplant [135]. Finally, a before versus after study showed an increase in blood flow velocities of central retinal arteries and veins one year post-transplant, although no clinical or person-important outcomes (e.g. the use of laser photocoagulation) were reported [136]. We recommend close ophthalmological follow-up post-transplant, since some people may suffer from vitreous haemorrhage and/or need laser photocoagulation or vitrectomy after islet cell transplantation [119].

Neuropathy

On average, ~30% of persons undergoing islet cell transplantation have peripheral neuropathy [115]. Whether islet cell transplantation has an impact on this outcome remains controversial. Two studies comparing islet cell transplantation to intensive insulin therapy found no significant deterioration of nerve conduction velocities following islet cell transplantation [133,134], while two other studies showed improvement in nerve conduction velocities through time [135,136]. One of these latter studies showed decreased expression of advanced glycation end products and their specific receptor in nerves and perineurial vessels from skin biopsies of people undergoing islet-after-kidney transplantation (IAK) versus kidney transplantation alone [137]. Finally, a study including 21 individuals undergoing IAK showed no deterioration of motor measurements, as well as improvement in sensory measurements at five years post-transplant [138]. Autonomic neuropathy is present in ~20% of people pre-transplant, but the evidence on the impact of islet cell transplantation on this condition is scarce.

Nephropathy

Evaluation of renal function is common in many clinical reports concerning islet cell transplantation. It should be emphasized that, compared to whole pancreas transplantation, most (~80%) individuals undergoing islet cell transplantation do not have ESRD at baseline [115]. Despite optimal glycaemic management during follow-up, some studies have reported a decline in eGFR following islet cell transplantation. In a previous report from our group, we observed a median rate of decline of 0.39 ml/min/1.73 m²/month, although with wide inter-person variability. Additionally, the proportion of those with micro- and macroalbuminuria also increased post-transplant [139]. However, more recent studies have reported lower rates of renal function decline (GFR measured by ^{99m}Tc-DTPA) following islet cell transplantation compared to medically treated individuals [133,134,140]. A recent study reported no statistically significant reduction of eGFR, even after 10 years of follow-up [117].

These conflicting findings may be explained by differences in immunosuppression regimens and baseline renal function. In this regard, the combination of tacrolimus + sirolimus might be more nephrotoxic than tacrolimus + MMF [133,134,140–142]; unfortunately, reports with longer follow-up have introduced some controversy into this notion [117]. Studies directly comparing these two regimens are lacking and further research is needed. Renal function status should be considered in the selection process for islet cell transplantation, and particularly in decisions regarding immunosuppression regimens and post-transplant care.

Cardiovascular disease

While islet cell transplantation may be the preferred treatment modality in individuals with a high burden of cardiovascular disease, the prevalence of coronary artery disease, cerebrovascular disease, and peripheral vascular disease according to the latest CITR report is <10%, <3%, and <5%, respectively [115]. These low numbers might be due to underreporting, since there are studies reporting that ~43% of asymptomatic islet cell transplantation candidates have evidence of coronary artery disease on angiography [143]. Additionally, these low numbers may be driven by the fact that most individuals undergo islet-transplant-alone (ITA), as other studies including SIK individuals show a higher prevalence of coronary heart disease [144,145]. In general, cardiovascular death rates seem to be lower in individuals with a successful islet cell transplant compared to those with unsuccessful islet cell transplant [146]. Following islet cell transplantation, the incidence of coronary artery disease events does not substantially increase compared to non-transplanted people with type 1 diabetes, with a rate of 11 events per 1000 person-years, which is slightly higher than that of the general type 1 diabetes population (8.9 events per 1000 patient-years) [147].

Although more studies are needed to assess important cardiovascular outcomes following islet cell transplantation, there are reports showing improvements in echocardiographic measures (e.g. ventricular ejection fraction), vascular measures (e.g. intima media thickness), cardiovascular biomarkers (e.g. atrial natriuretic peptide, triglycerides, LDL), as well as haemostatic variables (e.g. prothrombotic factors, platelet function, or ultrastructure) [62,146,148,149].

Whole pancreas and islet cell transplantation: competing or complementary therapies?

It is tempting to compare whole pancreas and islet cell transplantation, but this might not be appropriate. Overall, there are few studies directly comparing these two therapies (Table 34.2). Importantly, although some indications overlap, people undergoing whole pancreas and islet cell transplantation are inherently different. Current reports consistently show that compared to whole pancreas transplantation, those undergoing islet cell transplantation are older and with a longer duration of disease [144,145,150–153]. Additionally, studies have found that people undergoing SIK have a higher prevalence of coronary artery disease compared to those undergoing SPK [144,145], and lower survival rates [145]. These differences might be confounded by indications and contraindications for each treatment (e.g. older persons might not be eligible for whole pancreas transplantation, those having SIK might be too sick for SPK). In contrast, studies focusing on whole pancreas and islet cell transplantation alone have not reported differences in cardiovascular status and/or person survival [150,152]. In terms of morbidity, there is consistency regarding early mortality (<1 year) and post-transplant complications (e.g. relaparotomy), where whole pancreas transplantation has been associated with a higher frequency of these outcomes (Table 34.2). Regarding insulin independence, there is also controversy. Two studies from a single centre comparing SPK to SIK or IAK report higher rates and longer duration of insulin independence [144,145]. Conversely, studies evaluating whole pancreas and islet cell transplantation alone show similar rates and duration of insulin independence [151,152]. Glycaemic indices

(i.e. HbA_{1c} levels), on the other hand, seem to be *better* with whole pancreas transplantation compared to islet cell transplantation, although the clinical impact remains unknown.

Finally, there is evidence that a whole pancreas transplant after a failed islet cell transplant has similar benefits to a primary whole pancreas transplant, despite the potential for sensitization [154]. Similarly, a small case series suggests that islet cell transplantation after a failed whole pancreas transplant may be a feasible alternative given the complexity of a second major surgical procedure [155]. Accordingly, whole pancreas and islet cell transplantation should be looked at as complementary rather than competing therapies.

Whole pancreas and islet cell transplantation: challenges and potential solutions

The main challenges for β -cell replacement therapies concern:

- Organ or tissue source and preservation.
- Peri-procedural management, including postoperative care or complications and engraftment.
- Chronic immunosuppression.

These challenges predominate at different moments during the transplantation process (Figure 34.3). While out of the scope of this chapter, several interesting aspects regarding potential solutions to these challenges will be discussed.

Organ or tissue source and preservation

The lack of organs or tissues affects both whole pancreas and islet cell transplantation. Currently, only ~17% of donors have pancreas graft recovery with the intention to transplant [156]. Multidisciplinary strategies including changes in legislation (i.e. *opt-out* policies for organ donation), together with national transplant coordination networks and coordinators (i.e. organ donation specialists in every hospital) and promotion of a culture of donation (physician and public driven), could substantially increase the pool of donors [157]. Other strategies to increase the quality (and quantity) of organs for transplantation involve organ perfusion and preservation technologies. These have evolved over the years; however, while there is pre-clinical evidence of improved outcomes with both whole pancreas [158, 159] and islet cell transplantation [160], research is scarce in comparison to kidney, liver, and lung grafts [161]. These technologies, nevertheless, could expand the donor pool to include marginal donors (e.g. donation after cardiac death), and should be further explored in the future.

Islet isolation for transplantation consumes a significant proportion of the costs [162], which demands resource optimization. Many of these are fixed costs, so central or regional isolation hubs might be a strategy. Another approach is standardization of donor selection. Scores like the North American Islet Donor Score, which have been derived by studying donor characteristics associated with successful isolations (>400 000 IEQ per pancreas), could be useful to optimize donor selection for islet isolation [163]. Optimization of enzymatic digestion [164] and post-isolation islet culture or preservation (~15–20% of the isolated islets are lost during culture) [165] are also actively being investigated. Increasing islet yield and quality to reduce the number of pancreata needed to support long-term glycaemic management after transplantation is a vital research avenue that should continue to be explored in the future.

Perhaps the most exciting developments concerning tissue source for β -cell replacement therapies relate to xenotransplantation and

stem cell-based therapies. Islet xenotransplantation has been steadily moving towards the clinic over the past decades. Preliminary clinical experience with xenotransplantation, although limited, has demonstrated safety, albeit with moderate efficacy. This might be explained by the overall lower doses used and the stronger immune responses compared to human islet cell transplantation. However, recent results are promising, showing a 45% decrease in insulin requirements and a 22.5% decrease in HbA_{1c} levels at one year post-transplant of neonatal pig islets [166]. Immune responses following xenotransplantation have also been tackled by using cellular encapsulation (see later), with documented survival of encapsulated neonatal porcine islet for up to 9.5 years [167]. The risk of zoonosis, particularly with the porcine-endogenous retrovirus, has been proven to be mostly theoretical, as no cases of *in vivo* transmission in pre-clinical and clinical trials have been documented [168]. Considering the advances in large-scale isolation of porcine islets, more clinical trials with xenotransplantation in the near future are expected.

Regarding stem-cell therapies in type 1 diabetes, there are two sources for cellular products: human embryonic stem cells (hESCs) and human-induced pluripotent stem cells (hiPSCs). Stem-cell therapies build on recapitulating *in situ* islet differentiation processes (i.e. embryogenesis) to generate functional human islets *in vitro*. Stem-cell therapies provide a potentially unlimited islet supply, but also the capacity to modify cell products to optimize their potency and decrease or even eliminate their immunogenicity [169]. Additionally, hiPSCs offer the possibility of individualized regenerative therapies. Islet-like structures differentiated from hESCs were the first to show similar potency to mature islets in terms of diabetes reversal in mouse models [170–172]. After Takahashi and Yamanaka first generated hiPSCs in 2006 [173], efforts permeated into the field of diabetes and hiPSC-derived islet-like structures were quickly generated from individuals with type 1 diabetes [174]; demonstration of diabetes reversal in mouse models promptly followed [175] and has been increasingly reported in recent years [176]. Whether hESCs or hiPSCs are similar in their capacity to generate functional human islets and in their translational potential is debated. Ethical considerations favour hiPSCs, but aspects regarding genome integrity and regulation, abnormal developmental potential, as well as costs and scalability should also be considered. Currently, hESCs have accumulated more evidence than hiPSCs in terms of differentiation efficiency and overall safety; clinical trials in people with type 1 diabetes are limited to hESC-derived islet-like cells (NCT03162926, NCT03163511, NCT02239354, and NCT02939118). However, the unavoidable fact that hiPSCs represent the only option for truly personalized regenerative medicine is a strong argument driving ongoing research efforts.

Peri-procedural care

There are distinct challenges associated with peri-procedural care in whole pancreas and islet cell transplantation. Optimal donor and recipient selection, as well as pre-transplant care, is essential to decrease the incidence of peri- and post-transplant complications. To optimize donor selection in whole pancreas transplantation, there are identified risk factors and tools, such as the pancreas donor risk index (PDRI) and the pre-procurement pancreas allocation suitability score (P-PASS), which have been used to assess the quality of the graft, the risk of allograft failure, and complications such as graft thrombosis [177]. However, they have not been widely implemented

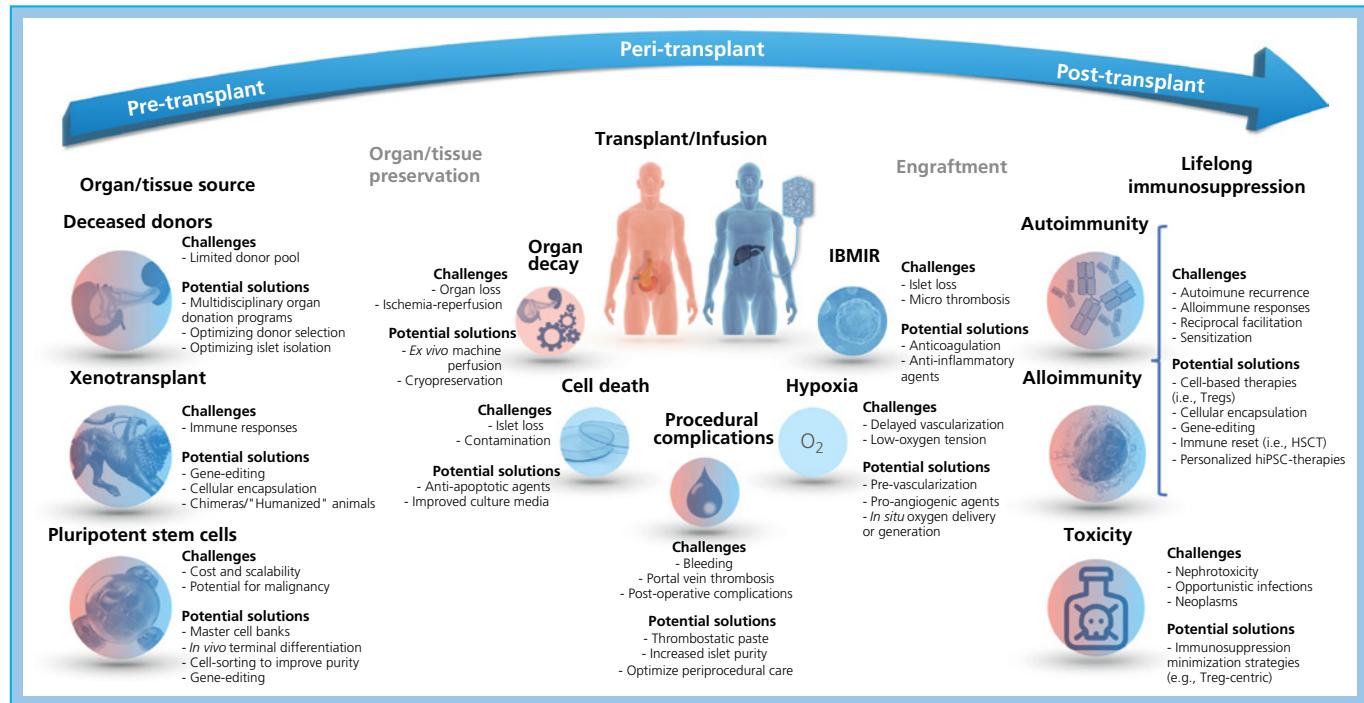

Figure 34.3 Challenges to advance β-cell replacement therapies and potential solutions. The relative importance of these challenges within the context of each type of transplant is highlighted using different colours: red for whole pancreas and blue for islet cell transplantation. hiPSC, human-induced pluripotent stem cell; HSCT, haematopoietic stem cell transplantation; Treg, regulatory T cell.

and, since donors are still relatively scarce, rejecting organs based on any score may not be cost-efficient. Aspects related to surgery, such as optimal back-table preparation, the use of intravenous heparin at the moment of implantation, avoidance of venous extension grafts, as well as avoidance of intraoperative hypotension, should be considered to decrease the risk of major complications after whole pancreas transplantation such as bleeding and thrombosis [178].

Acute graft pancreatitis is another issue. While *physiological* pancreatitis occurs in most cases, this condition has uncertain clinical implications. Mannitol, furosemide, and octreotide have been recommended prior to completion of the vascular anastomosis to prevent this condition [178]. Conversely, early pancreatitis (<3 months post-transplant) occurs in 3–38% of cases, while late acute pancreatitis (>3 months post-transplant) occurs in 14–25% of cases [178]. Risk factors for pancreatitis are related to the donor (i.e. age >50 years, cardiovascular death, haemodynamic instability prior to procurement), graft procurement and preparation, surgery (i.e. bladder exocrine drainage), and infections (i.e. cytomegalovirus). It is important to prevent this outcome, since it decreases graft and patient survival [179].

The only way of decreasing the incidence of postoperative complications is by gaining experience with surgical techniques and peri-procedural care. Unfortunately, the number of whole pancreas transplants has decreased in recent years, which raises concerns for a potential surge in technical complications related to a lack of exposure and inexperience with this procedure [156]. The reasons for this decrease are multifactorial and include a lack of referral of suitable recipients, the competition with novel insulin therapies and islet cell transplantation, as well as the excitement over novel therapies (e.g. immunotherapies, stem cell-based therapies), and the lack of dissemination of improving outcomes, among others [180]. A potential approach is to conduct outreach sessions involving engaged physicians (e.g. transplant surgeons, endocrinologists) and recipients. Expanding the recipient pool (e.g. older, non-type 1 diabetes individuals), which ultimately drives the need for pancreatic grafts, is another alternative [180]. This would increase experience and have positive impacts on the quality of the surgical procedures involved in whole pancreas transplantation.

There are two major complications following islet cell transplantation: bleeding and portal thrombosis. The overall incidence of bleeding after islet cell transplantation is 7%, the main risk factors being high-dose heparin (>45 IU/kg) and the number of infusions [181]. The use of coils or haemostatic agents (e.g. Avitene™, Becton, Dickinson, Franklin Lakes, NJ, USA; or D-Stat™, Teleflex, Wayne, PA, USA) to obliterate the percutaneous tract substantially decreases the risk of major bleeding [182]. This allows safer initiation of systemic anticoagulation with intravenous heparin [31, 59], which ameliorates the instant blood-mediated inflammatory response and contributes to preventing portal vein thrombosis. This latter complication presents in 3–10% of cases, typically as a partial thrombosis. Risk factors include a portal pressure during infusion of >22–25 mmHg, a large packed-cell volume (>5.5 ml or 0.25 ml/kg), and thrombophilic disorders [31], thus these scenarios should be avoided [31, 182].

Early cell death is another major concern in islet cell transplantation, and one of the main explanations behind the need for repeated infusions. The surviving islet mass directly correlates with graft survival [183]. Unfortunately, at least 25% of islets are lost within minutes of infusion into the portal circulation [184]; the central phenomenon believed to explain this is the instant blood-mediated inflammatory response, an innate immune response triggered by

direct exposure of islets (and tissue factor) to blood. It compromises activation of the coagulation cascade, the complement pathway, cytokine secretion, and cell-mediated injury [185]. Blocking this response with anticoagulation [59] and anti-inflammatory agents such as TNF- α inhibitors (etanercept) and interleukin-1 inhibitors (anakinra) improves clinical outcomes [60, 121, 151]. Finally, hypoxia represents another relevant factor affecting islet survival. β cells are ill-equipped to handle hypoxia and reactive oxidative stress due to low expression of antioxidants [186]. The process of neovascularization after infusion requires ~7–14 days [187], and many islets die within this period. Strategies to decrease hypoxia and enhance vascularization, even in the most hostile implantation sites (i.e. the subcutaneous space), using pre-vascularization [188], extracellular matrix-based scaffolding, proangiogenic factors, co-culture, or co-transplantation with pro-angiogenic supporting cells, show promise and great potential for clinical translation [189].

Chronic immunosuppression

The need for lifelong immunosuppression is perhaps the greatest obstacle to β -cell replacement therapies becoming a true cure for diabetes. The holy grail of transplantation is operational tolerance; that is, maintaining organ or graft function and survival without immunosuppression. Unfortunately, the probability of achieving operational tolerance after whole pancreas or islet cell transplantation is minimal compared to other organs (e.g. the liver). This may be explained by the underlying autoimmune process in most individuals, which may potentiate alloimmune responses after transplant and vice versa (reciprocal facilitation or regulation) [190].

Despite the hostile immunological milieu, there are potential approaches to minimize or even eliminate the need for lifelong immunosuppression. First, certain immunosuppressants may work better than others at controlling autoreactivity. For example, ATG (compared to daclizumab) and tacrolimus or MMF (compared to sirolimus) have been associated with an increased risk of autoantibody recurrence in people undergoing islet cell transplantation [190]. This has motivated an interest in the *off-target* immunoregulatory effects of pharmacological immunosuppression, such as those involving regulatory T cells (Tregs). In this sense, a *Treg-centric* view on immunosuppression post-transplant has been contemplated [191]. Tregs are central in immunological tolerance and key players in autoimmune diseases. In transplantation, these cells have gained astounding research momentum [192]. Recent studies suggest that different immunosuppressants evoke distinct Treg responses, and that these can potentially be used to foster a Treg-rich environment post-transplant. Alemtuzumab [193] and ATG + daclizumab [194] have both been associated with increased Treg percentages and higher Treg-to-effector T-cell ratios following islet cell transplantation. Sirolimus and MMF have a Treg-favouring effect compared to tacrolimus and cyclosporine A [195]. These preliminary findings should be deepened and extended to other immunosuppressants, as well as to other immunoregulatory mechanisms beyond Tregs.

Other interesting research avenues include adoptive cell transfer (ACT) therapies, cellular encapsulation, and cellular gene editing. Clinical trials using Treg-based ACT therapies have demonstrated safety and efficacy in delaying disease progression in people with type 1 diabetes [196, 197]. In transplantation, the multicentre ONE study showed that Treg-based ACT following kidney transplantation enabled minimization of immunosuppression (i.e. tacrolimus monotherapy) in 40% of individuals compared to 2% of those in the standard care group [198].

Additionally, ACT-treated individuals showed significantly lower rates of opportunistic infections compared to controls [198], which suggests that these therapies provide a more nuanced regulation of immune responses than pharmacological immunosuppression. Enhanced and more targeted cellular products, such as donor alloantigen-reactive Tregs (darTregs) or chimeric T-cell receptor Tregs (CAR-Tregs) [199], are entering the clinical realm, which will further elucidate the potential of ACT therapies to enable operational tolerance.

Cellular encapsulation, which involves providing a physical barrier made of different biomaterials to protect cells from the immune responses, represents a promising alternative to abrogate immunosuppression altogether. Naturally, these technologies apply only to islet cell transplantation and stem cell-based therapies, as it is not possible to encapsulate a whole pancreas. Overall, the clinical and pre-clinical experience is encouraging. The introduction of low-fouling, immune-friendly biomaterials [200] and composite bioscaffolds enabling localized immunosuppression and immunoregulation [201, 202] has resulted in improved graft acceptance and longer duration of diabetes reversal in pre-clinical models of islet cell transplantation. Moreover, these strategies are compatible with xenotransplantation [203] and stem-cell therapies [204–206]. Clinical trials are ongoing with encapsulated hESC-derived pancreatic endocrine progenitors (ViaCyte, San Diego, CA, USA) that differentiate into fully mature islet-like structures *in vivo*, but preliminary results suggest that these cells can survive for up to two years within macroencapsulation devices [207]. Achieving safe and effective cellular encapsulation could broaden indications for β -cell replacement therapies to individuals with other forms of diabetes.

Finally, the advent of efficient gene-editing techniques to prevent allo- [208, 209] and autoimmune [210] destruction of stem cell-derived islets could revolutionize the field. In this regard, ViaCyte has developed the cellular product PEC-QT, an edited clonal hESC line that lacks the $\beta 2$ -microglobulin gene and express a transgene encoding PD-L1 (programmed death-ligand 1) to

protect cells from immune attack [211]. It is expected that many of these potentially game-changing strategies will move into clinical trials soon.

Conclusion

β -cell replacement therapies are now consolidated options in the therapeutic arsenal of physicians caring for people with diabetes and persistent problematic hypoglycaemia. The path to clinical success has been paved by brilliant researchers who have carried the field forward with unwavering perseverance and uninterrupted innovation. Today, both whole pancreas and islet cell transplantation are safe and effective. Additionally, both therapies improve life expectancy and have positive impacts on the natural history of diabetes by ameliorating the progression of chronic complications. For these notable achievements, they have earned the well-deserved title of potential cures for diabetes. While it is tempting to compare them to each other, whole pancreas and islet cell transplantation seem to benefit different populations and have their specific niches. In this regard, they can perfectly function as complementary therapies and succeed when the other one has failed.

Currently, β -cell replacement therapies are limited to a very selected group of individuals in which the benefits outweigh the risks associated with these procedures. The main challenges include expanding the supply of organs or tissues to treat as many individuals as needed, optimizing peri-procedural care to decrease procedural risks, and minimizing or eliminating the need for lifelong immunosuppression to avoid long-term adverse effects. Fortunately, the legacy of those brilliant, persistent, and innovative researchers endures and continues to thrive in today's graduate students, scientists, and clinicians involved in the field of β -cell replacement therapies. In the past, the paradigm in diabetes care changed from saving to treating people with diabetes, but the moment has come to shift our paradigm once again from treating to curing people with diabetes.

² Institute for Cardiovascular and Metabolic Research, University of Reading, Reading, UK

³ Department of Population Health Sciences, King's College London, London, UK

Key points

- Treatment of hyperglycaemia is a fundamental part of the management of type 2 diabetes in order to address acute symptoms and to prevent, defer, or reduce the severity of chronic microvascular and macrovascular complications.
- Treating type 2 diabetes is complicated by the multivariable and progressive natural history of the disease. Insulin resistance, a progressive decline in β -cell function, and defects of other gluco-regulatory hormones and of nutrient metabolism give rise to continually changing manifestations of the disease that require therapy to be adjusted accordingly. People with diabetes often have overweight or obesity, exhibit substantial comorbidity and elevated cardiovascular and renal risk, and receive many other medications that may further complicate treatment.
- Care plans and treatment programmes should be tailored to fit the prevailing circumstances of the individual. Lifestyle management (diet and exercise) should be emphasized from the time of diagnosis and reinforced thereafter. Drug treatment should be undertaken promptly if lifestyle intervention does not achieve adequate glycaemic levels.
- Choice of drug therapy should ideally address underlying pathophysiology, but any safe means of restraining the escalating hyperglycaemia may be appropriate. Combinations of differently acting agents are frequently required to provide additive efficacy, and single-tablet, fixed-dose combinations are available to facilitate therapy. Contraindications and precautions associated with each component of pharmacotherapy must be respected.
- The biguanide metformin is often selected as initial oral glucose-lowering therapy. It counters insulin resistance and lowers blood glucose through several insulin-dependent and -independent mechanisms, notably reducing hepatic glucose production, increasing intestinal glucose-lactate turnover, and increasing glucose uptake by skeletal muscle. It does not stimulate insulin secretion, carries a low risk of hypoglycaemia, and does not cause weight gain. Metformin also exerts several potentially beneficial effects on cardiovascular risk factors independently of glycaemic levels, with evidence of improved long-term cardiovascular outcomes. Metformin may be conveniently combined with other classes of anti-diabetes drugs. Gastrointestinal side effects including diarrhoea limit the use of metformin in some people. The rare but serious adverse effect of lactic acidosis precludes use of the drug in people with severe renal insufficiency, advanced liver disease, or any condition predisposing to hypoxia or hypoperfusion, including decompensated heart failure or respiratory failure.
- Sulfonylureas (e.g. gliclazide, glimepiride, glibenclamide/glyburide, glipizide) act on the pancreatic β cells to stimulate insulin secretion. They bind to the transmembranal complex of sulfonylurea receptors SUR1 with ATP-sensitive Kir6.2 potassium efflux channels. This closes the channels, depolarizes the membrane, opens voltage-dependent calcium channels, and raises intracellular free calcium concentrations. This in turn activates proteins that regulate insulin secretion. The efficacy of sulfonylureas depends on adequate residual β -cell function. Hypoglycaemia is the most serious adverse effect, particularly with longer-acting sulfonylureas and in older people. Caution with hepatic and/or renal insufficiency is warranted in accordance with the metabolism and elimination of individual preparations, and interactions with other protein-bound drugs can occur.
- Meglitinides (repaglinide and nateglinide), also known as prandial insulin releasers, are rapid- and short-acting insulin secretagogues taken before meals to boost insulin levels during digestion, thereby reducing prandial hyperglycaemia and decreasing the risk of inter-prandial hypoglycaemia. They act in a similar manner to sulfonylureas by binding to a benzamido site on the SUR1–Kir6.2 complex. They are conveniently used in combination with an agent that reduces insulin resistance.
- Dipeptidyl peptidase 4 (DPP-4) inhibitors (sitagliptin, vildagliptin, saxagliptin, linagliptin, and alogliptin), also termed gliptins, act predominantly as prandial insulin secretagogues by raising the circulating concentrations of endogenous incretin hormones, notably glucagon-like peptide 1 (GLP-1). This enhances the ‘incretin’ effect of endogenous GLP-1 to potentiate nutrient-stimulated insulin secretion and reduce excess glucagon secretion. DPP-4 inhibitors are weight neutral and, as monotherapy, they carry a low risk of inter-prandial hypoglycaemia. They are often used in combination with metformin or a thiazolidinedione.
- Sodium–glucose cotransporter-2 (SGLT-2) inhibitors (canagliflozin, dapagliflozin, empagliflozin, ertugliflozin) increase the elimination of excess glucose in the urine (glucosuria) by reducing glucose reabsorption

from the renal filtrate. They carry a low risk of hypoglycaemia and the glucosuria facilitates weight loss. Their action is independent of insulin, enabling use with other glucose-lowering agents irrespective of the extent of insulin resistance or β -cell dysfunction, but their efficacy requires adequate renal function. The glucosuria can increase the risk of mycotic genital infection, although an associated osmotic diuresis may assist in blood pressure control. SGLT-2 inhibitors reduce the onset and progression of heart failure and exert renal protective effects independently of their glucose-lowering efficacy. Reductions in cardiovascular and all-cause mortality have been reported in cardiovascular outcome trials of some agents in this class.

- An oral formulation of the GLP-1 receptor agonist semaglutide is available in some regions. It mimics the incretin effect to potentiate nutrient-stimulated insulin secretion and suppress excess glucagon secretion with low risk of hypoglycaemia: it also delays gastric emptying and exerts a satiety effect, typically facilitating weight loss. The GLP-1 receptor agonist class has improved outcome measures of atherosclerotic cardiovascular disease and albuminuria in trials in type 2 diabetes.
- Thiazolidinediones (e.g. pioglitazone) produce a slow-onset glucose-lowering effect, attributed mainly to increased insulin sensitivity. They alter the expression of certain insulin-sensitive genes by stimulating the transcription factor peroxisome proliferator-activated receptor γ , increasing adipogenesis, and rebalancing the glucose–fatty acid (Randle) cycle. Thiazolidinediones can be used as monotherapy or in combination

with other classes of glucose-lowering agents. They have a low risk of hypoglycaemia but often cause weight gain. The potential for fluid retention and an attendant risk of congestive heart failure should be borne in mind, especially in combination with insulin. Thiazolidinediones are not recommended for individuals at high risk for cardiac decompensation or women with reduced bone density, and members of this class have been discontinued in some countries.

- α -Glucosidase inhibitors (acarbose, miglitol, voglibose) slow the digestion of carbohydrates by competitive inhibition of intestinal α -glucosidase enzymes. This delays glucose absorption and reduces post-prandial glucose excursions without stimulating insulin secretion. These agents must be used in conjunction with meals rich in digestible complex carbohydrate. They do not cause weight gain or hypoglycaemia as monotherapy and can be used alongside any other glucose-lowering agents.
- The dopamine D2 receptor agonist bromocriptine and the bile sequestrant colestevam have an indication for the treatment of type 2 diabetes in some countries. Their glucose-lowering mechanisms are unclear, but they do not cause weight gain and carry a low risk of hypoglycaemia.
- As type 2 diabetes advances, combinations of glucose-lowering agents with different modes of action are often required. Eventually β -cell function can become too severely compromised to support the continued use of oral agents alone and/or other non-insulin treatments. Insulin therapy should then be initiated, continuing one or more other agents where appropriate.

Treatment of hyperglycaemia is fundamental to the management of type 2 diabetes. It is required to prevent and relieve acute symptoms and complications of hyperglycaemia; prevent, defer, and reduce the severity of microvascular complications; and afford some benefits against macrovascular complications (Table 35.1) [1]. Correction of the hyperglycaemia is an integral part of individualized care that takes account of coexisting diseases and personal circumstances, offers suitable advice on lifestyle and diet, includes other measures to address modifiable cardiovascular risk, selects realistic targets, and facilitates patient education and empowerment. This chapter focuses on the role of oral blood glucose-lowering agents (other anti-diabetes therapies are addressed in Chapters 36 and 37) in the treatment of type 2 diabetes [2–5].

Table 35.1 Aims of appropriate glycaemic management in type 2 diabetes.

Purpose	Complications
Prevent acute symptoms of hyperglycaemia	Dehydration, thirst, polyuria, blurred vision, increased infections
Prevent acute complications	Hyperosmolar non-ketotic state
Prevent, defer, or reduce severity of chronic complications	Microvascular and neuropathic: retinopathy, nephropathy, neuropathy Macrovascular: coronary, cerebrovascular, peripheral vascular disease

Pathophysiological considerations

The interdependent multiplicity of genetic and environmental factors underlying type 2 diabetes gives rise to a highly heterogeneous and progressive natural history [1,6,7]. The pathophysiology typically involves defects of insulin secretion *and* insulin action. Obesity, especially visceral adiposity, and abnormalities of glucagon secretion, incretin hormone action, the microbiome, inflammation, and neurotransmitters contribute to the disease process, while cellular disturbances of nutrient metabolism participate as both causes and consequences of glucotoxicity and lipotoxicity [6,7]. An ideal approach to therapy might therefore address the basic endocrine defects, but any other safe means of ameliorating the hyperglycaemia and attendant biochemical disruptions should provide clinical benefits.

The progressive nature of type 2 diabetes was well illustrated by the UK Prospective Diabetes Study (UKPDS), a randomized trial of 5102 individuals with newly diagnosed type 2 diabetes followed for a median of 10 years while receiving either conventional (diet) therapy or intensive therapy with various oral glucose-lowering agents or insulin (Figure 35.1). Note that insulin was introduced earlier than is usual in clinical practice, and insulin was also used as necessary when oral agents were deemed inadequate. Although the glycated haemoglobin (HbA_{1c}) level deteriorated with time irrespective of the treatment, the improvement in glycaemic indices afforded by intensive therapy (median HbA_{1c} reduced by 0.9% [10 mmol/mol]) was associated with a 12% reduction in overall diabetes-related endpoints and a 25% reduction in microvascular endpoints [8]. An epidemiological analysis showed that benefits of intensive therapy continued to accrue until glucose levels were

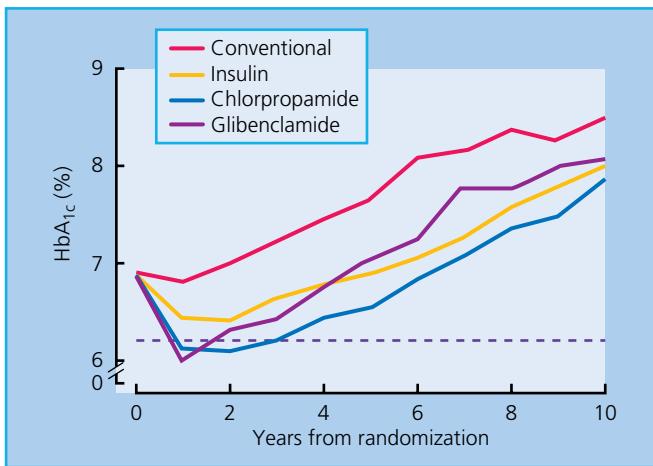

Figure 35.1 The UK Prospective Diabetes Study (UKPDS) shows the progressive rise in glycated haemoglobin ($\text{HbA}_{1\text{c}}$) occurring with time in groups receiving conventional (diet) therapy and intensive therapy with various glucose-lowering drugs (two sulfonylureas – chlorpropamide and glibenclamide – and insulin). Source: Data from UK Prospective Study (UKPDS) Group 1998 [8].

returned to the normal range [9]. Moreover, the benefits of earlier intensive management were continued during an unrandomized post-trial follow-up (median 8.5 years) during which glycaemic differences between the former groups were not maintained [10]. This illustrates the glycaemic *legacy effect*, in which early intensive glycaemic management confers an extended reduction in complications, even when glycaemia deteriorates at later stages in the disease process.

Other large randomized trials [11–13] have confirmed fewer microvascular complications among those receiving more intensive glycaemic management (Table 35.2). One such study, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, noted increased mortality during highly intensified (5% mortality, 257/5128) versus standard (4% mortality, 205/5123) glycaemic management. Although the cause of the increased mortality associated with highly intensified management remains uncertain, deaths were more common among those individuals who continued to have hyperglycaemia [14]. In this context, it is noteworthy that an acceptable $\text{HbA}_{1\text{c}}$ value does not exclude excessive daily fluctuations in blood glucose with hyperglycaemic excursions and hypoglycaemic troughs, the latter often unrecognized nocturnally. Survival following a myocardial event appears to be reduced by both hypo- and hyperglycaemia [15].

Guidelines and algorithms

Factors to consider when selecting a glycaemic target for a particular individual are deliberated in detail in Chapter 37, but it is pertinent to reiterate here that the general principle is to return glycaemia safely as close to normal as practicable, while avoiding hypoglycaemia, minimizing adverse effects on body weight and potential drug interactions, and observing other necessary cautions and contraindications. An individualized approach is recommended. Current treatment algorithms [3, 4] provide a framework for initiating and intensifying therapy, but clinical judgement should be applied to harmonize this with the circumstances of the people with diabetes.

Thus, a younger, newly diagnosed individual without comorbidity who is responsive to therapy might be expected to meet a more rigorous target, whereas an older, frail individual with comorbidity or a long history of problems with diabetes management may require a less rigorous target. Management of hyperglycaemia should always be part of a comprehensive management programme to address coexisting disease and modifiable cardiovascular risk factors.

It is emphasized that diet, exercise, and other lifestyle measures should be introduced at diagnosis and reinforced at every appropriate opportunity thereafter. These measures can provide valuable blood glucose-lowering efficacy and may initially enable the desired glycaemic target to be achieved. However, even when lifestyle advice is successfully implemented, the progressive natural history of the disease dictates that the majority of people with type 2 diabetes will later require pharmacological therapy, and this should be introduced promptly if the glycaemic target is not met or maintained. Choice of agent is often limited by comorbidities and driven by the need to address obesity, cardiovascular or renal disease, and avoid the risk of hypoglycaemia [3, 4]. To date, precision medicine approaches that could provide more personalized pharmacotherapy for people with type 2 diabetes remain underdeveloped. In part, this reflects a deficit of clinically useful biomarkers, for example for insulin action and/or deficiency, together with the limited practical utility of relevant pharmacogenomics. This said, evidence of cardio-renal protective effects of some sodium–glucose cotransporter-2 (SGLT-2) inhibitors and some glucagon-like peptide-1 (GLP-1) receptor agonists has prompted recommendations to refine the treatment algorithm for individuals with type 2 diabetes to consider earlier use of agents with such benefits in individuals at high risk of cardiovascular disease [1, 3, 4].

The main classes of oral glucose-lowering drugs and their principal modes of action are listed in Table 35.3. Not all agents are available in all countries and prescribing information may vary between countries. The main tissues through which agents exert their glucose-lowering effects are illustrated in Figure 35.2, and the main cautions and contraindications are listed in Table 35.4. Although there are several different classes from which to choose, many dilemmas continue to impinge on both strategy and individualization of treatment. For example, an increase in fasting glycaemia usually accounts for the majority of the total burden of hyperglycaemia in type 2 diabetes; ideally, therefore, this should be adequately addressed using appropriate therapy [16]. It is also pertinent to note the link between post-prandial hyperglycaemic excursions and cardiovascular risk, which mandates the need also to address this component of the hyperglycaemic day profile [17]. Additionally, consideration should be given to the improvements in glycaemic measures that can be achieved through the treatment of obesity [18]. By the time of diagnosis, insulin resistance is usually well established and typically shows only a modest further increase with extended duration of the disease [6, 7]. Nevertheless, the association between insulin resistance and cardiovascular risk warrants the amelioration of insulin resistance as a valued therapeutic strategy. The ongoing deterioration in glycaemic measures after diagnosis is considered to be largely attributable to a further progressive decline in β -cell function [6, 7]. Thus, preserving β -cell function and mass are important considerations in the quest to maintain long-term glycaemic targets. If β -cell function deteriorates beyond the capacity of oral agents and non-insulin injectable agents (GLP-1 receptor agonists) to provide adequate glycaemic levels, then the introduction of insulin should not be delayed [19]. Incorporating

Part 6 Treatment of Diabetes

Table 35.3 Classes of oral glucose-lowering drugs and their main modes of action.

Class with examples	Main mode of glucose-lowering action	Main cellular mechanism of action
Biguanide Metformin	Counter insulin resistance (especially decrease hepatic glucose output)	Enhance various insulin-dependent and -independent actions including effects on AMPK, mitochondrial respiratory chain, and insulin receptor signalling
Sulfonylureas Glimepiride, gliclazide, glipizide, glyburide (=glibenclamide) ^a	Stimulate insulin secretion (typically 6–24 h)	Bind to SUR1 sulfonylurea receptors on pancreatic β cells, which closes ATP-sensitive Kir6.2 potassium channels
Meglitinides Repaglinide, nateglinide	Stimulate insulin secretion (faster onset and shorter duration of action than sulfonylureas)	Bind to benzamido site on SUR1 receptors on pancreatic β cells, which closes ATP-sensitive Kir6.2 potassium channels
DPP-4 inhibitors (gliptins) Sitagliptin, vildagliptin, saxagliptin, linagliptin, alogliptin	Increase prandial insulin secretion	Inhibit DPP-4 enzyme, resulting in increased plasma half-life of incretin hormones, notably GLP-1
Thiazolidinediones (PPAR-γ agonists) Pioglitazone, rosiglitazone ^b	Increase insulin sensitivity (especially increase peripheral glucose utilization)	Activate nuclear receptor PPAR-γ mainly in adipose tissue, which affects insulin action and glucose–fatty acid cycle
Sodium-glucose cotransporter-2 (SGLT-2) inhibitors Canagliflozin, dapagliflozin, empagliflozin, ertugliflozin	Increase elimination of glucose in the urine	Inhibit SGLT-2 transporters in renal proximal tubules
α-Glucosidase inhibitors Acarbose, miglitol, voglibose	Slow rate of carbohydrate digestion	Competitive inhibition of intestinal α-glucosidase enzymes
Dopamine agonist Bromocriptine ^b	Reduce hepatic glucose production	Central dopaminergic effect
Bile acid sequestrant Colesevelam ^b	Not established	Not established
Glucagon-like peptide-1 (GLP-1) receptor agonist Semaglutide	Increase prandial insulin secretion and reduce glucagon secretion, delay gastric emptying, and exert central effects on increased satiety	Activate GLP-1 receptors on pancreatic β and α cells and in other tissues including upper gastrointestinal tract, portal system, and brain

AMPK, adenosine 5'-monophosphate-activated protein kinase; ATP, adenosine triphosphate; DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide-1; PPAR-γ, peroxisome proliferator-activated receptor γ; SGLT-2, sodium–glucose cotransporter-2.

^a Glyburide is the same active compound as glibenclamide.

^b Rosiglitazone has been withdrawn in many countries, pioglitazone is no longer available in some countries, and bromocriptine and colesevelam are not widely used for the treatment of type 2 diabetes.

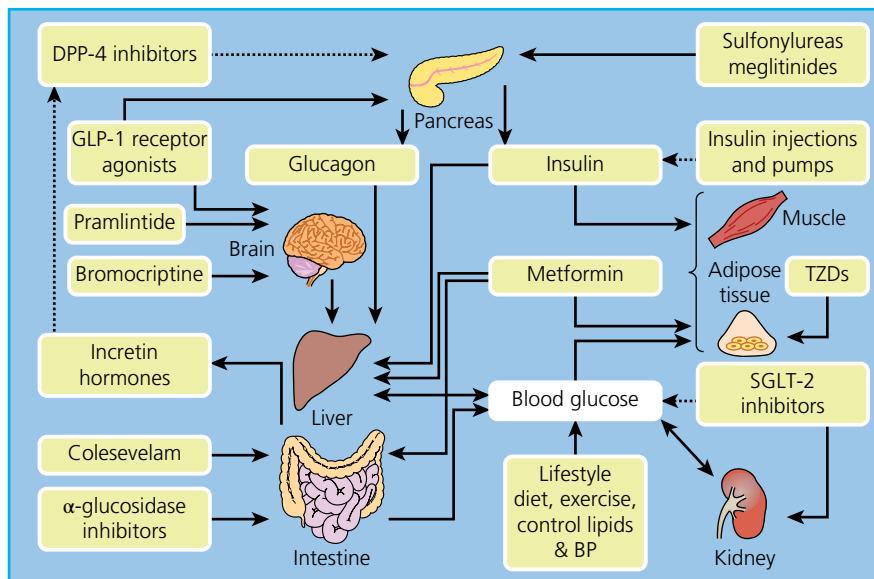

Figure 35.2 Main tissues through which oral glucose-lowering agents exert their glucose-lowering effects. BP, blood pressure; DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide-1; SGLT-2, sodium–glucose cotransporter-2; TZD, thiazolidinedione.

Table 35.5 Drug interactions with oral glucose-lowering agents that may affect their glucose-lowering effects.

Agent	Increase glucose-lowering effect	Decrease glucose-lowering effect
Any	Combination with other glucose-lowering drugs Minor insulin releasers (e.g. aspirin) Minor insulin sensitivity enhancers (e.g. ACE inhibitors, magnesium or chromium supplements)	Agents that impair insulin action (e.g. glucocorticoids, some antipsychotics, minor effects of diuretics, β -blockers, some β_2 -agonists) Impair insulin secretion (e.g. octreotide, some calcium channel blockers)
Metformin	Renal cation secretion competition by cimetidine Minor PK interaction with furosemide and nifedipine	—
Sulfonylureas	Reduce hepatic metabolism (e.g. some antifungals and MAOIs) Displace plasma protein binding (e.g. coumarins, NSAIDs, sulfonamides) Decrease excretion (e.g. probenecid) Reduce hepatic metabolism (e.g. gemfibrozil) Potentially displace plasma protein binding	K ⁺ -ATP channel openers (e.g. diazoxide) Metabolism secondary to enzyme induction (e.g. rifampicin)
Meglitinides	Reduce hepatic metabolism, gemfibrozil Potentially displace plasma protein binding	Metabolism secondary to enzyme induction (e.g. rifampicin, barbiturates, carbamazepine)
Thiazolidinediones	Potentially displace plasma protein binding	Metabolism secondary to enzyme induction (e.g. rifampicin)
SGLT-2 inhibitors	—	Impaired renal function
DPP-4 inhibitors	Potential interactions with liver and renal metabolism and plasma protein binding	—
GLP-1 receptor agonist	—	If not taken on an empty stomach
α -Glucosidase inhibitors	Slow gut motility (e.g. cholestyramine)	Potentially with agents that increase gut motility

ACE, angiotensin-converting enzyme; DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide-1; MAOI, mono oxidase inhibitor; NSAID, non-steroidal anti-inflammatory drug; PK, pharmacokinetic; SGLT-2, sodium–glucose cotransporter-2.

some or all of these into the treatment process is inevitably a challenge, and the need to explore suitable combinations of therapies to accommodate the changing status of the disease is common practice [3, 4].

The increasing prevalence of type 2 diabetes among children, adolescents, and young adults adds an extra long-term dimension to risk–benefit considerations [20]. Although initial adequate intervention remains paramount, there is limited experience with oral glucose-lowering agents in children and adolescents; metformin has been used safely in paediatric practice from 10 years of age; and sulfonylureas have been used in paediatric presentations of certain monogenic forms of diabetes, such as maturity-onset diabetes of the young (MODY). Treating type 2 diabetes in women who are of childbearing age carries the risk of unplanned pregnancy while receiving oral glucose-lowering agents. Treatment with metformin or a sulfonylurea at the time of conception and during the first trimester has not been shown to have any adverse effects on mother or fetus, and judicious use of metformin may reduce miscarriage and gestational diabetes. Insulin remains the preferred glucose-lowering medication in pregnancy, as there is a substantial evidence base for the safety and flexibility of insulin in gestational diabetes. A paucity of evidence, allied with animal toxicity data or theoretical considerations for some classes, contraindicates thiazolidinediones, dipeptidyl peptidase-4 (DPP-4) inhibitors, SGLT-2 inhibitors, and GLP-1 receptor agonists during pregnancy and lactation.

Older people are more vulnerable to most of the cautions and contraindications for glucose-lowering drugs, and a deterioration in pathophysiological status can occur rapidly, necessitating more frequent monitoring [21]. Hypoglycaemia is a particular concern in this age group. Although safety must be judged on an individual drug–patient basis, it is noteworthy that several commonly used concomitant medications can impair glucose levels (e.g. glucocorticoids, certain antipsychotics, diuretics, and β -blockers), whereas

others may have their own minor glucose-lowering effect (e.g. aspirin, some angiotensin-converting enzyme [ACE] inhibitors, and mineral supplements; Chapter 21). The most frequent interactions with glucose-lowering drugs are summarized in Table 35.5.

Descriptive terminology applied to glucose-lowering drugs may simplify the use of the different agents. Hypoglycaemic agents have the capacity to lower blood glucose below normal to the extent of frank hypoglycaemia (e.g. sulfonylureas, meglitinides, and insulin). Anti-hyperglycaemic agents can reduce hyperglycaemia, but when acting alone they do not usually have the capability to lower blood glucose below normoglycaemia to the extent of frank hypoglycaemia (e.g. metformin, DPP-4 inhibitors, thiazolidinediones, SGLT-2 inhibitors, GLP-1 receptor agonists, α -glucosidase inhibitors, bromocriptine, and colesvelam).

Biguanides

Metformin (dimethylbiguanide) is the only biguanide currently used in most countries (Figure 35.3). The history of biguanides stems from a guanidine-rich herb, *Galega officinalis* (goat's rue or French lilac), which was used as a traditional treatment in Europe [22]. Guanidine has a glucose-lowering effect, and several guanidine derivatives were adopted for the treatment of diabetes in the 1920s. These agents all but disappeared as insulin became available, but three biguanides – metformin, phenformin, and buformin – were introduced in the late 1950s. Phenformin and buformin were withdrawn in many countries in the late 1970s because of a high incidence of lactic acidosis. Metformin remained and was introduced into the United States in 1995 [23], and it has since become the most prescribed glucose-lowering agent worldwide [24].

Mode of action

Metformin exerts a range of actions that counter insulin resistance and lower blood glucose; the drug also offers some protection against vascular complications independently of its anti-hyperglycaemic effect (Table 35.6) [25, 26]. At the cellular level, metformin exerts insulin-dependent and -independent effects on glucose metabolism that vary with the concentration of metformin to which the tissue is exposed and the prevailing gluco-regulatory mechanisms in that tissue (Figure 35.4). For example, high concentrations of metformin in the intestinal wall can suppress the mitochondrial respiratory chain at complex 1 independently of insulin and promote anaerobic glycolysis to lactate. The conversion of lactate to glucose in other tissues (increased glucose turnover as part of the Cori cycle) may help to prevent weight gain. Lower concentrations

of metformin can suppress mitochondrial glycerol-phosphate dehydrogenase and modestly improve insulin sensitivity in liver and muscle, in part by enhancing post-receptor signalling pathways for insulin, and also by effects on nutrient metabolism and energy

Table 35.6 Diverse metabolic and vascular effects of metformin.

Features associated with diabetes	Effects of metformin	
Hyperglycaemia	↓	↓ HGP, ↑ peripheral glucose uptake, ↑ glucose turnover
Insulin resistance	↓	↑ Receptor-postreceptor insulin signals
Hyperinsulinaemia	↓	↓ Fasting and often post-prandial insulin
Obesity	↓/–	↓ Or stabilizes body weight
IGT	↓	↓ Progression to type 2 diabetes
Dyslipidaemia	↓/–	Modest benefits if abnormal ↓ VLDL-TG, ↓ LDL, ↑ HDL May decrease FA oxidation
Blood pressure	–	No significant effect
Pro-coagulant state	↓	Antithrombotic (↓ fibrinogen, ↓PAI-1, ↓ platelet aggregation)
Endothelial function	↑	↓ Vascular adhesion molecules
Atherosclerosis	↓	↓ MI, ↓ stroke, ↑ vascular reactivity, ↓ cIMT, ↑ life expectancy, anti-atherogenic in animals

↑, Increase; ↓, decrease; –, no significant effect.

cIMT, carotid intima-media thickness; FA, fatty acid; HDL, high-density lipoprotein cholesterol; HGP, hepatic glucose production; IGT, impaired glucose tolerance; LDL, low-density lipoprotein cholesterol; MI, myocardial infarction; PAI-1, plasminogen-activator inhibitor-1; VLDL-TG, very low-density lipoprotein triglyceride.

Figure 35.3 Chemical structures of guanidine and metformin.

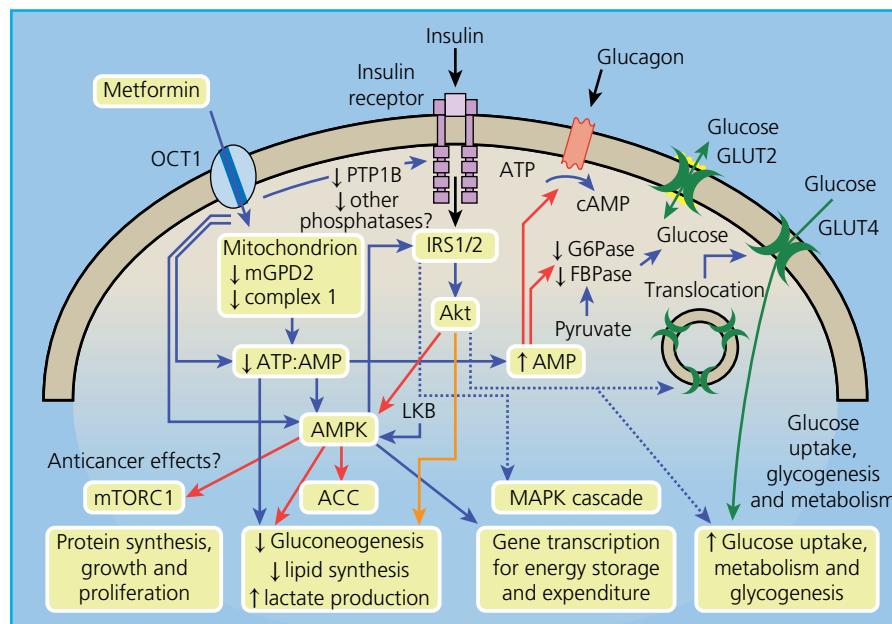

Figure 35.4 Multiple cellular actions of metformin involve insulin-dependent and -independent effects and vary according to the tissue and the level of exposure to metformin. For example, very high exposure to metformin in the intestine can reduce oxidative phosphorylation and promote anaerobic metabolism. Lower concentrations of metformin can improve insulin sensitivity in liver and muscle via effects on insulin receptor signalling and post-receptor signalling pathways of insulin action. Metformin can influence cellular nutrient metabolism and energy production independently of insulin via activation of adenosine 5'-monophosphate (AMP)-activated protein kinase (AMPK). ACC, acetyl-CoA carboxylase; Akt, protein kinase

B (PKB); AMPK, adenosine monophosphate-activated protein kinase; FBPase, fructose 1,6-bisphosphatase; G6Pase, glucose 6-phosphatase; GLUT, glucose transporter isofrom; IRS, insulin receptor substrate; LKB1, liver kinase B1; MAPK, mitogen-activated protein kinase; mGPD, mitochondrial glycerol-phosphate dehydrogenase; mTORC1, mammalian target of rapamycin complex 1; OCT1, organic cation transporter 1; PTP, protein tyrosine phosphatase. Blue lines indicate positive effects; red lines indicate negative effects; dashed lines indicate multistep pathways; up arrows indicate positive effect; down arrows indicate negative effect.
Source: Adapted from Bailey 2012 [27].

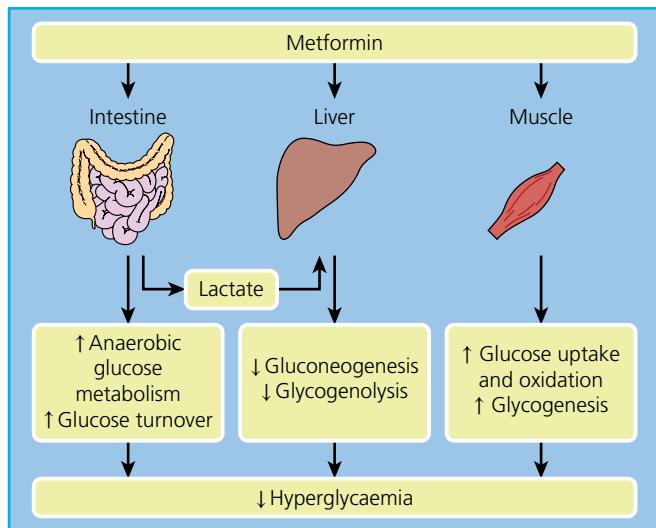

Figure 35.5 Main sites of action of metformin contributing to glucose-lowering effect.

production independently of insulin via activation of adenosine 5'-monophosphate-activated protein kinase (AMPK) [28].

The glucose-lowering efficacy of metformin requires the presence of at least some insulin, because metformin does not mimic or activate the genomic effects of insulin. Also, metformin does not stimulate insulin release; its main glucose-lowering effect appears to be a reduction of hepatic glucose production by suppressing gluconeogenesis and glycogenolysis, but not sufficiently to cause frank hypoglycaemia when used as monotherapy. Metformin reduces gluconeogenesis by increasing hepatic insulin sensitivity, reducing hepatic glucagon receptor signalling, and decreasing hepatic extraction of some gluconeogenic substrates such as lactate (Figure 35.5). Metformin can enhance insulin-stimulated glucose uptake in skeletal muscle by increasing the translocation of insulin-sensitive glucose transporters (GLUT4) into the cell membrane and increasing the activity of glycogen synthase, which promotes glycogen synthesis.

Pharmacokinetics

Metformin is rapidly but incompletely absorbed, shows little binding to plasma proteins, and is not metabolized, and so it does not interfere with co-administered drugs. Metformin is widely distributed at concentrations similar to plasma (about 10^{-5} mol/l), but much higher concentrations are retained in the walls of the gastrointestinal tract. The plasma half-life ($t_{1/2}$) is about 6 hours with elimination of unchanged drug in the urine, mostly within 12 hours [29]. Although renal clearance is achieved more by tubular secretion than glomerular filtration, metformin is contraindicated for people with significant impairment of glomerular filtration. Cimetidine is the only drug known to compete for clearance sufficiently to cause a clinically significant increase in plasma metformin concentrations.

Indications and contraindications

Because metformin does not cause weight gain, it is often preferred for people who have overweight or obesity and type 2 diabetes, although it shows similar anti-hyperglycaemic efficacy in individuals with normal weight [30]. To preclude drug accumulation, patient suitability and dose should be considered very carefully if

there is evidence of impaired renal function (e.g. creatinine clearance is <60 ml/min). Starting metformin is not encouraged if the estimated glomerular filtration rate (eGFR) is <45 ml/min/1.73 m², although reduced doses of the drug are permitted in most countries down to an eGFR of 30 ml/min/1.73 m². Further contraindications include significant cardiac or respiratory insufficiency, or any other condition predisposing to hypoxia or reduced tissue perfusion (e.g. hypotension, septicaemia), and also significant liver disease, alcohol abuse, or a history of metabolic acidosis. Because the potential for acute deterioration in renal, cardiopulmonary, and hepatic function should be considered, it is difficult to identify precise cut-offs for starting or stopping metformin therapy. With this in mind, metformin can be used in older people provided that renal insufficiency and other exclusions are not present. Ovulation can resume in women with anovulatory polycystic ovary syndrome (PCOS), which is an unlicensed purpose for which the drug has been used in the absence of diabetes [31]. Metformin is also under investigation for a possible inhibitory effect on tumour formation and progression in some tissues.

A standard (so-called immediate release, IR) tablet or liquid formulation of metformin should be taken with meals or immediately before meals to minimize possible gastrointestinal side effects. Treatment should start with 500 or 850 mg once daily, or 500 mg twice daily (divided between the morning and evening meals). The dosage is increased slowly – one tablet at a time – at intervals of about 1–2 weeks until the target level of blood glucose is attained. If the target is not attained and an additional dose produces no further improvement, the previous dose should be resumed. In the case of monotherapy, combination therapy can be considered by adding a differently acting agent (e.g. an insulin-releasing drug, SGLT-2 inhibitor, or thiazolidinedione). The maximal effective dosage of metformin is about 2000 mg/day, taken in divided doses with meals, and the maximum is 2550 or 3000 mg/day in different countries [30].

Slow-release formulations (XR/SR/ER) of metformin are available in most countries; they can be taken once daily in the morning, or if necessary morning and evening. Metformin can also be used in combination with any other class of glucose-lowering agent, including insulin, and an extensive range of fixed-dose combination tablets is available in which metformin is combined with either a sulfonylurea, SGLT-2 inhibitor, DPP-4 inhibitor, or thiazolidinedione (see later). It should be noted that although metformin alone is unlikely to cause serious hypoglycaemia, it can occur when metformin is used in combination with an insulin-releasing agent or insulin.

During long-term use of metformin, it is advisable to check at least annually for the emergence of contraindications, particularly renal. Metformin can reduce gastrointestinal absorption of vitamin B₁₂, and although this is rarely a cause of frank anaemia, an annual haemoglobin measurement is recommended, especially for individuals with known or suspected nutritional deficiencies. Metformin should be stopped temporarily when using intravenous radiographic contrast media, or during surgery with general anaesthesia or other intercurrent situations in which the exclusion criteria could be invoked. Substitution with insulin may be appropriate at such times [30].

Efficacy

As monotherapy in people whose diabetes is not adequately managed by lifestyle modification, optimally titrated metformin typically reduces fasting plasma glucose by 2–4 mmol/l, corresponding

to a decrease in HbA_{1c} by ~1–2% (11–22 mmol/mol) [23, 24, 29, 30]. This is largely independent of body weight, age, and duration of diabetes, provided that some β-cell function is still present. To accommodate the progressive nature of type 2 diabetes, it is likely that uptitration of dosage and addition of a second agent will be required to maintain glycaemic targets in the long term.

Metformin carries minimal risk of significant hypoglycaemia or weight gain when used as monotherapy. It may lead to a decrease in basal insulin concentrations, notably in people with hyperinsulinaemia, which should help to improve insulin sensitivity. Minor improvements in the blood lipid profile have been observed during metformin therapy, mostly in those with hyperlipidaemia: plasma concentrations of triglycerides, fatty acids, and low-density lipoprotein (LDL) cholesterol tend to fall, whereas that of high-density lipoprotein (HDL) cholesterol tends to rise [24, 30]. These effects appear to be independent of the anti-hyperglycaemic effect, although a lowering of triglyceride and free fatty acids is likely to help improve insulin sensitivity and benefit the glucose–fatty acid (Randle) cycle.

In the UKPDS, individuals with overweight who started oral glucose-lowering therapy with metformin showed a 39% reduced risk of myocardial infarction (MI) compared with conventional treatment ($p = 0.01$) [32]. There was no obvious relationship with metformin dosage, suggesting that people who can tolerate only a low dose of metformin may benefit from continuing the drug, even when other agents are required to meet adequate glycaemic targets. The decrease in MI was not related to the extent of the glucose-lowering effect of metformin, or effects on classic cardiovascular risk factors such as blood pressure or plasma lipids. Reported benefits of metformin on various atherothrombotic risk markers and factors have been reported, including reduced carotid intima-media thickness (cIMT), increased fibrinolysis, and reduced concentrations of the anti-thrombolytic factor plasminogen activator inhibitor-1 (PAI-1) (Table 35.6) [24, 25, 30].

When metformin is added to the regimens of people receiving insulin therapy, a reduction of insulin dosage is often required, consistent with the ability of metformin to improve insulin sensitivity. Similarly, addition of insulin in people already receiving metformin usually requires lower dosages of insulin and results in less weight gain. Lower amounts of insulin are also associated with fewer and less severe episodes of hypoglycaemia [24, 30]. In some regions of the world metformin is indicated for the prevention of diabetes: the US Diabetes Prevention Program found metformin to reduce the incidence of new cases of diabetes in participants who had overweight or obesity with impaired glucose tolerance (IGT) by 33%, compared with a reduced risk of 58% using an intensive regimen of diet and exercise [33, 34]. The preventive effect of metformin was most evident among individuals who were younger or with a higher level of obesity.

Adverse effects

The main tolerability issue with metformin is abdominal discomfort and other gastrointestinal adverse effects, including diarrhoea. These are often transient and can be ameliorated by taking the drug with meals and titrating the dose slowly. Symptoms may remit if the dose is reduced, but around 10% of people cannot tolerate the drug at any dose. The most serious adverse event associated with metformin is lactic acidosis; it is rare (probably about 0.03–0.06 cases per 1000 patient-years), but about half of cases are fatal [35]. Because the background incidence of lactic acidosis among people with type 2 diabetes has not been established, it is possible that some cases previously attributed to metformin were caused by other factors.

Most reported cases of lactic acidosis in people receiving metformin have been caused by inappropriate prescription, particularly overlooking renal insufficiency. The resulting accumulation of metformin is likely to increase lactate production, and increasing lactate will be aggravated by any hypoxic condition or impaired liver function. Hyperlactataemia occurs in cardiogenic shock and other illnesses that decrease tissue perfusion, and so metformin may be only an incidental factor in some cases. Nevertheless, metformin should be stopped immediately in all cases of suspected or proven lactic acidosis, regardless of cause.

Lactic acidosis is typically characterized by a raised blood lactate concentration (e.g. >5 mmol/l), decreased arterial pH, and/or bicarbonate concentration with an increased anion gap ($[Na^+] - [Cl^- + HCO_3^-] > 15 \text{ mmol/l}$). Presenting symptoms are generally non-specific, but often include hyperventilation, malaise, and abdominal discomfort. Treatment should be commenced promptly without waiting to determine whether metformin is a cause; bicarbonate remains the usual therapy, but evidence of its efficacy is limited. Haemodialysis to remove excess metformin can be helpful, and may assist restoration of fluid and electrolyte balance during treatment with high-dose intravenous bicarbonate.

Sulfonylureas

Since their introduction in the 1950s, sulfonylureas have been used extensively as insulin secretagogues for the treatment of type 2 diabetes. Sulfonylureas were developed as structural variants of sulfonamides after the latter were reported to cause hypoglycaemia [36]. Early sulfonylureas such as carbutamide, tolbutamide, acetohexamide, tolazamide, and chlorpropamide are often referred to as *first-generation* compounds. These have been largely superseded by more potent *second-generation* sulfonylureas, notably glibenclamide (=glyburide), gliclazide, glipizide, and glimepiride (Figure 35.6).

Mode of action

Sulfonylureas act directly on the β cells of the islets of Langerhans to stimulate insulin secretion (Figure 35.7). They enter the β cell and bind to the cytosolic surface of the sulfonylurea receptor 1 (SUR1), which forms part of the transmembrane complex of ATP-sensitive Kir6.2 potassium channels (K⁺ATP channels) (Figure 35.8) [37]. Binding of a sulfonylurea closes the K⁺ATP channel, reducing the efflux of potassium and enabling membrane depolarization. Localized membrane depolarization opens adjacent voltage-dependent L-type calcium channels, increasing calcium influx and raising the cytosolic free calcium concentration. This activates calcium-dependent signalling proteins that control the contractility of microtubules and microfilaments that mediate the exocytotic release of insulin granules. Preformed insulin granules adjacent to the plasma membrane are promptly released (*first-phase* insulin release), followed by a protracted (*second-phase*) period of insulin release that begins about 10 minutes later [38]. The second phase of insulin release involves translocation of preformed and newly formed insulin granules to the plasma membrane for secretion. Sulfonylureas continue to stimulate insulin release while they are bound to the SUR1 provided that the β cells are functionally competent. Some desensitization, however, occurs during repeated and protracted stimulation [39]. Because sulfonylureas can stimulate insulin release when glucose concentrations are below the normal

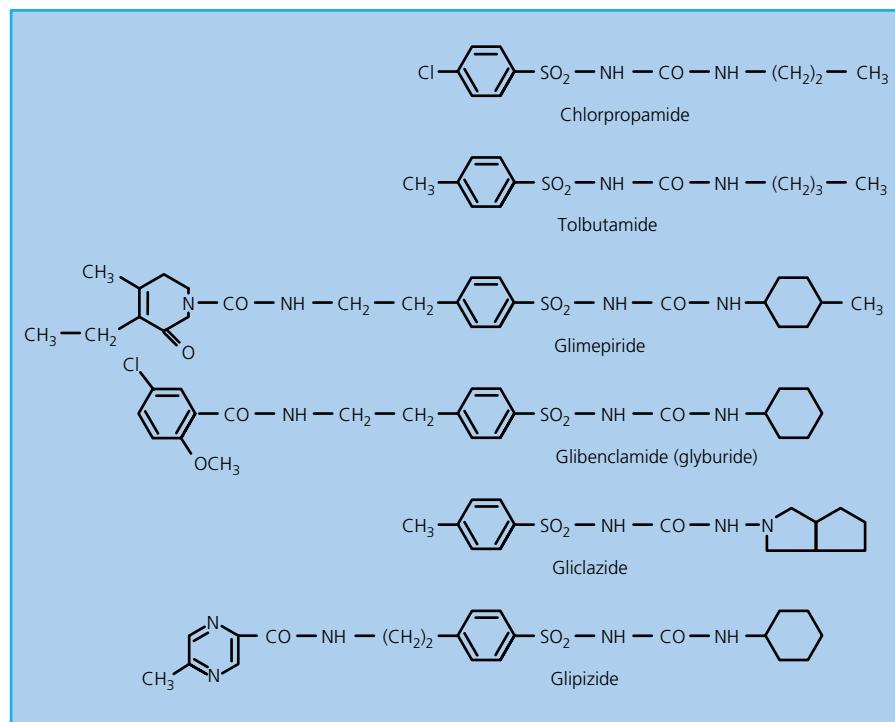

Figure 35.6 Chemical structures of sulfonylureas.

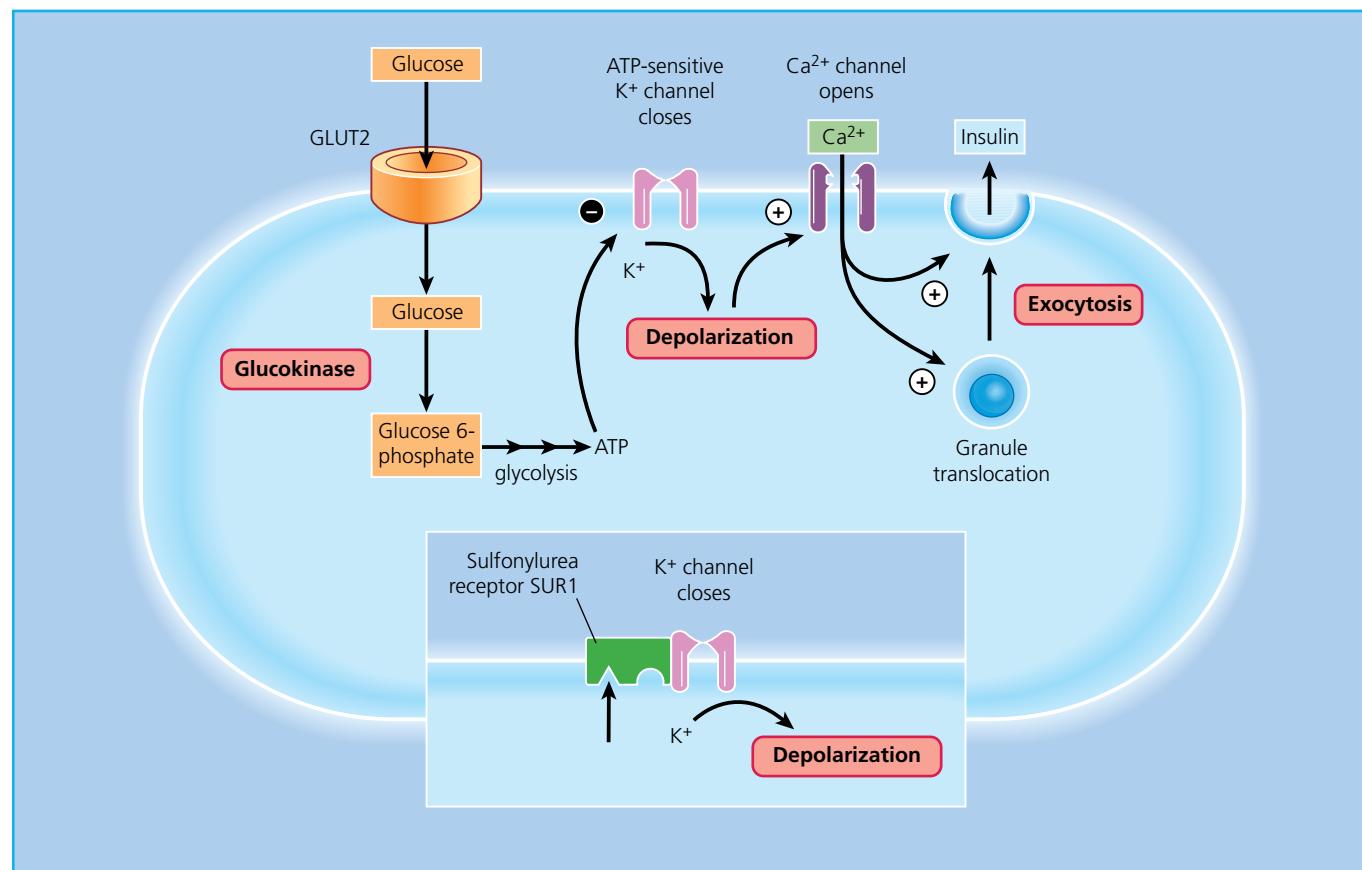

Figure 35.7 Sulfonylureas act on the pancreatic β cell to stimulate insulin secretion. They bind to the cytosolic surface of the sulfonylurea receptor 1 (SUR1), causing closure of ATP-sensitive Kir6.2 potassium channels, depolarizing the plasma membrane, opening calcium channels, and activating calcium-dependent signalling proteins that control insulin exocytosis.

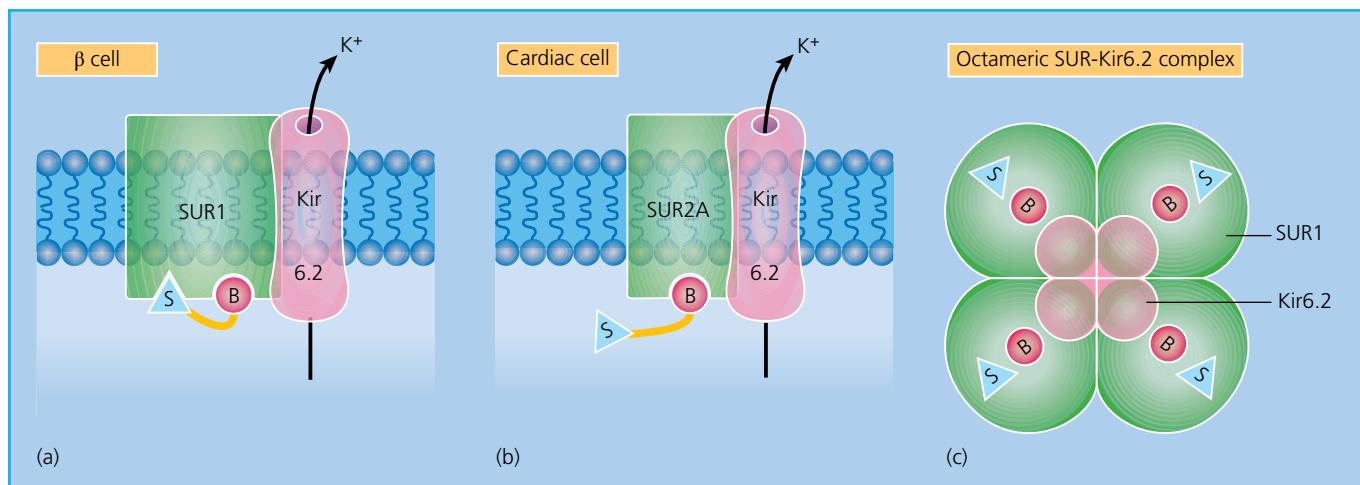

Figure 35.8 (a) The transmembrane complex of the SUR1 sulfonylurea receptor and the ATP-sensitive Kir6.2 potassium efflux channel on the pancreatic β cells. Each SUR1 has a cytosolic sulfonylurea (S) binding site and a benzamido (B) binding site. (b) SUR2A on cardiac muscle cells (and SUR2B on vascular smooth muscle cells) does not have a sulfonylurea binding site. (c) The SUR1–Kir6.2 complex is a non-covalently bonded octamer comprising 4 \times SUR1 and 4 \times Kir6.2, illustrated from the cytosolic surface to show the sulfonylurea and benzamido binding sites. The Kir6.2 components are located at the centre and form the K^+ efflux pore. The Kir6.2 channel has a cytosolic binding region for ADP/ATP.

Table 35.7 Sulfonylureas.

Agent ^a	Dose range (mg/day)	Duration of action (h)	Metabolites	Elimination
Tolbutamide	500–2000	6–10	Inactive	Urine 100%
Glipizide	2.5–20	6–16	Inactive	Urine ~70%
Gliclazide	40–320	12–20	Inactive	Urine ~65%
Gliclazide MR	30–120	18–24	Inactive	Urine ~65%
Glimepiride	1.0–6.0	12–>24	Active	Urine ~60%
Glibenclamide ^b	1.25–15	12–>24	Active	Bile >50%
Chlorpropamide ^c	100–500	24–50	Active	Urine >90%

MR, modified release.

^a People with newly diagnosed type 2 diabetes are not usually started on first-generation sulfonylureas (tolbutamide, chlorpropamide).

^b Glibenclamide is also known as glyburide in some countries.

^c Chlorpropamide is no longer available in many countries.

can increase the risk of hypoglycaemia (Table 35.5). Sulfonylureas are metabolized in the liver to varying extents to a range of active and inactive metabolites that are eliminated along with unchanged drug via the bile and urine. Longer-acting sulfonylureas can be given once daily but carry a greater risk of hypoglycaemia, especially with active metabolites. Sites and rates of metabolism and elimination are also important considerations, especially in older people and individuals with coexisting liver or kidney disease or taking several other medications.

The formulation of some sulfonylureas has been altered to modify the duration of action. For example, a micronized formulation of glibenclamide (termed glyburide) in the USA increases the rate of gastrointestinal absorption for earlier onset of action. A longer-acting (extended-release) formulation of glipizide and a modified-release (MR) formulation of gliclazide have been introduced for once-daily dosing. Interestingly, the 30 mg preparation of gliclazide MR gives similar efficacy to 80 mg of unmodified gliclazide and reduces the risk of severe hypoglycaemia [43].

Indications and contraindications

Sulfonylureas are widely used as monotherapy and in combination with metformin or a thiazolidinedione. They can also be used with an α -glucosidase inhibitor or SGLT-2 inhibitor, and there are individuals who can benefit from a combination of a sulfonylurea with an incretin agent or insulin. Combination of a sulfonylurea with a different type of glucose-lowering agent usually affords approximately additive glucose-lowering efficacy, at least initially, but there is an increased risk of hypoglycaemia. The additive efficacy of a sulfonylurea with another type of insulin secretagogue is dependent on different modes of action on the β cell.

The pharmacological theory of adding a sulfonylurea (or other insulin secretagogue) to insulin therapy for people with type 2 diabetes is that subcutaneous insulin injections do not mimic the normal endogenous delivery of more insulin to the liver than to the periphery. Thus, where there is residual endogenous β -cell function, a stimulus to increase delivery of endogenous insulin to the liver should assist in reducing hepatic glucose production,

threshold for glucose-stimulated insulin release (~ 5 mmol/l), they are capable of causing hypoglycaemia, mainly through insulin-induced suppression of hepatic glucose production.

Sulfonylureas may exert minor glucose-lowering effects independently of increased insulin secretion [40, 41]. A small reduction in glucagon concentrations, increased peripheral glucose transport, and increased hepatic glucose deposition have been reported, but these effects are not considered to be of sufficient magnitude to be clinically relevant.

Pharmacokinetics

Sulfonylureas vary considerably in their pharmacokinetic properties (Table 35.7), which in turn affects their clinical suitability for different individuals [40–42]. They are generally well absorbed, and reach peak plasma concentration in 2–4 hours. Sulfonylureas are highly bound to plasma proteins, which can lead to interactions with other protein-bound drugs such as salicylates, sulfonamides, and warfarin. Also, displacement of protein-bound sulfonylurea

particularly during digestion of a meal. Hence daytime sulfonylurea is sometimes given with bedtime insulin, and this can substantially, if only temporarily, reduce the required insulin dose [40, 42]. Guidelines generally include sulfonylureas as alternative first-line oral therapy where metformin is not appropriate or not tolerated, although DPP-4 inhibitors, SGLT-2 inhibitors, and GLP-1 receptor agonists are generally favoured in recent guidelines. Because sulfonylurea therapy is associated with weight gain, these agents have customarily been preferred for people who are not overweight.

Sulfonylurea therapy is begun with a low dose, preferably with self-monitoring of blood glucose by the individual at least once daily during the first few weeks. This is especially recommended where there are strong concerns about the potential consequences of hypoglycaemia (e.g. in older individuals and those living alone, operating machinery, or driving). In general, people who have responded to some extent (but still inadequately) with lifestyle measures and have less marked fasting hyperglycaemia are more likely to incur hypoglycaemia with a sulfonylurea. The dosage is uptitrated at 2–4-week intervals as required. Hypoglycaemia or early hypoglycaemic symptoms are the main limitation to dose escalation of sulfonylureas. If evidence of hypoglycaemia occurs before the glycaemic target is achieved, or if a dosage increment produces no further glycaemic benefit, it is advisable to return to the previous dose. Adjustment of the administration regimen may assist or an alternative class of insulin secretagogue may be more suitable. Where the sulfonylurea is taken as monotherapy and the glycaemic target is not achieved, then addition of an agent to reduce insulin resistance or an SGLT-2 inhibitor or an α -glucosidase inhibitor is the usual recourse. Note that the maximal blood glucose-lowering effect of a sulfonylurea is usually achieved at a dose that is well below the recommended maximum, indicating that maximal stimulation of insulin secretion has already been achieved.

Efficacy

As monotherapy in people whose diabetes is inadequately managed by lifestyle measures, sulfonylureas can be expected to reduce fasting plasma glucose by about 2–4 mmol/l, equating to a decrease in HbA_{1c} of 1–2% (11–22 mmol/mol) [2, 5, 40–43]. The glucose-lowering effect of sulfonylureas is immediate, and they are particularly effective in the short term. Efficacy is dependent, however, on sufficient reserve of β -cell function, and this is set against the inevitable decline in β -cell function as the natural history of type 2 diabetes proceeds. Hence it is expected that the dose will need to be escalated to counter the progressive loss of β -cell function, which can reduce the durability of the glucose-lowering efficacy. A rapid deterioration of glycaemic indices during sulfonylurea therapy (sometimes termed *secondary sulfonylurea failure*) occurs in ~5–10% of people per annum. Although this may possibly vary between compounds, it largely reflects the progression of β -cell failure [2, 5, 40–43]. Early intervention in people with a greater reserve of β -cell function usually produces a better and longer response to sulfonylureas, although not without risk of hypoglycaemia, whereas late intervention in those with severely compromised β -cell function is less effective.

Sulfonylureas generally have little effect on blood lipids. Occasionally, their use will cause a small decrease in plasma triglyceride or increase in HDL cholesterol.

Adverse effects

Weight gain, typically in the range 1–4 kg, is common after initiation of sulfonylurea therapy; it stabilizes by about six months [40–42]. The weight gain probably reflects the anabolic effects of increased

plasma insulin concentrations together with reduced loss of glucose in the urine.

Hypoglycaemia is a common and potentially the most serious adverse effect of sulfonylurea therapy. Although it is only rarely life threatening in people with type 2 diabetes, even mild impairment of neural or motor function can endanger the individual and others, and may predispose to a poor prognosis after a myocardial infarction [44]. People treated with sulfonylureas should be given instruction on the prevention and recognition of hypoglycaemia and the prompt actions required. In the UKPDS, ~20% of sulfonylurea-treated participants reported one or more episodes of hypoglycaemic symptoms annually. Other studies have suggested similar rates [9, 12, 42]. Severe hypoglycaemia (requiring third-party assistance) during sulfonylurea therapy occurred in ~1% of participants annually in the UKPDS, and lower rates (~0.2–2.5 episodes per 1000 patient-years) have been reported elsewhere. The mortality risk from sulfonylurea-induced hypoglycaemia is reported to be 0.014–0.033 per 1000 patient-years [44]. Longer-acting sulfonylureas, irregular meals, combination with other glucose-lowering drugs, especially insulin, excessive alcohol consumption, already near-normal fasting glycaemia, old age, and interacting drugs can predispose to an increased risk of hypoglycaemia.

Sulfonylurea-induced hypoglycaemia requires prompt admission to hospital. Treatment with glucose by continuous intravenous infusion, probably for more than one day, is applied to guard against the tendency for a recurrence of hypoglycaemia where long-acting sulfonylureas are concerned. If accumulation of chlorpropamide is suspected, renal elimination may be enhanced by forced alkaline diuresis. The vasodilator diazoxide and the somatostatin analogue octreotide have been used successfully (but with extreme caution) to inhibit insulin secretion in severe sulfonylurea-induced hypoglycaemia. Use of glucagon in people with type 2 diabetes should be avoided as this is itself an insulin secretagogue.

Very occasionally, sulfonylureas produce sensitivity reactions, usually transient cutaneous rashes. Erythema multiforme is rare. Fever, jaundice, acute porphyria, photosensitivity, and blood dyscrasias are also rare. Chlorpropamide (no longer in common use) was known for its propensity to cause facial flushing with alcohol and increasing renal sensitivity to antidiuretic hormones, occasionally causing water retention and hyponatraemia. Glibenclamide is claimed to have a mild diuretic action.

Although the efficacy of sulfonylureas depends on the stimulation of insulin secretion, this seldom raises plasma insulin concentrations beyond the range of normal individuals without diabetes and those with IGT. The suggestion emanating from the University Group Diabetes Program study in the 1960s that tolbutamide-induced hyperinsulinaemia might have a detrimental effect on the cardiovascular system remains unsubstantiated.

Further studies on the cardiovascular safety of sulfonylureas were prompted by the finding that two isoforms of the sulfonylurea receptor, SUR2A and SUR2B, are expressed in cardiac muscle and vascular smooth muscle, respectively. These isoforms lack the sulfonylurea binding site, but they retain the benzamido binding site (Figure 35.8). Therefore, SUR2A/B can only bind those sulfonylureas that contain a benzamido group (glibenclamide, glipizide, glimepiride) [37]. Sulfonylureas without a benzamido group (e.g. tolbutamide, chlorpropamide, gliclazide) show very little interaction with the cardiac and vascular SUR receptors. The effects of the K⁺ATP channel opener nicorandil (an anti-anginal drug with cardioprotective properties) are blocked by sulfonylureas that have a benzamido group. Compounds with a benzamido group could

theoretically interfere with ischaemic preconditioning and increase vascular contractility at a time when this might be undesirable (e.g. severe myocardial ischaemia). However, there is no clear evidence that therapeutic concentrations of sulfonylureas exert such an effect. Indeed, hyperglycaemic states appear to obviate ischaemic preconditioning, but some authorities continue to advocate that the use of sulfonylureas is kept to a minimum in people with overt coronary artery disease [41, 45].

Meglitinides (short-acting prandial insulin releasers)

Meglitinide analogues (sometimes termed glinides) were evaluated as potential glucose-lowering agents after an observation in the 1980s that meglitinide – the non-sulfonylurea moiety of glibenclamide that contains the benzamido group – could stimulate insulin secretion similarly to a sulfonylurea [46]. The pharmacokinetic properties of these compounds favoured a rapid but short-lived insulin secretory effect that suited administration with meals to promote prandial insulin release. By generating a prompt increase of insulin to coincide with meal digestion, these agents help to restore partially the first-phase glucose-induced insulin response

that is lost in type 2 diabetes. Specifically targeting post-prandial hyperglycaemia might also address the vascular risk attributed to prandial glucose excursions and reduce the risk of inter-prandial hypoglycaemia [47]. Two agents, the meglitinide derivative repaglinide and the structurally related phenylalanine derivative nateglinide, were introduced in 1998 and 2001, respectively, as *prandial insulin releasers* (Figure 35.9). Although acting mainly during the prandial and early post-prandial periods, their effects extend sufficiently to produce some reduction of fasting hyperglycaemia, particularly with repaglinide.

Mode of action

Prandial insulin releasers bind to the benzamido site on the sulfonylurea receptor SUR1 in the plasma membrane of the islet β cells (Figure 35.8). This site is distinct from the sulfonylurea site, but the response to binding is the same as for sulfonylureas, causing closure of the K^+ ATP channel. Thus, there is usually no therapeutically additive advantage of using the two types of agents together.

Pharmacokinetics

Repaglinide is almost completely and rapidly absorbed with peak plasma concentrations after about one hour. It is quickly metabolized in the liver to inactive metabolites, which are mostly excreted in the bile (Table 35.8). Taken about 15 minutes before a meal,

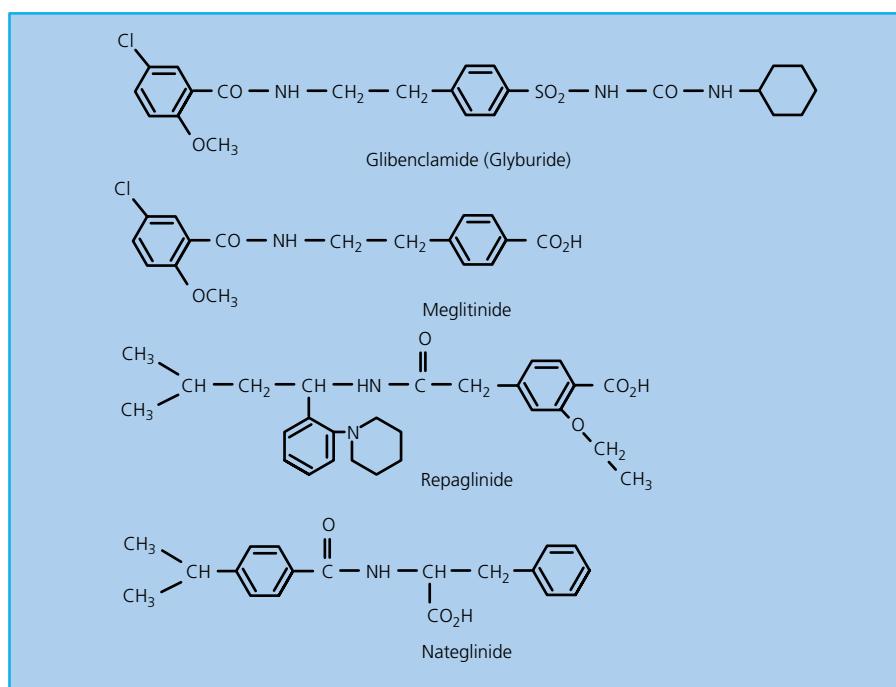

Figure 35.9 Chemical structures of meglitinide and the prandial insulin releasers repaglinide and nateglinide compared with glibenclamide (glyburide).

Table 35.8 The meglitinides: repaglinide and nateglinide.

Agent	Dose range (mg/meal)	Maximum daily dose (mg)	Duration of action (h)	Metabolites	Elimination
Repaglinide	0.5–4.0	16	4–6	Inactive	Bile ~90%
Nateglinide	60–180	540	3–5	One slightly active	Urine ~80%

repaglinide produces a prompt insulin response that lasts about three hours, coinciding with the duration of meal digestion. Nateglinide has a slightly faster onset and shorter duration of action [47].

Indications and contraindications

Prandial insulin releasers can be used as monotherapy in people whose diabetes is inadequately managed by non-pharmacological measures. They are perhaps most suited for individuals who exhibit post-prandial glycaemic excursions while retaining near-normal fasting glycaemia. As rapid-acting insulin releasers, they can be helpful to individuals with irregular lifestyles with unpredictable or missed meals. The lower risk of hypoglycaemia also provides a useful option for some older individuals, particularly if other agents are contraindicated, although the need for multiple daily dosages may be a disincentive.

Repaglinide is ideally taken 15–30 minutes before a meal. Therapy is introduced with a low dose (e.g. 0.5 mg) and glycaemic levels are monitored during titration every two weeks up to a maximum of 4 mg before each main meal. When a meal is not consumed, the corresponding dose of repaglinide should be omitted. With appropriate caution and monitoring, repaglinide can be given to those with moderate renal impairment where some sulfonylureas and metformin are contraindicated.

Nateglinide can be used as monotherapy in much the same way as repaglinide, although nateglinide tends to be faster and shorter acting and requires caution in people with hepatic disease. Note that in some countries, such as the UK, nateglinide is not licensed for use as monotherapy, only for combination therapy.

If the desired glycaemic target is not met with a prandial insulin releaser, early introduction of combination therapy (e.g. with an agent to reduce insulin resistance) can be considered. Prandial insulin releasers can also be useful add-ons to monotherapy with metformin or a thiazolidinedione.

Efficacy

Consistent with their use to boost prandial insulin secretion, repaglinide (0.5–4 mg) and nateglinide (60–180 mg) taken before meals produce dose-dependent increases in insulin concentrations and reduce post-prandial hyperglycaemia. There is usually a small reduction in fasting hyperglycaemia. Reductions in HbA_{1c} are similar to or smaller than with sulfonylureas, as predicted by their shorter duration of action. As an add-on to metformin, they can reduce HbA_{1c} by an additional 0.5–1.5% (6–17 mmol/mol).

Adverse effects

Hypoglycaemic episodes are fewer and less severe with prandial insulin releasers than with sulfonylureas. Sensitivity reactions, usually transient, are uncommon. Plasma levels of repaglinide may be increased during co-administration with gemfibrozil. Prandial insulin releasers may cause a small increase in body weight when started as initial monotherapy, but body weight is little affected among people switched from a sulfonylurea or when a prandial insulin releaser is combined with metformin.

Thiazolidinediones

The glucose-lowering activity of a thiazolidinedione (ciglitazone) was reported in the early 1980s. In the early 1990s, the peroxisome proliferator-activated receptor (PPAR) family was identified as part

of the nuclear receptor superfamily 1, and it became evident that thiazolidinediones were potent agonists of PPAR- γ [48]. The PPAR- γ -mediated transcriptional effects of thiazolidinediones improved whole-body insulin sensitivity, and troglitazone became the first thiazolidinedione to enter routine clinical use, introduced in the USA in 1997. The drug, however, was associated with fatal cases of idiosyncratic hepatotoxicity and was withdrawn in 2000. Troglitazone was available for only a few weeks in 1997 in the UK. Two other thiazolidinediones, rosiglitazone and pioglitazone (Figure 35.10), which did not show hepatotoxicity, were introduced in the USA in 1999 and in Europe in 2000. Fixed-dose combinations of each agent with metformin also became available.

By 2007, meta-analyses of safety data for rosiglitazone were indicating increased risks of heart failure, myocardial infarction, and cardiovascular death, resulting in withdrawal of rosiglitazone in Europe in 2010 and restricted use in the USA (placement on Risk Evaluation and Mitigation Strategy, REMS) [49]. However, evaluation of a large prospective cardiovascular outcome study with rosiglitazone (Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycemia in Diabetes, RECORD) did not confirm the increased risk of myocardial infarction and cardiovascular death, and the REMS restriction in the USA was lifted in 2013. An earlier study in 2007 with pioglitazone (Prospective Pioglitazone Clinical Trial in Macrovascular Events, PROactive) had not shown increased risk of myocardial infarction or cardiovascular death, and pioglitazone has since been shown to reduce risk of stroke [50,51]. However, concerns regarding weight gain, oedema, risk of bone fracture, and other potential cautions have limited the use of pioglitazone in some countries [5].

Mode of action

Most of the glucose-lowering efficacy of thiazolidinediones appears to be achieved through stimulation of PPAR- γ , leading to increased insulin sensitivity [5, 48, 52]. PPAR- γ is highly expressed in adipose tissue, and to a lesser extent in muscle and liver. When activated it forms a heterodimeric complex with the retinoid X receptor and binds to a nucleotide sequence (AGGTCAAGGTCA) termed the peroxisome proliferator response element (PPRE) located in the promoter regions of PPAR-responsive genes. In conjunction with co-activators such as PGC-1, this alters the transcriptional activity of a range of insulin-sensitive and other genes (Table 35.9). Many of these genes participate in lipid and carbohydrate metabolism (Figure 35.11). Stimulation of PPAR- γ by a thiazolidinedione promotes differentiation of pre-adipocytes into mature adipocytes; these new small adipocytes, mostly in subcutaneous depots, are particularly sensitive to insulin, and show increased uptake of fatty acids with increased lipogenesis. This in turn reduces circulating

non-esterified (free) fatty acids, which rebalances the glucose–fatty acid (Randle) cycle, facilitating glucose utilization and restricting fatty acid availability as an energy source for hepatic gluconeogenesis. By reducing circulating fatty acids, ectopic lipid deposition in muscle and liver is reduced, which further contributes to improvements of glucose metabolism. Thiazolidinediones also increase mitochondrial biogenesis, but may act directly on mitochondria to reduce respiratory function.

Thiazolidinediones increase glucose uptake into adipose tissue and skeletal muscle via increased availability of GLUT4 glucose transporters. Improvements in insulin sensitivity are likely to be assisted by reduced production of several adipocyte-derived proinflammatory cytokines, notably tumour necrosis factor α (TNF- α), which is implicated in muscle insulin resistance. Thiazolidinediones also increase the production of adiponectin, which enhances insulin action and exerts potentially beneficial effects on vascular reactivity. Because PPAR- γ is expressed to a small extent in many tissues, thiazolidinediones can affect responsive genes at these locations, and this has given rise to the tag *pleiotropic effects* [52, 53].

Thiazolidinediones, like metformin, require the presence of sufficient insulin to generate their blood glucose-lowering effect. Plasma insulin concentrations are typically lowered by thiazolidinediones, and long-term viability of islet β cells might be improved [53].

Pharmacokinetics

Absorption of rosiglitazone and pioglitazone is rapid and almost complete, with peak concentrations at 1–2 hours, but slightly delayed when taken with food. Both drugs are metabolized extensively by the liver. Pioglitazone is metabolized predominantly by CYP2C8 and CYP3A4 to active metabolites that are eliminated in the bile (Table 35.10). Pioglitazone does not cause any clinically significant reductions in plasma concentrations of other drugs metabolized by CYP3A4, such as oral contraceptives. Both thiazolidinediones are almost completely bound to plasma proteins, but their concentrations are not sufficient to interfere with other protein-bound drugs.

Indications and contraindications

Thiazolidinediones can be used as monotherapy in individuals with type 2 diabetes with and without obesity in whom lifestyle does not afford adequate glycaemic levels. Various treatment algorithms ascribe different positions for thiazolidinediones, but in general they can be used as monotherapy if metformin is inappropriate or not tolerated, and as an add-on to metformin for those in whom weight gain is not an issue and an insulin secretagogue is not favoured. Because of their slow onset of action, it is not straightforward to substitute a thiazolidinedione for another class of glucose-lowering agent without a temporary deterioration in glycaemic levels. Combination of a thiazolidinedione with insulin can improve

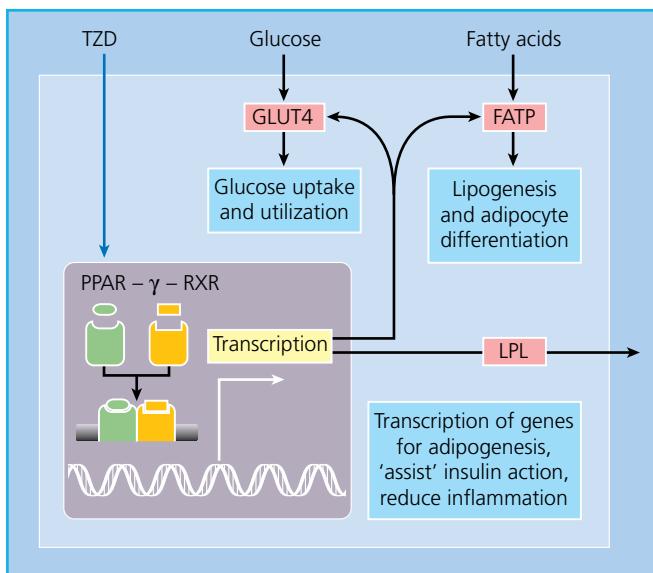

Figure 35.11 Mechanism of action of thiazolidinediones. Most actions of a thiazolidinedione (TZD) are mediated via stimulation of the nuclear peroxisome proliferator-activated receptor γ (PPAR- γ), which is highly expressed in adipose tissue. When stimulated, PPAR- γ forms a heterodimeric complex with the retinoid X receptor (RXR). The complex binds to the peroxisome proliferator response element (PPRE) nucleotide sequence (AGGTCAAGGTCA) in the promoter regions of certain genes, recruits co-activators, and alters the transcriptional activity of these genes. This modifies nutrient uptake and metabolism, and also the other functions of the cell.

Table 35.10 The thiazolidinediones: pioglitazone and rosiglitazone.

Agent	Dose range (mg/day)	Duration of action (h)	Metabolites	Elimination
Pioglitazone	15–45	~24	Active	Bile >60%
Rosiglitazone	4–8	~24	Inactive	Urine ~64%

glycaemic indices while reducing insulin dosages, especially in individuals with obesity, but requires extra caution as peripheral oedema is more common [53].

The propensity for fluid retention with thiazolidinediones, which can increase plasma volume by up to 500 ml, reduce haematocrit, and decrease the haemoglobin concentration up to 1 g/dl, contraindicates these agents for people with evidence of heart failure. The exclusion criteria, based on cardiac status, vary between countries; for example, New York Heart Association classes I–IV are exclusions in Europe, whereas classes III and IV are exclusions in the USA [5]. Appropriate clinical monitoring is important, especially for people considered at higher risk for cardiac failure and those showing marked initial weight gain. Despite an increased fluid volume, thiazolidinediones do not increase, and usually slightly decrease, blood pressure.

The troglitazone experience of idiosyncratic hepatotoxicity prompted vigilance with liver function by measuring serum alanine aminotransferase (ALT) before starting rosiglitazone and pioglitazone therapy, and periodically thereafter. Pre-existing liver disease, development of clinical hepatic dysfunction, or elevated ALT levels >2.5 times the upper limit of normal are contraindications to thiazolidinediones. Interestingly, because of the effects of thiazolidinediones to reduce hepatic fat, recent studies have suggested that this class of drug might be useful for the treatment of non-alcoholic steatohepatitis [53].

If there are no contraindications, a thiazolidinedione can be used in older people. A thiazolidinedione can also be considered for individuals with mild renal impairment, while appreciating the potential for oedema. Use of a thiazolidinedione in women with anovulatory PCOS can cause ovulation to resume, but thiazolidinediones should not be continued in pregnancy.

Efficacy

Thiazolidinediones produce a slowly generated anti-hyperglycaemic effect, which usually requires 2–3 months to reach maximum effect [52, 53]. This tends to prolong the dose titration process, and because the therapeutic response can vary considerably between individuals, it is appropriate to consider the individual as a non-responder and to switch to another treatment if there is no clinically meaningful effect after three months. Thiazolidinediones reduce HbA_{1c} by around 0.5–1.5% (6–17 mmol/mol). In a long-term monotherapy comparison with metformin or a sulfonylurea (A Diabetes Outcome Progression Trial, the ADOPT study), rosiglitazone showed a slower onset but more durable glucose-lowering effect over more than three years [54]. The effect of thiazolidinediones may be better in people with greater β-cell reserve and in more overweight individuals, but a clear indicator of the best responders has not been established. Thiazolidinediones do not cause hypoglycaemia as monotherapy.

Thiazolidinediones substantially reduce circulating non-esterified (free) fatty acids, but effects on other components of the plasma lipid profile have been the subject of debate. Rosiglitazone tends to cause a small rise in the total cholesterol concentration, which stabilizes by about three months, although this may be mitigated by adequate statin therapy. The effect appears to reflect a rise in both LDL and HDL cholesterol, leaving the LDL-to-HDL cholesterol ratio and the total-to-HDL cholesterol ratio little changed or slightly improved. Pioglitazone generally appears to have little effect on total cholesterol, and has frequently reduced triglyceride concentrations in clinical trials. Both thiazolidinediones reduce the proportion of the smaller, denser (more atherogenic) LDL particles [53].

Weight gain, similar in magnitude to sulfonylurea therapy (typically 1–4 kg) and stabilizing over 6–12 months, is usually observed after initiation of thiazolidinedione therapy. Several studies indicate that the distribution of body fat is altered; the visceral adipose depot is little changed or reduced, while the subcutaneous depot is increased as new small, insulin-sensitive adipocytes are formed [53].

Thiazolidinediones exert beneficial effects on a selection of atherothrombotic risk markers, indices of vascular reactivity, and components of the metabolic syndrome. For example, thiazolidinediones downregulate PAI-1 expression, decrease urinary albumin excretion to a greater extent than expected for the improvement in glycaemic levels, reduce cIMT and coronary restenosis, and reduce circulating markers of chronic low-grade inflammation [53]. However, a recent pragmatic trial (Thiazolidinediones Or Sulfonylureas and Cardiovascular Accidents. Intervention Trial, TOASCA.IT) noted that the incidence of cardiovascular events was similar when either pioglitazone or a sulfonylurea was added to metformin [55]. Thiazolidinediones also reduce the occurrence of new-onset diabetes in individuals with IGT or those with a history of gestational diabetes [53].

Adverse effects

Despite improvements in several atherothrombotic risk factors, the main concerns over thiazolidinediones have focused on the cardiovascular impact of oedema, reduced haemoglobin levels, and congestive heart disease. Although long-term cardiovascular events were reduced during a large prospective study with pioglitazone (PROactive), the cardiovascular safety issues raised over rosiglitazone reduced confidence in the class, and the TOSCA.IT pragmatic study indicated no overall cardiovascular benefit of pioglitazone [49, 50, 53, 55].

Recent studies have noted an approximate doubling of the risk of a bone fracture with use of a thiazolidinedione, mainly at distal sites and among postmenopausal women [53]. This has been attributed at least in part to a reduction in bone mineral density. Stimulation of PPAR-γ in colonic cells has been reported both to increase and to decrease the risk of tumours in animals and cell models; thus, familial polyposis coli is a contraindication to thiazolidinediones on theoretical grounds. There has been debate concerning a possible increased risk of bladder cancer with pioglitazone, and the drug is not recommended for people with active bladder disease or a history of bladder disease. However, long-term safety analyses have not confirmed a significant increase in risk of bladder cancer with pioglitazone [53].

Hypoglycaemia may occur several weeks after adding a thiazolidinedione to a sulfonylurea; self-monitoring of blood glucose can be helpful to identify when the dosage of the sulfonylurea should be reduced.

Dipeptidyl peptidase 4 inhibitors

DPP-4 inhibitors (often termed gliptins) inhibit the enzyme DPP-4, which is responsible for the rapid degradation of two key incretin hormones, glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1). Thus DPP-4 inhibitors enhance endogenous incretin activity by preventing the rapid degradation of these incretin hormones. The history, structure, and function of incretin hormones, and the therapeutic role of subcutaneously injected GLP-1 receptor agonists such as exenatide,

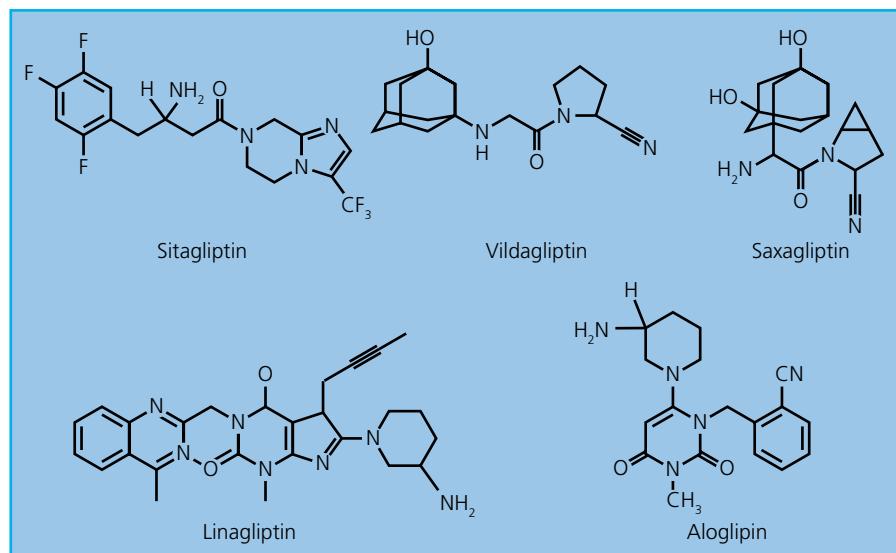

Figure 35.12 Chemical structures of the dipeptidyl peptidase 4 (DPP-4) inhibitors (gliptins) sitagliptin, vildagliptin, saxagliptin, linagliptin, and alogliptin.

liraglutide, lixisenatide, and dulaglutide, are covered in Chapter 36. Briefly, incretin hormones are secreted from the intestine in response to meal digestion; one of their main actions is to increase glucose-induced insulin secretion by the pancreatic islet β cells, thereby reducing prandial glucose excursions [5, 56, 57]. GLP-1 also suppresses glucagon secretion from the islet α cells, exerts a satiety effect, and delays gastric emptying.

It was noted in the 1980s that the incretin effect is reduced in type 2 diabetes, and subsequent studies have shown that this is largely due to reduced activity of GLP-1 [58, 59], suggesting that administration of extra GLP-1 might be therapeutically useful. Because GLP-1 is rapidly degraded ($t_{1/2} < 2$ minutes) by DPP-4, the potential of DPP-4 inhibitors was investigated in the 1990s, giving rise to the introduction of several specific inhibitors [60], notably sitagliptin (2007), vildagliptin (2008), saxagliptin (2008), linagliptin (2011), and alogliptin (2013) (Figure 35.12).

Mode of action

DPP-4 inhibitors act to prevent the aminopeptidase activity of DPP-4; the enzyme is found free in the circulation and tethered to endothelia and other epithelial cells in most tissues, especially in the intestinal mucosa [61]. DPP-4 cleaves the N-terminal dipeptide from peptides that have either an alanine or a proline residue penultimate to the N-terminus. The incretins GLP-1 and GIP are prime targets for DPP-4, and DPP-4 inhibitors more than double their circulating concentrations (although this is not as high as the concentrations of subcutaneously administered GLP-1 receptor agonists) [58]. Raised endogenous incretin concentrations enhance nutrient-induced insulin secretion. Increased insulin biosynthesis and increased β -cell mass have also been noted in some animal studies, but these effects have not been confirmed in clinical studies (Table 35.11). Increased GLP-1 concentrations also suppress excessive glucagon secretion. Because these effects are glucose dependent, there is a low risk of inducing significant hypoglycaemia, and this is a key reason for the increased use of DPP-4 inhibitors in preference to sulfonylureas. The elevation of GLP-1 levels produced by DPP-4 inhibitors is not generally sufficient to create a measurable satiety effect or sufficient to delay gastric emptying, hence avoiding any nausea. Body weight is usually little changed or slightly reduced by DPP-4 inhibitors (Figure 35.13).

Because the incretin-mediated effect of DPP-4 inhibitors potentiates glucose-dependent insulin secretion, the activity period of these agents is mostly prandial. Although they are particularly effective in lowering post-prandial hyperglycaemia, there is a substantial carryover effect to benefit inter-prandial glycaemia [58, 60, 61]. By contrast, DPP-4 inhibitors do not initiate insulin secretion and so they do not increase basal insulin secretion. Also, they only suppress glucagon secretion in the hyperglycaemic state, and so there is a low risk of inter-prandial overshoot into hypoglycaemia.

Pharmacokinetics

The pharmacokinetic properties of DPP-4 inhibitors are summarized in Table 35.12. DPP-4 inhibitors are selective, competitive, and reversible inhibitors of DPP-4 (IC_{50} in the lower nmol/l range). They mimic the N-terminal dipeptide structure of the incretins, which enables them to block the catalytic site of DPP-4 through either covalent (vildagliptin and saxagliptin) or non-covalent

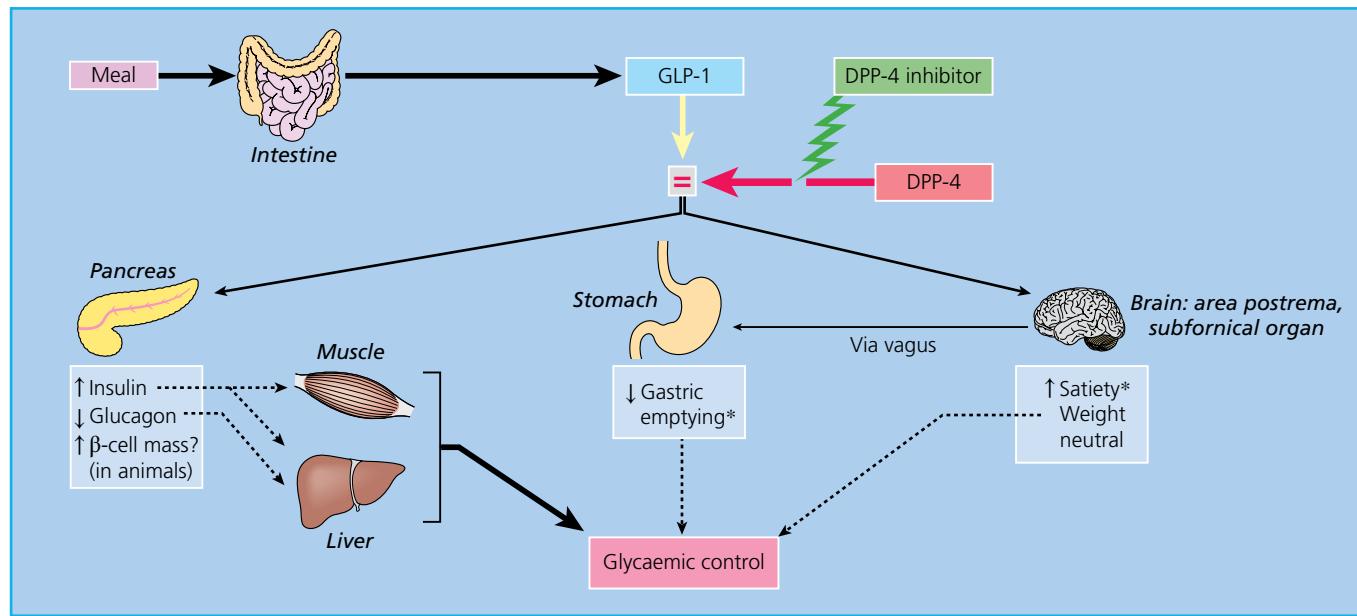

Figure 35.13 Sites of action of dipeptidyl peptidase 4 (DPP-4) inhibitors (gliptins). Incretin hormones such as glucagon-like peptide-1 (GLP-1) are released in response to a meal. These hormones are normally degraded rapidly by the enzyme DPP-4. Inhibiting DPP-4 allows the normal effects of the incretin hormones to be enhanced. The main site of the enhanced incretin effect is on the pancreas to increase nutrient-induced insulin secretion. GLP-1 also reduces glucagon secretion. *Potential effects to slow gastric emptying and increase satiety probably contribute little to the therapeutic efficacy of DPP-4 inhibitors.

(sitagliptin, linagliptin, and alogliptin) interactions. DPP-4 inhibitors are absorbed rapidly, with onset of activity in <10 minutes of administration and t_{max} achieved mostly within 2 hours. They produce >90% inhibition of DPP-4 activity for most of a 24-hour period, although the shorter elimination half-life of vildagliptin requires twice-daily administration compared with once daily for other agents in the class. Two DPP-4 inhibitors are substantially metabolized (vildagliptin to inactive metabolites and saxagliptin to active metabolites), whereas the others undergo little metabolism. Linagliptin is eliminated mostly via the bile into the faeces and can be used without dose adjustment in people with moderate to severe renal impairment. Other members of the class are eliminated in the urine, necessitating dose reduction in people with moderate renal impairment (typically an eGFR <50 ml/min) [60, 60].

Indications and contraindications

DPP-4 inhibitors can be used as monotherapy in people whose type 2 diabetes has responded inadequately to lifestyle measures, and as add-on therapy when metformin or a thiazolidinedione alone has not brought the glucose levels into the target range. DPP-4 inhibitors could be used with other classes of oral agent or insulin, as their mode of action on the β cell is different from that of sulphonylureas and meglitinides, and their ability to reduce glucagon levels might be useful as add-on therapy to insulin even without β-cell function. In practice, however, full efficacy in type 2 diabetes requires adequate β-cell reserve, and there is usually little additional efficacy if a DPP-4 inhibitor is added to a GLP-1 receptor agonist. Lack of weight gain makes DPP-4 inhibitors suitable for individuals with overweight or obesity, and the low risk of hypoglycaemia when used as monotherapy (and

when used with non-insulin-releasing agents) favours their use in people who have only slightly raised basal glycaemia, are close to glycaemic target, or have unpredictable meal times [60,61].

Efficacy

The anti-hyperglycaemic effect of DPP-4 inhibitors is quickly generated, with HbA_{1c} values typically reduced by ~0.7–1.0% (8–11 mmol/mol). Post-prandial glucose excursions are reduced by ~3 mmol/l and basal glycaemia by ~1–1.5 mmol/l. The glucose-dependent mode of action (i.e. DPP-4 inhibitors only potentiate insulin secretion when glucose concentrations are raised) reduces the risk of any significant hypoglycaemia, lowering concern over missed meals. Thus, there is no dose titration, but it is recommended that fasting and post-prandial glycaemia are reviewed after about two weeks of therapy, especially when added as a second agent. The incretin-raising effects of DPP-4 inhibitors do not appear to be sufficient to reduce gastric emptying or produce a measurable satiety effect. Accordingly, DPP-4 inhibitors do not cause weight gain and may assist with slight weight loss [61–63].

Adverse effects

Substantial clinical experience with DPP-4 inhibitors has indicated a good safety profile to date. In clinical trials (typically 6–12 months), measures of tolerability and adverse events were generally similar to those with placebo or comparator. Owing to their glucose-dependent action on the pancreas, DPP-4 inhibitors carry a low risk of serious hypoglycaemia unless administered along with an agent that itself carries significant risk of hypoglycaemia. Thus, when a DPP-4 inhibitor is used in combination with a sulfonylurea or with insulin, it may be appropriate initially to lower the dose of the sulfonylurea or insulin, especially for those who are only modestly hyperglycaemic and more vulnerable to hypoglycaemia. DPP-4 inhibition has been associated with some hyperplasia of the exocrine pancreas, and there is evidence from several prospective and retrospective clinical studies that DPP-4 inhibition can increase the risk of acute pancreatitis in type 2 diabetes. Although this has not been consistently observed, or numerical data have not been statistically significant, appropriate caution is recommended and a DPP-4 inhibitor should be stopped if pancreatitis is suspected, and alternative therapy sought for people with a history of pancreatitis. Long-term cardiovascular safety studies have raised the possibility of an increased risk of angina during use of some DPP-4 inhibitors, but the evidence is equivocal, and there is lingering concern from these studies that saxagliptin and possibly alogliptin could carry a small increased risk of heart failure [62–64].

In addition to GLP-1 and GIP, there are many natural substrates for DPP-4, including bradykinin, enkephalins, neuropeptide Y, peptide YY1–36, gastrin-releasing polypeptide, substance P, insulin-like growth factor I, the α chains of thyrotropin, luteinizing hormone, and chorionic gonadotropin, and several chemokines such as monocyte chemotactic protein 1 (MCP-1). Hence DPP-4 inhibitors have the potential to influence the hunger–satiety system, gastrointestinal motility, growth, vascular reactivity, and immune mechanisms, but there is little evidence of any clinically significant changes in these physiological processes [61,63]. DPP-4 is also the CD26 T-cell activation antigen, but neither CD26 knockout mice nor the DPP-4-specific inhibitors used in animals or humans have shown any significant untoward immune-related effects. The importance of selective DPP-4 inhibition is also noted because inhibition of related enzymes such as DPP-8 and DPP-9 has

produced blood dyscrasias and skin lesions in some species, although not in clinical use. No significant drug interactions have been noted with DPP-4 inhibitors, but evidence of reproductive toxicity in animals warrants discontinuation in pregnancy.

Sodium–glucose cotransporter-2 inhibitors

SGLT-2 is highly expressed in the first segment of the proximal tubules of the kidneys, where it is responsible for the reabsorption of ~90% of glucose in the glomerular filtrate. Partial inhibition of SGLT-2 provides a non-insulin-dependent mechanism to reduce glucose reabsorption, eliminate excess glucose in the urine, and so reduce hyperglycaemia [65]. Studies in the 1980s showed that phlorizin, a naturally occurring inhibitor of sodium–glucose transporters found in apple tree bark, could reduce hyperglycaemia in partially pancreatectomized rodents with diabetes. Phlorizin was degraded too rapidly in the intestine to be used therapeutically, but chemical modifications to minimize intestinal breakdown and increase selectivity against SGLT-2 have given rise to a class of selective SGLT-2 inhibitors represented by canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin (Figure 35.14).

Mode of action

SGLT-2 is a high-capacity secondary active cotransporter that transfers one sodium ion with one glucose molecule down an electrochemical gradient for sodium, generated by, for example, the activity of an Na⁺–K⁺ ATPase pump [65,66]. SGLT-2 inhibitors interact with SGLT-2 transporters located at the luminal surface of the epithelium lining the initial region of the renal proximal tubules (Figure 35.15). They competitively inhibit the transporter, reducing glucose reabsorption and thereby lowering the renal threshold for glucosuria. In this way, SGLT-2 inhibitors enable ~20–30% of filtered glucose (about 50–100 g glucose/d) to be eliminated in the urine of people with type 2 diabetes [66,68,69]. As the blood glucose concentration declines, both the amount of filtered glucose and the glucosuria decline, minimizing the effect of SGLT-2 inhibition in the euglycaemic range and avoiding frank hypoglycaemia. Because the mechanism is independent of insulin, it will continue to operate under conditions of insulin resistance and β -cell failure, but requires adequate kidney function to filter sufficient glucose for partial SGLT-2 inhibition to create enough glucosuria to impact the hyperglycaemia. The glucosuria induced by SGLT-2 inhibition can assist weight loss and generate a mild osmotic diuresis that may contribute to a small reduction in blood pressure [5,70–73].

SGLT-2 inhibitors can weakly suppress the activity of SGLT-1 transporters (transfer two sodium ions with one glucose or galactose). SGLT-1 is abundant in the intestine and accounts for the absorption of glucose; it is also expressed in the third (straight descending) segment of the proximal tubules, where it is responsible for ~10% of glucose reabsorption. Canagliflozin may interact with SGLT-1 to defer intestinal glucose absorption slightly more distally along the intestinal tract, but it is uncertain whether the concentration of the drug in the renal tubule is sufficient to exert any meaningful inhibition SGLT-1 activity in the kidney [70]. Sotagliflozin is a stronger inhibitor of SGLT-1 and also inhibits SGLT-2; at the time of writing studies in individuals with type 2 diabetes are ongoing.

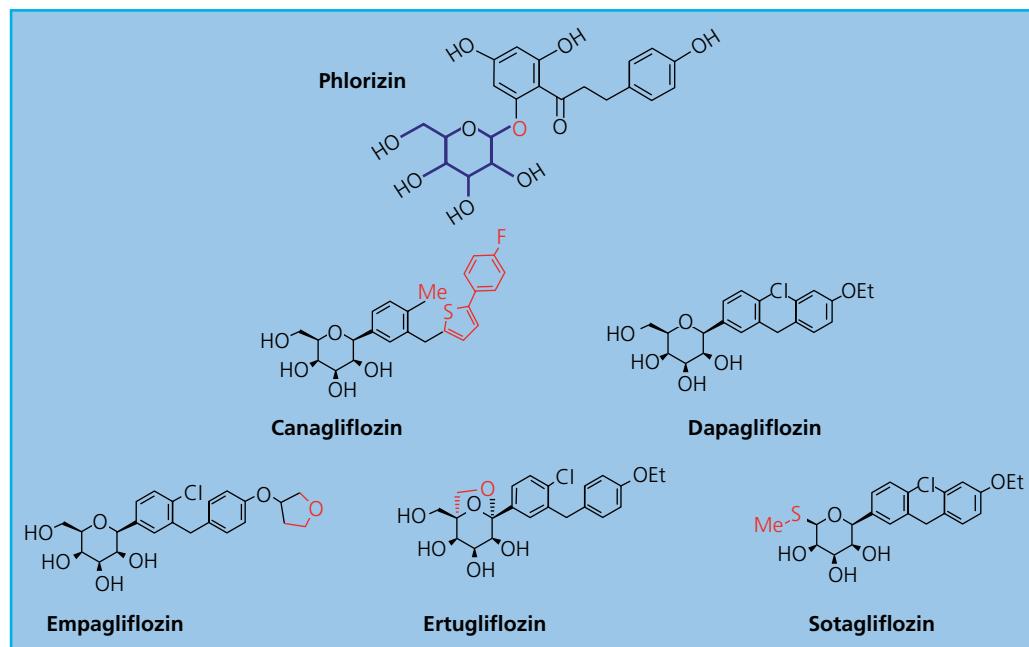

Figure 35.14 Structures of sodium–glucose cotransporter (SGLT) inhibitors. Phlorizin is a naturally occurring inhibitor of SGLT-1 and SGLT-2. Canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin are selective inhibitors of SGLT-2, and sotagliflozin is an inhibitor of SGLT-1 and SGLT-2.

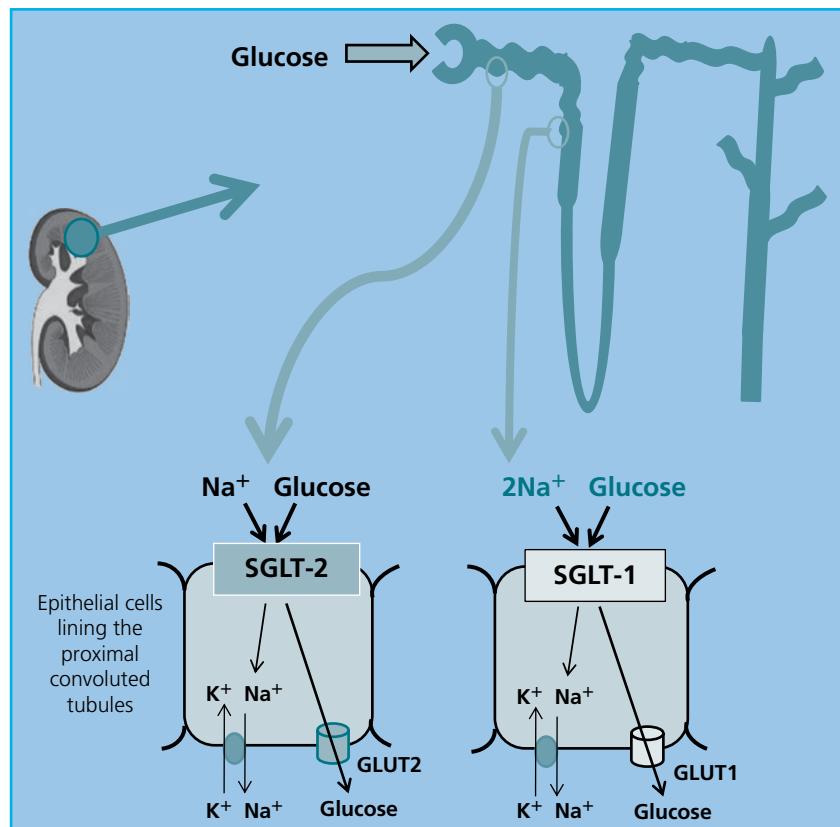

Figure 35.15 Renal sodium–glucose cotransporters (SGLT) reabsorb glucose from the renal proximal tubules. Glucose is filtered at the glomerulus into the proximal tubule and mostly reabsorbed from the initial region of the proximal tubule via the high-capacity transporter SGLT-2. Remaining glucose is reabsorbed more distally along the proximal tubule via the low-capacity transporter SGLT-1. Source: Bailey 2015 [67]. Reproduced by permission.

Table 35.13 Sodium–glucose cotransporter-2 (SGLT-2) inhibitors: dapagliflozin, canagliflozin, empagliflozin, and ertugliflozin.

Agent	Dose (mg/d)	IC ₅₀ SGLT2 vs SGLT1 (nM)	t _{max} (h)	C _{max}	t _{1/2} (h)
Dapagliflozin	5–10	1.1 vs 1390	1–2	~160 µg/l	~13

Ertugliflozin	5–15	0.9 vs 1960	~1	~260 µg/l	~17

Pharmacokinetics

The pharmacokinetic properties of SGLT-2 inhibitors are summarized in Table 35.13. They reversibly inhibit SGLT-2 at low nmol/l concentrations by blocking the glucose site for several minutes. SGLT-2 inhibitors are taken as once-daily tablets; they are rapidly absorbed with high bioavailability. In plasma they are mostly protein bound and are degraded mainly through glucuronidation by uridine diphosphoglucuronosyltransferases to inactive metabolites. They show little or no inhibition by or induction of P450 isoforms that metabolize other common medications, and no clinically significant drug interactions have been noted [74].

Indications and contraindications

SGLT-2 inhibitors can be used as monotherapy in people whose type 2 diabetes has not responded adequately to lifestyle measures, although they are more often used as add-on therapy in those whose diabetes is inadequately managed by metformin or another glucose-lowering agent. In principle, an SGLT-2 inhibitor can be used with any other class of oral agent or insulin, as the mode of action is different from those of all other classes of glucose-lowering agents. Body weight reduction makes an SGLT-2 inhibitor suitable for individuals with overweight or obesity, and the low risk of hypoglycaemia renders this class of agent suitable for people with glucose values close to target. Modest reductions of blood pressure in individuals with hypertension can also be expected [71].

Adequate renal function is an important consideration for use of an SGLT-2 inhibitor to enable glucosuric efficacy. Recommendations vary between countries, but an SGLT-2 inhibitor can be used at full daily dosage for eGFR >60 ml/min/1.73 m². Although SGLT-2 inhibitors have evident reno-protective effects in clinical trials, current product labels suggest a reduced dose for people with an eGFR value persistently <45 ml/min/1.73 m² [75]. Treated individuals with diabetes should be informed about the need to remain hydrated and the risk of initial nocturia and mycotic genital infections. People with insulin-treated type 2 diabetes should ensure that they maintain an adequate insulin dose, since insulin is required for many more physiological purposes than glucose regulation. At the time of writing, some SGLT-2 inhibitors are approved for use as adjunctive therapy with insulin in type 1 diabetes mellitus; again, the importance of maintaining adequate insulin is emphasized to avoid diabetic ketoacidosis. SGLT-2 inhibitors should be discontinued in pregnancy.

Efficacy

The glucose-lowering efficacy of SGLT-2 inhibitors in type 2 diabetes has been confirmed in prospective randomized clinical trials during use as monotherapy and in combination with other glucose-lowering therapies including insulin [71–73]. There is a rapid onset of action to reduce post-prandial and basal hyperglycaemia. HbA_{1c} is typically reduced by ~0.6–1.2% (7–13 mmol/mol), although larger reductions may be seen in people with severe hyperglycaemia and those with good renal function [76]. Efficacy during trials has extended over several years and risk of hypoglycaemia has been low unless SGLT-2 inhibitors are used in combination with an agent that can itself cause hypoglycaemia (such as a sulfonylurea or insulin). Most people achieve a weight loss of ~2–4 kg, which typically levels out by 6–12 months, possibly reflecting an increase in metabolic efficiency or some increase in food intake as the glucose level declines. The weight loss is predominantly a decrease in fat mass, notably from the visceral adipose depot. In clinical trials involving participants with insulin-treated type 2 diabetes, glycaemic indices are often improved while the insulin dose is slightly lowered, and the improvement is maintained over time without insulin dose escalation. Combination of an SGLT-2 inhibitor with insulin can also reduce the weight gain normally associated with insulin therapy.

Randomized controlled cardiovascular outcome trials in individuals with type 2 diabetes have consistently confirmed that SGLT-2 inhibitors reduce systolic and diastolic blood pressure by about 3–5 and 2–3 mmHg, respectively, without dipping into hypotension. These trials have also noted that use of SGLT-2 inhibitors is associated with a reduced occurrence of new-onset heart failure and less worsening of established heart failure, with about 30% fewer hospitalizations for heart failure, mainly among individuals with reduced ejection fraction [77, 78]. Fewer cardiovascular deaths have also been recorded with use of SGLT-2 inhibitors in some trials, but this has not been a consistent finding. The reductions in blood pressure and risk of heart failure appear to be independent of the glucose-lowering and weight-lowering effects of SGLT2 inhibitors; indeed, similar reductions in blood pressure and heart failure have been noted in people without diabetes [79]. The cardiovascular effects of SGLT-2 inhibitors are also independent of age, prior history of cardiovascular disease, or treatments for hypertension and heart failure, and occur irrespective of normal or impaired renal function.

Several possible mechanisms appear to contribute to these potentially cardioprotective effects of SGLT-2 inhibitors. Lower blood pressure may initially result in part from the osmotic diuresis and reduction in plasma volume, and be assisted in the longer term by reductions in body weight, glucotoxicity, insulin resistance, and uric acid. The myocardium could also benefit from reduced plasma volume, reduced vascular resistance, and increased availability of ketones as an energy source from whole-body fatty acid metabolism. Additionally, SGLT-2 inhibitors have been reported to improve myocardial energetics by increasing myocardial catabolism of branched-chain amino acids and inhibiting the Na⁺/H⁺ exchanger [80].

SGLT-2 inhibitors often cause an initial temporary drop in eGFR by ~5 ml/min/1.73 m², which usually recovers by 3–6 months. Thereafter, use of an SGLT-2 inhibitor slows the long-term decline in eGFR, accompanied by reductions in the onset and progression of micro- and macroalbuminuria. These effects, which preserve

renal function, are independent of the glucose-lowering and weight-lowering effects of SGLT-2 inhibitors and are also evident in people without diabetes. The effects are also independent of age, baseline eGFR, prior or existing cardiovascular disease, or antihypertensive therapies. One postulated mechanism is the effect of SGLT-2 inhibition to increase sodium retention within the lumen of the nephron. The raised luminal sodium concentration carries through to the ascending limb of the loop of Henle, where it is sensed by the macula densa. This increases the tubulo-glomerular feedback of adenosine to constrict the afferent glomerular arterioles, which reduces intra-glomerular pressure [81]. Additional potential reno-protective effects of SGLT-2 inhibitors may include localized reductions of oxidative stress and inflammation within the kidney.

Adverse effects

The glucosuric effect of SGLT-2 inhibitors increases the risk of genital infections, particularly vulvovaginal mycotic infections in women during the initial months of therapy, and there has also been a small increase in the risk of urinary tract infections in some studies. The occurrence and severity of these infections can be reduced by appropriate advice when starting therapy and most of these infections respond to standard treatments, often by self-management. The osmotic diuresis generated by the glucosuria (usually <500 ml/d) requires patient attention to adequate hydration, especially in hot climates, and should be emphasized when initiating therapy. Because the eGFR may temporarily decline after introduction of an SGLT-2 inhibitor, extra caution is recommended for people receiving diuretic therapy, although electrolyte imbalances have not been seen in clinical trials [75].

Accounts of atypical ketoacidosis in individuals treated with an SGLT-2 inhibitor have described a hyperosmolar ketoacidosis with only modest hyperglycaemia. Many of these people had type 1 diabetes or were insulin-treated individuals of unclear diagnosis in whom the insulin dose had been over-reduced because the hyperglycaemia was reduced by the SGLT-2 inhibitor. Basal insulin should be maintained in insulinopenic individuals, as this reduces lipolysis (thereby reducing the supply of fatty acids for ketogenesis) and is required for other physiological purposes beyond glycaemic management. SGLT-2 inhibition may also reduce renal clearance of ketones and may cause a compensatory increase in glucagon release, especially at low glucose levels, which can promote ketogenesis [82]. Thus, people with a history of ketotic episodes are unlikely to be appropriate for SGLT-2 inhibitor therapy.

Because SGLT-2 inhibitors do not interfere with P450 isoenzymes, they do not appear to have any clinically meaningful drug interactions. Minor changes in the circulating lipid profile have been reported with SGLT-2 inhibitors, notably some increases in LDL and HDL cholesterol, but without altering the LDL-to-HDL ratio. During clinical trials, the numbers of major adverse cardiovascular events have generally been similar to or fewer than with comparator therapies, leaving uncertainty regarding any significant class effects on atherosclerotic disease.

Oral glucagon-like peptide-1 receptor agonist

As noted in the section on DPP-4 inhibitors and considered in detail in Chapter 36, GLP-1 is an incretin hormone secreted from intestinal L cells during meal digestion. It potentiates nutrient-induced

insulin secretion, suppresses excess glucagon secretion, exerts a satiety effect, and delays gastric emptying. Several subcutaneously injected analogues of GLP-1 that mimic the effects of the native hormone are established therapies for type 2 diabetes. Recently introduced (2019) is an oral formulation of the GLP-1 receptor agonist semaglutide [83].

Semaglutide is structurally similar to native GLP-1: it has a substitution of alanine to aminoisobutyric acid at position 8 (N2 of the active peptide) to prevent degradation by DPP-4. There is a C18 fatty di-acid chain attached to the lysine at position 26 to enable binding to albumin to prolong circulation time, and a lysine to arginine substitution at position 34 to ensure fatty acid linkage only at position 26. To facilitate absorption across the gastric epithelium, semaglutide is formulated into a tablet with the absorption enhancer sodium hydroxybenzoylaminocaprylate (SNAC), which protects the peptide from proteolytic degradation by raising the pH around the peptide and assisting transcellular absorption. Oral semaglutide is taken on an empty stomach, usually in the morning, and food is avoided for at least 30 minutes to allow adequate drug absorption.

Oral and injectable formulations of semaglutide are similarly effective in reducing blood glucose (with low risk of hypoglycaemia) and body weight, as considered in detail in Chapter 36. In clinical trials, oral semaglutide has similar beneficial cardio-renal effects, safety profile, and therapeutic applications to injectable semaglutide.

α -Glucosidase inhibitors

Studies conducted in the late 1970s noted that inhibitors of intestinal α -glucosidase enzymes could retard the final steps of carbohydrate digestion, with a consequent delay in the absorption of sugars. By the early 1980s, it was demonstrated that this approach could reduce postprandial hyperglycaemia in diabetes [84]. Acarbose, the first α -glucosidase inhibitor, was introduced in the early 1990s. Subsequently, two further agents, miglitol and voglibose, were introduced in some countries (Figure 35.16). In people who consume meals containing complex carbohydrate, α -glucosidase inhibitors can effectively reduce post-prandial glucose excursions. These agents also have a good safety record, but their application has been limited by gastrointestinal side effects and modest efficacy.

Mode of action

α -Glucosidase inhibitors competitively inhibit the activity of α -glucosidase enzymes in the brush border of enterocytes lining the intestinal villi (Figure 35.17). They bind to the enzymes with high affinity, preventing the enzymes from cleaving disaccharides and oligosaccharides into monosaccharides. This delays completion of carbohydrate digestion and can defer the process distally along the intestinal tract, leading to a delay in glucose absorption [84,85]. Different α -glucosidase inhibitors have different affinities for the various α -glucosidase enzymes. This gives slightly different activity profiles (e.g. acarbose has greatest affinity for glycoamylase > sucrase > maltase > dextrinases, whereas miglitol is a stronger inhibitor of sucrase).

It is emphasized that α -glucosidase inhibitors can only be effective if the person is consuming complex digestible carbohydrate. These agents do not significantly affect the absorption of glucose *per se*. By moving glucose absorption more distally along the intestinal tract, α -glucosidase inhibitors may alter the release of

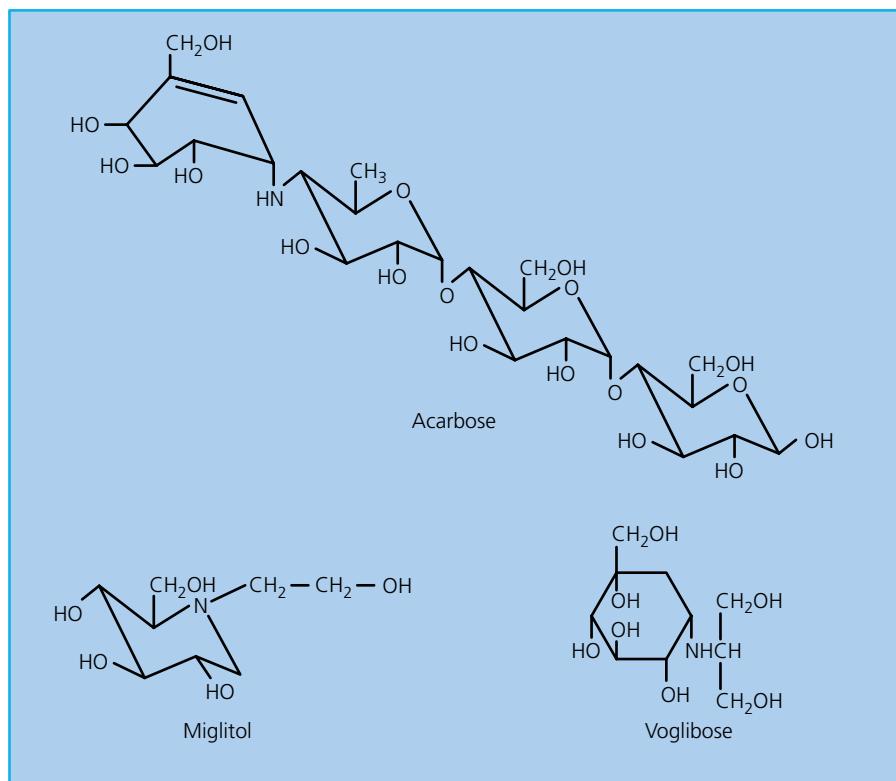

Figure 35.16 Chemical structures of the α -glucosidase inhibitors acarbose, miglitol, and voglibose.

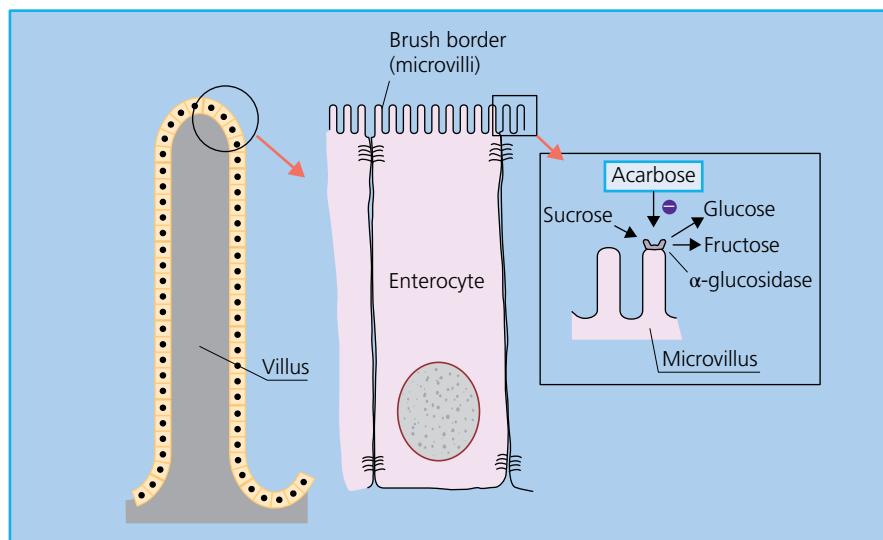

Figure 35.17 Mode of action of α -glucosidase inhibitors. α -Glucosidase inhibitors competitively inhibit the activity of α -glucosidase enzymes in the brush border of enterocytes lining the intestinal villi, preventing these enzymes from cleaving disaccharides and oligosaccharides into monosaccharides. This delays carbohydrate digestion.

glucose-dependent incretin hormones such as GIP and GLP-1, which affect nutrient-induced insulin secretion. Hence release of GIP, which occurs mainly from the jejunal mucosa, may be reduced by α -glucosidase inhibitors, whereas secretion of GLP-1 (mostly from the ileal mucosa) is increased. α -Glucosidase inhibitors probably reduce post-prandial insulin concentrations through the attenuated rise in post-prandial glucose levels [84, 85].

Pharmacokinetics

Acarbose is degraded by amylases in the small intestine and by intestinal bacteria; <2% of the unchanged drug is absorbed along

with some of the intestinal degradation products. Absorbed material is mostly eliminated in the urine within 24 hours [84]. Miglitol is almost completely absorbed and eliminated unchanged in the urine.

Indications and contraindications

α -Glucosidase inhibitors can be used as monotherapy, usually for people with type 2 diabetes with post-prandial hyperglycaemia but only slightly raised fasting glycaemia; however, they are more commonly used as an add-on to other therapies, again to target post-prandial hyperglycaemia [84, 85]. α -Glucosidase inhibitors can also

be used to extend the post-prandial period to reduce inter-prandial glycaemic troughs or hypoglycaemia in individuals receiving a sulfonylurea and/or insulin. Acarbose prevents the progression of IGT to type 2 diabetes [86], although this is not a licensed use.

When starting an α -glucosidase inhibitor, advice should be given that a diet containing complex digestible carbohydrate is important. α -Glucosidase inhibitors should be taken with meals, starting with a low dose (e.g. 50 mg/day acarbose) and slowly uptitrating over several weeks. Monitoring of post-prandial glycaemia is often helpful. Hypoglycaemia is unlikely when used as monotherapy, but gastrointestinal symptoms commonly limit initial tolerability and dose titration. Symptoms tend to be reduced by slow titration and usually subside with time, possibly reflecting some adaptation of the intestinal tract, but tolerability is poor.

α -Glucosidase inhibitors are contraindicated for people with a history of chronic intestinal disease, and as high dosages of acarbose can occasionally increase liver enzyme concentrations, it is recommended to measure transaminase concentrations periodically in those receiving a maximum dosage (200 mg acarbose three times daily). Raised liver enzymes should remit as the dosage is reduced, otherwise alternative causes of hepatic dysfunction should be considered.

Efficacy

Because α -glucosidase inhibitors target post-prandial glucose excursions during meals that contain complex carbohydrate, their effectiveness is entirely dependent on following an appropriate diet. As monotherapy, these agents can reduce peak post-prandial glucose concentrations by 1–4 mmol/l. The incremental area under the post-prandial plasma glucose curve can be more than halved in some individuals, and there is usually some extended duration of effect to modestly lower basal glycaemia up to ~1 mmol/l. The decrease in HbA_{1c} can be 0.5–1.0% (6–11 mmol/mol), provided that a high dose of the drug is tolerated and an appropriate diet is maintained [84, 85].

Although overall reductions in HbA_{1c} are usually modest, α -glucosidase inhibitors offer several useful features: they do not cause weight gain or frank hypoglycaemia and they may reduce inter-prandial episodes of hypoglycaemia. When combined with other anti-diabetes agents, α -glucosidase inhibitors can reduce post-prandial hyperinsulinaemia, and they often lower plasma triglyceride concentrations. An α -glucosidase inhibitor can produce minor alterations to the intestinal absorption of other oral glucose-lowering agents when used in combination therapy, but α -glucosidase inhibitors usually provide additive efficacy gains when used in combination with any other class of glucose-lowering agent [84, 85]. Despite the link between post-prandial hyperglycaemia and cardiovascular risk, a five-year study in people with coronary heart disease and IGT found no effect of acarbose on a composite of major adverse cardiovascular events (cardiovascular death, non-fatal MI or stroke, unstable angina, or hospitalization for heart failure) [87].

Adverse effects

Gastrointestinal side effects represent the main problem with α -glucosidase inhibitors. For example, in the Study to Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM) trial, 31% of acarbose-treated participants compared with 19% on placebo discontinued treatment early [88]. If the dosage is too high (relative to the amount of complex carbohydrate in the meal), undigested oligosaccharides pass into the large bowel. These are fermented, causing flatulence, abdominal discomfort, and sometimes diarrhoea, but usually ameliorating with slower titration and time. Hypoglycaemia is uncommon and there are no clinically significant

drug interactions, although use in conjunction with agents affecting gut motility or cholestyramine is not recommended.

Bromocriptine

The dopamine D2 receptor agonist bromocriptine (Figure 35.18), which has long been used to treat pituitary tumours and Parkinson disease (albeit in a different formulation), has an indication for use in the treatment of type 2 diabetes in some countries [89, 90].

Mode of action

Studies in animals have noted that the interruption of dopaminergic pathways in the hypothalamus is associated with the development of insulin resistance, and this can be reversed by localized dopamine infusion. Studies in individuals with type 2 diabetes suggest that a low dose of a rapid-acting formulation of bromocriptine administered early in the morning soon after waking can temporarily boost hypothalamic dopamine. This appears to rebalance several features of the circadian periodicity of glucose homeostasis by reducing sympathetic tone and enhancing the neural suppression of hepatic glucose production. Additionally, there is a reduction of adipose tissue lipolysis and an improvement in peripheral glucose disposal without elevation of plasma insulin, indicating improved peripheral insulin sensitivity [89, 90].

Pharmacokinetics

The low-dose quick-release formulation of bromocriptine used for blood glucose lowering is rapidly absorbed (t_{max} by 1 hour), highly protein bound, rapidly removed by the liver (mostly metabolized by CYP3A4), and eliminated via the bile; the half-life is ~6 hours. Prolactin levels are reduced consistent with increased dopaminergic activity.

Indications and contraindications

Based on considerable experience with the use of bromocriptine for other purposes, use to treat type 2 diabetes requires caution if individuals are prone to low blood pressure, various psychotic disorders, or somnolence, and exclusion of those who experience migraine or take dopaminergic antagonists. Potential interactions with other medications that influence or may be influenced by changes in CYP3A4 should be appreciated, and evidence regarding use during pregnancy is limited.

Efficacy

In clinical trials, participants with type 2 diabetes receiving a low dose (0.8–4.8 mg) of quickly acting bromocriptine early in the morning showed HbA_{1c} reductions of ~0.5–0.7% (5–8 mmol/mol) when it

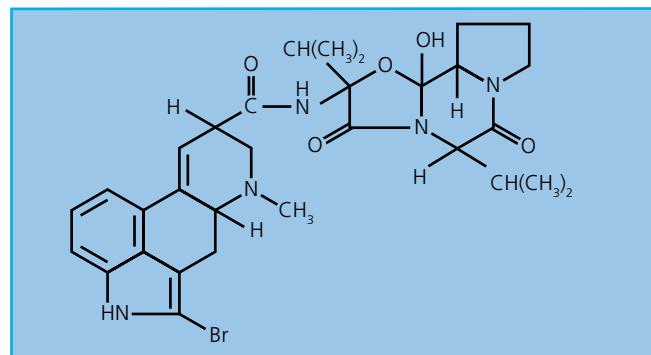

Figure 35.18 Chemical structure of bromocriptine.

was taken as monotherapy or in combination with other oral glucose-lowering agents. Fasting and post-prandial glucose, fatty acid, and triglyceride concentrations were reduced, insulin was not raised, risk of hypoglycaemia was low, and there was no weight gain [89,90].

Adverse effects

Although high doses of bromocriptine carry some long-term risk for pulmonary and pericardial fibrosis, hypotension, and aggravation of psychotic disorders, these were not seen with low doses during clinical trials for type 2 diabetes.

Colesevelam

In addition to its use as a bile acid sequestrant, colesevelam (a polyallylamine derivative) also has an indication for glucose lowering in some countries.

Mode of action

The glucose-lowering mechanism of colesevelam is not clear. By interrupting the enterohepatic circulation of bile acids, colesevelam appears to reduce the availability of bile acids to activate the bile acid receptor-1 (TGR5) and the farnesoid X receptor (FXR), which results in increased hepatic glucose metabolism [91]. A further possibility is that the bile acids are carried more distally along the intestine owing to their entrapment by colesevelam. This could bring more bile acids into contact with TGR5 receptors on L cells, which could enhance the secretion of GLP-1.

Pharmacokinetics

Up to three 625 mg tablets of colesevelam can be taken with each of two main meals daily; the colesevelam is not absorbed.

Indications and contraindications

Colesevelam requires caution if any intestinal disorders, especially obstruction, are known or suspected. Colesevelam can alter the absorption of other oral medications, including oral glucose-lowering therapies, and dose adjustments may be required.

Efficacy

Clinical trials with colesevelam in type 2 diabetes have noted modest reductions of HbA_{1c} of ~0.5% (5 mmol/mol) when used as an add-on to metformin, sulfonylurea, or insulin. There is no effect on body weight, low risk of hypoglycaemia, and, consistent with its use in the treatment of hypercholesterolemia, there is usually a reduction in LDL cholesterol [91].

Adverse effects

Colesevelam may increase circulating triglycerides and cause abdominal symptoms, especially constipation.

Anti-obesity therapies

Obesity, especially excess visceral adiposity, predisposes to diabetes, increases insulin resistance, complicates glycaemic management, and substantially increases the risk of vascular disease [92]. The blood glucose-lowering efficacy of lifestyle measures to reduce adiposity in individuals with type 2 diabetes and obesity is well appreciated, although it is often difficult to achieve and maintain significant weight loss in these people [93]. Several studies have

noted the reductions in blood glucose that accompany the use of pharmacological anti-obesity therapies in type 2 diabetes. Whether this is entirely explained by greater weight loss and improved diet is unclear, because some anti-obesity therapies may have some modest independent glucose-lowering effects [94].

In conjunction with a mildly hypocaloric and reduced-fat diet, the intestinal lipase inhibitor orlistat (120 mg three times daily with meals) can reduce dietary fat absorption by up to 30%. In individuals with type 2 diabetes and overweight or obesity, this typically reduces weight by an extra 2–3 kg, and additional reductions in HbA_{1c} of 0.28–1.1% (3–12 mmol/mol) have been reported [94].

Other anti-obesity agents, notably a phentermine-topiramate combination (Qsymia[®], Vivus, Campbell, CA, USA), and a buproprion–naltrexone combination (Contrave[®], Currax Pharmaceuticals, Brentwood, TN, USA), have been shown in clinical trials to improve glycaemic indices in people with type 2 diabetes in association with weight loss [94]. However, these anti-obesity therapies are not approved in many regions; carry their own contraindications, cautions, and side effects; and may interfere with the absorption or actions of other therapies, including glucose-lowering agents. The use of high doses of some GLP-1 receptor agonists to address obesity as well as type 2 diabetes is considered in Chapters 36 and 38.

Fixed-dose combinations

As early, individualized, and intensified interventional approaches to manage hyperglycaemia in type 2 diabetes have gained acceptance, the use of combinations of two or more oral agents with different mechanisms of action has become commonplace [3,4]. Indeed, some guidelines suggest that individuals presenting with moderate to severe hyperglycaemia may be considered for initial pharmacotherapy with a combination of glucose-lowering agents [4]. To facilitate combination therapy, several fixed-dose, single-tablet dual combinations are available (Table 35.14). These are designed to provide bioequivalence and thereby similar efficacy, although minor adjustments to the formulation may also allow some extra blood glucose-lowering efficacy.

Fixed-dose dual combinations can offer convenience, reduce the *pill burden*, and simplify administration regimens, and they may increase medication taking compared with equivalent combinations of separate tablets. Lower doses of two different types of agents rather than a high dose of one agent may also provide a way to achieve efficacy while circumventing adverse effects [95]. Although single tablets could reduce titration flexibility, most of the commonly used dosage combinations have been accommodated. A recent study has demonstrated rapid and sustained improvements in glucose levels with initial triple therapy [96], and fixed-dose triple combination tablets (e.g. metformin/linagliptin/empagliflozin and metformin/saxagliptin/dapagliflozin) are now becoming available [97]. It is reiterated that dose-related side effects of any combination therapy necessitate the same cautions and contraindications as apply to each active component.

Conclusions

A minimalistic archetypal algorithm to treat hyperglycaemia in type 2 diabetes is shown in Figure 35.19. This illustrates the typical sequence of pharmacological interventions advocated in most

Table 35.14 Fixed-dose single-tablet dual combinations of glucose-lowering agents.

Tablet ^a	Components	Strengths (mg)
Glucovance	Metformin + glibenclamide	250:1.25; 500:2.5; 500:5

Names vary between Europe and the USA. Alternative names are given in parentheses.

current guidelines. Guidelines should be interpreted with flexibility, however, to ensure that the care plan, treatment targets, and selection of therapies are individualized to suit the circumstances of the patient. The value of lifestyle intervention as initial and ongoing therapy in conjunction with pharmacological agents should not be underestimated. In view of the progressive natural history of type 2 diabetes, the introduction of drug therapy, the need for periodic uptitration of dosage, and the use of combination therapy can be expected for most people with type 2 diabetes.

A consensus report by the American Diabetes Association and the European Association for the Study of Diabetes suggests that the preferred first-line glucose-lowering agent is usually metformin. If adequate glycaemic levels are not achieved or maintained, the addition of a second pharmacological agent should take particular account of a high level of risk or existence of cardiovascular and/or renal disease irrespective of the extent of hyperglycaemia [3]. Addition of a GLP-1 receptor agonist is favoured if atherosclerotic cardiovascular disease predominates, whereas addition of an SGLT-2 inhibitor is favoured if heart failure or chronic kidney disease predominates. All available glucose-lowering agents could be considered as second-line pharmacotherapy for individuals at lesser risk of cardiovascular or renal complications, taking account of the need to avoid hypoglycaemia, control body weight, and respect affordability.

The latest consensus statement by the American Association of Clinical Endocrinologists and American College of Endocrinology also gives emphasis to the importance of weight management and addressing key cardiovascular risk factors (blood pressure and lipids) while avoiding hypoglycaemia [4]. Metformin remains the

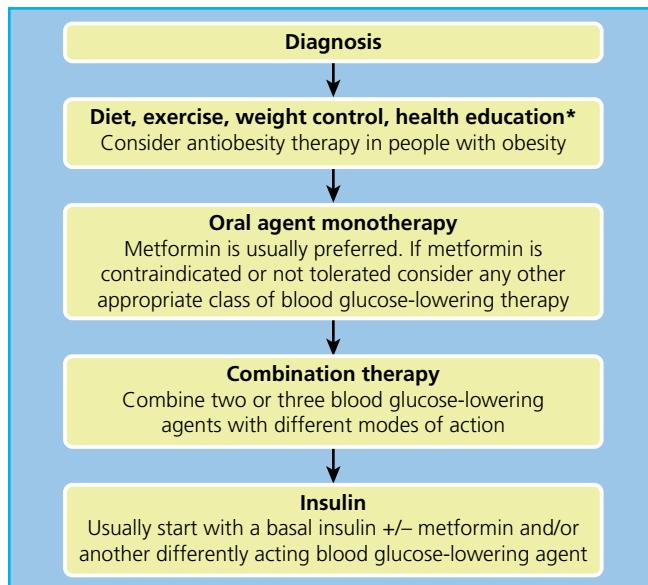

Figure 35.19 Archetypal algorithm used in the treatment of hyperglycaemia in type 2 diabetes (except for those presenting with severe hyperglycaemia who may require immediate insulin therapy). Start with lifestyle measures (diet and exercise). If the individualized glycaemic target is not achieved quickly using lifestyle measures, then add pharmacological therapy without delay. The selected monotherapy is uptitrated to achieve the desired glycaemic effect. If an uptitration step does not add benefit or is not tolerated, go back a step. When the desired glycaemic effect is not achieved or adequate titration is not tolerated, move promptly to the addition of a second agent with a different mode of action and uptitrate. If the desired glycaemic control is not achieved or maintained, consider triple therapy or introduce insulin while maintaining one or two of the existing therapies where appropriate. Respect drug cautions and contraindications at all times, monitor as required, and try to select glycaemic targets that are realistic, safely achievable, and avoid hypoglycaemia. Various guidelines (e.g. see [3, 4]) offer more detail with suggested glycaemic targets and suggested sequence orders for the introduction of the pharmacotherapies. *Lifestyle advice is reinforced throughout.

preferred first-line glucose-lowering agent, but this consensus defines HbA_{1c} levels at which dual and triple combination therapy should be considered, whether newly diagnosed or not. Thus, two differently acting glucose-lowering agents are suggested for people with HbA_{1c} ≥ 7.5% (59 mmol/mol) and triple therapy if HbA_{1c} > 9% (75 mmol/mol), or insulin if significantly symptomatic.

A range of differently acting oral agents is available: metformin and thiazolidinediones counter insulin resistance, but in different ways; sulfonylureas, meglitinides, and DPP-4 inhibitors increase insulin secretion, but with differences of time course and mechanism; SGLT-2 inhibitors increase renal glucose elimination; and α-glucosidase inhibitors slow carbohydrate digestion. Additionally, GLP-1 receptor agonists increase insulin secretion and reduce glucagon. When adequate glycaemic levels are not achieved or not maintained, it is important to proceed to the next therapeutic stage without delay to avoid periods of excessive hyperglycaemia. Insulin should be considered when other therapies do not provide adequate glycaemic levels or are unsuitable. Integrated management to address cardiovascular risk and comorbid conditions is essential. Glucose monitoring, making therapeutic adjustments for efficacy, safety, avoidance of hypoglycaemia, and contraindications, requires constant vigilance and forms an integral part of the treatment process. Early, effective, and sustained glycaemic management is essential to minimize the risk of complications later in life.

Non-insulin Parenteral Therapies

Tina Vilsbøll, Mikkel Christensen, Andreas Andersen, and Filip K. Knop

University of Copenhagen, Copenhagen, Denmark

Key points

- Obtaining sufficient systemic exposure of peptide-based drugs following oral administration is challenging owing to the acidic environment, the presence of proteolytic enzymes in the stomach, and the limited permeability of peptides through the gastrointestinal epithelium.
- Several available non-insulin parenteral therapies used for the treatment of type 2 diabetes are based on the gut-derived hormone glucagon-like peptide 1 (GLP-1).
- GLP-1 is a glucose-lowering (via insulinotropic and glucagonostatic effects) and satiety-promoting hormone secreted from enteroendocrine L cells found in the intestinal epithelium.
- GLP-1 receptor agonists (GLP-1RAs) form part of the treatment algorithms and guidelines for type 2 diabetes.
- GLP-1RAs target a broad spectrum of the pathophysiology of type 2 diabetes, improving glycaemic levels and reducing hunger, food intake, and body weight.
- Differences in the structure, pharmacokinetics, and size of the different GLP-1RAs determine their individual effects on glycated haemoglobin (HbA_{1c}), body weight, dosing frequency (convenience), and tolerability (adverse effects).
- Adverse effects of GLP-1RAs typically affect the gastrointestinal tract (mainly nausea, vomiting, and/or diarrhoea) in a dose-dependent manner and diminish over time.
- Large-scale cardiovascular outcome trials have shown beneficial effects of continuous-acting GLP-1RA treatment added to standard of care, including a reduced risk of major adverse cardiovascular events (non-fatal stroke, non-fatal myocardial infarction, and cardiovascular-related death).
- One available non-insulin parenteral therapy based on the pancreatic β -cell hormone amylin is available as adjunct treatment of insulin-treated type 1 diabetes and type 2 diabetes.
- Amylin is co-secreted with insulin from β cells and reduces gastric emptying, appetite, and post-prandial glucagon secretion.
- Amylin analogues have clinical benefits on HbA_{1c} and body weight in diabetes.
- Non-insulin parenteral therapies based on single-molecule dual- or triple-receptor agonists acting via the GLP-1 receptor, the glucose-dependent insulinotropic polypeptide (GIP) receptor, the amylin receptor, and/or the glucagon receptor are currently being evaluated for the treatment of type 2 diabetes.

During recent decades, the globally increasing prevalence of obesity and associated type 2 diabetes has promoted extensive research with the aim of clarifying the physiological and pharmacological role of pancreas- and gut-derived peptide hormones in the regulation of glucose homeostasis and feeding behaviour. Exploitation of these peptide hormones for the treatment of diabetes has primarily relied on the development of stable peptide-based drugs (suitable for subcutaneous injection, i.e. parenteral therapies) mimicking and potentiating the effects of the endogenous peptide hormones.

the GLP-1 receptor (GLP-1R), has increased treatment options and helped clinicians tailor individualized treatments for people with type 2 diabetes. GLP-1-based treatment modalities (i.e. the small-molecule dipeptidyl peptidase 4 [DPP-4] inhibitors reducing the enzymatic inactivation and degradation of endogenous GLP-1 and the exogenous peptide-based GLP-1R agonists [GLP-1RAs]) have been welcomed by healthcare professionals and people with diabetes. In particular, the GLP-1RA drug class is a pivotal part of the international type 2 diabetes treatment algorithms and guidelines, because of its glucose-dependent glucose-lowering action (active only when plasma glucose levels are high with a consequent low risk of hypoglycaemia), body weight-reducing effect, and cardiovascular protective effects [1–3]. The GLP-1RA drug class represents one of the most thoroughly investigated and monitored in terms of safety and efficacy owing to the increased requirements of regulatory agencies (particularly the US Food and Drug Administration [FDA] and European Medicines Agency [EMA]) for extensive safety data on new anti-diabetes drugs coinciding with final development of these drugs. A few GLP-1RAs have also been

Glucagon-like peptide 1, the GLP-1 receptor, and GLP-1 receptor agonists

The successful development of glucose-lowering drugs based on the physiological effects of the gut incretin hormone glucagon-like peptide 1 (GLP-1), a peptide hormone released from enteroendocrine L cells in response to nutrient ingestion and acting through

approved for the treatment of overweight and obesity and currently several studies are evaluating the applicability of GLP-1RA treatment in other metabolic disease states and related conditions.

In the first part of the chapter, a historical overview of the investigations leading to the discovery of the gut incretin hormone GLP-1 and its potential as a glucose-lowering drug is presented. The physiology of native GLP-1 is outlined, followed by the pharmacology, safety, and efficacy of the individual GLP-1RAs currently available for the treatment of type 2 diabetes. We also include the recently developed, first orally available GLP-1RA, oral semaglutide (Rybelsus[®], Novo Nordisk, Bagsværd, Denmark). Finally, perspectives for GLP-1RA treatment within other disease areas and their potential position in future treatment algorithms are highlighted.

Historical overview

The introduction of GLP-1-based treatment modalities at the beginning of the third millennium was the result of a century of investigations. In 1906, extracts of mucosa from porcine small intestine were tested by Moore et al. as a treatment for diabetes in the hope that, ‘the pancreas secretion might be stimulated by the substance of the nature of a hormone yielded by the duodenal mucosa membrane’ [4]. In 1928, Zunz and LaBarre described a hypoglycaemic effect following injection of extracts from small intestinal mucosa and, using cross-circulation experiments, showed that the effect was mediated through the pancreas [5]. Four years later, LaBarre named the unidentified substance thought to exert this effect *incretin* in order to dissociate it from secretin (which stimulates exocrine pancreatic secretion), discovered by Bayliss and Starling at the beginning of the twentieth century [6]. Then, in 1964, McIntyre et al. and Elrick et al. demonstrated that orally administered glucose evokes a greater insulin response than intravenously administered glucose, and both groups hypothesized that gut-derived factors could have potentiating effects on insulin secretion after oral glucose ingestion [7, 8]. A few years later, in 1967, this finding was confirmed by Perley and Kipnis, who administered oral glucose and, on a separate day, copied the oral glucose curve with an isoglycaemic intravenous glucose infusion in individuals of normal weight and with obesity with diabetes, and in healthy individuals without diabetes [9]. They concluded that the insulin response to isoglycaemic intravenous glucose administration only

amounted to 30–40% of that seen after oral administration of glucose; they had come across the *incretin effect*, the phenomenon of oral glucose eliciting a higher insulin response than intravenous glucose at identical plasma glucose profiles. However, at that time the insulinotropic substances eliciting this effect were unknown.

In 1970, gastric inhibitory polypeptide, secreted from small intestinal enteroendocrine K cells in response to ingestion of nutrients, was discovered [10] and, eventually, this 42 amino acid polypeptide was shown to be insulinotropic at elevated glucose concentrations and was renamed glucose-dependent insulinotropic polypeptide (GIP) [11]. Later, experimental and clinical studies suggested that the gut produces more than a single insulinotropic hormone of importance for glucose homeostasis [12]. In 1983, the gene encoding the human pancreatic hormone, glucagon, was cloned, and the structure of its precursor, proglucagon, was surprisingly shown to include the sequence of two glucagon-like peptides including GLP-1 (Figure 36.1) in addition to glucagon itself [13]. The gene was found to be expressed in both pancreatic α cells and enteroendocrine L cells in the small intestine [14]. The primary transcripts and translational products of the gene in the two types of cells are identical, but the post-translational processing differs in the two tissues (Figure 36.2) [14–16]. In the pancreas, proglucagon is cleaved by prohormone convertase 2 to glucagon, glicentin-related pancreatic peptide (GRPP), and a major proglucagon fragment. Apart from glucagon, these fragments seem to be biologically inactive. In contrast, in the intestinal L cells, proglucagon is processed by prohormone convertase 1/3 to GLP-1, glucagon-like peptide 2 (GLP-2), and glicentin. The 30 amino acid peptide GLP-1 is secreted in response to nutrient ingestion and is strongly insulinotropic, an incretin hormone [17, 18]. GLP-2 is also secreted in response to nutrient ingestion and is a key regulator of small intestinal growth; GLP-2 receptor agonists have been developed for the treatment of short bowel syndrome [19, 20]. The bioactive forms of GLP-1, amidated and glycine-extended GLP-1, respectively, are designated GLP-1(7–36) amide and GLP-1(7–37) (Figure 36.1).

Many hormones have been suspected to contribute to the incretin effect, but today there is ample evidence to suggest that the incretin effect is mainly conveyed by the two incretin hormones, GIP and GLP-1. In 1983, Nauck et al. showed that the incretin effect is reduced in people with type 2 diabetes [21]. The

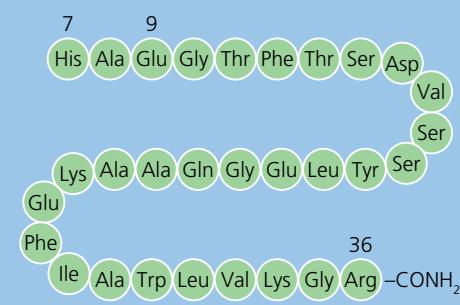

Figure 36.1 Native human glucagon-like peptide 1 (GLP-1) circulates as GLP-1(7–36) amide (illustrated here) or glycine-extended GLP-1(7–37). The enzyme dipeptidyl peptidase 4 (DPP-4) inactivates the hormone by cleaving off the two N-terminal amino acids (His and Ala).

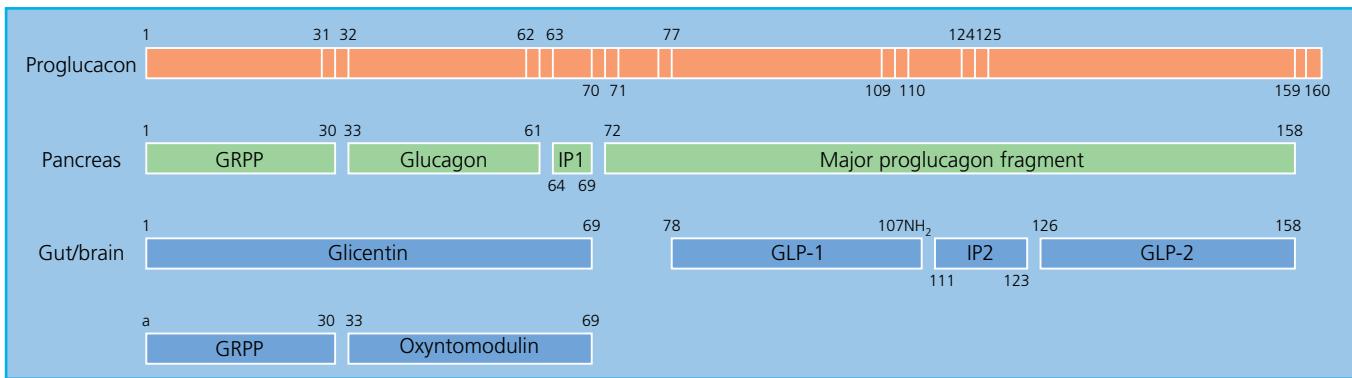

Figure 36.2 Proglucagon processing in human pancreatic α cells (predominantly by prohormone convertase 2) and in enteroendocrine L cells in the small intestine (predominantly by prohormone convertase 1/3). In proglucagon-producing neurons in the nucleus tractus solitarius (brain), proglucagon is most likely predominantly processed by prohormone convertase 1/3 as in the gut. GLP, glucagon-like peptide; GRPP, glicentin-related pancreatic peptide; IP, intervening peptide.

precise mechanisms behind this pathophysiological characteristic remain somewhat controversial. In the 2000s, publications reported reduced secretion of GLP-1 in individuals with type 2 diabetes [22, 23], but recent meta-analyses suggest that the secretion of GLP-1 among people with type 2 diabetes is generally normal [24, 25]. In contrast to the severely reduced insulinotropic effect of GIP in type 2 diabetes [26], the insulinotropic effect of GLP-1 is sustained in these individuals, albeit with reduced potency. Furthermore, GLP-1 retains its glucagonostatic effect in individuals with type 2 diabetes [27, 28].

The reduced incretin effect in type 2 diabetes, the early reports on reduced post-prandial GLP-1 responses, and the preserved glucose-dependent insulinotropic and glucagonostatic effects of GLP-1 constituted important incentives to pursue GLP-1 as a target for the treatment of type 2 diabetes. The other incretin hormone, GIP, was initially not pursued as a glucose-lowering drug owing to its severely diminished insulinotropic effect in type 2 diabetes combined with reports suggesting glucagonotropic effects of GIP. Other studies suggested that GIP may act as a fat storage hormone promoting lipogenesis, adipokine secretion, and weight gain. Nevertheless, as GIP, like GLP-1, is a substrate of DPP-4, it may contribute to the glucose-lowering effect of DPP-4 inhibitors, and dual or even triple hormonal receptor agonists involving GIP receptor stimulation are currently in clinical development for the treatment of type 2 diabetes and other metabolic disorders, such as obesity and non-alcoholic fatty liver disease. The dual GIP/GLP-1 receptor agonist tirzepatide developed for once-weekly subcutaneous injection exerts considerable reductions in glycated haemoglobin (HbA_{1c}) and body weight in individuals with type 2 diabetes and overweight or obesity in its Phase III clinical programme [29].

GLP-1 physiology and anti-diabetes effects

Proglucagon distribution, GLP-1 release, and metabolism

The glucagon gene is expressed in pancreatic α cells as well as in the enteroendocrine L cells and a subset of central nervous system neurons in the nucleus tractus solitarius. The processing of proglucagon into *pancreatic* glucagon or *intestinal* GLP-1 (and GLP-2) depends on tissue-specific prohormone convertases (Figure 36.2). In the pancreas, prohormone convertase 2 represents the predominant

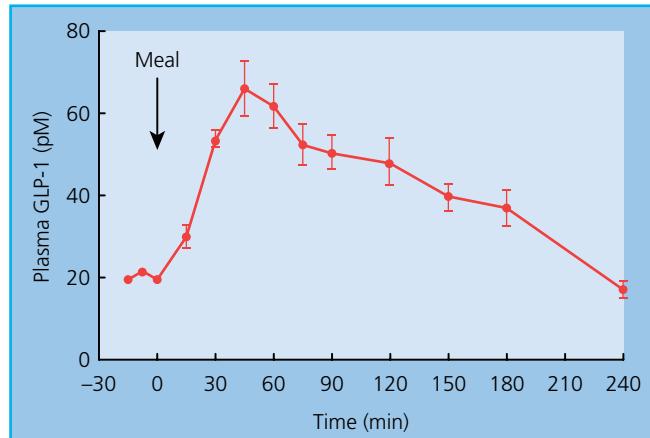

Figure 36.3 Mean post-prandial plasma concentrations (\pm standard error of the mean) of glucagon-like peptide 1 (GLP-1) in healthy individuals. Source: Based on Sonne et al. 2014 [31].

prohormone convertase and, therefore, glucagon production is favoured. Conversely, in the gut, prohormone convertase 1/3 is abundant and processing of proglucagon predominantly yields the hormones GLP-1 and GLP-2 (and oxyntomodulin) (Figure 36.2). Nevertheless, the distribution of the two prohormone convertases may not be as stringent and their enzymatic specificities may not be as high as previously considered and, thus, small amounts of GLP-1 and GLP-2 may be formed in the pancreas, and similarly, gut-derived glucagon secretion may also occur [30].

The most robust physiological stimulus for GLP-1 secretion is meal ingestion. Within 5–15 minutes of eating, plasma GLP-1 concentrations start to rise, and peak levels are typically reached after 45–60 minutes (Figure 36.3). Fat, carbohydrates, and protein all stimulate GLP-1 secretion. The interaction of nutrients with luminal microvilli of the L cell apical parts results in GLP-1 secretion from the baso-lateral parts into the intestinal bloodstream. In this process, associations between glucose absorption and metabolism within the L cell and GLP-1 secretion have been observed. Furthermore, L cells express several G protein-coupled receptors, which can be activated by short- and long-chain fatty acids, bile acids, and possibly other factors that thereby stimulate GLP-1 secretion. In addition, paracrine (e.g. via somatostatin and GIP) and neurohormonal mechanisms (via vagus and sympathetic

neural activation) have been suggested to contribute to post-prandial GLP-1 secretion.

After secretion, GLP-1 is degraded by the enzyme DPP-4. This enzyme is widely expressed and is highly active in the liver, the intestinal and renal brush border membranes, and the lungs. It is also found on capillary surfaces and in a soluble form in plasma. DPP-4 cleaves off the two N-terminal amino acids of peptides with a penultimate proline or alanine residue, and this completely abolishes the insulinotropic activity of GLP-1. Thus, after secretion of GLP-1, the active hormone is rapidly degraded to an inactive metabolite in the circulation, resulting in a clearance, which exceeds cardiac output, and an apparent half-life of 1–1.5 min. The truncated metabolite is eliminated more slowly through the kidneys and endogenous protease activity, with a half-life of 4–5 min.

GLP-1 receptor distribution and physiological effects of GLP-1

The GLP-1R is found within the pancreas, lung, adipose tissue, kidney, heart, vascular smooth muscle, peripheral nervous system, and several specific nuclei in the central nervous system (CNS) [32, 33]. The exact effect of receptor activation in several of these tissues remains to be established, and here emphasis will be put on receptor activation that relates to the clinical effects observed with GLP-1RA treatment.

Effects on pancreatic insulin and glucagon secretion

Specific receptors for GLP-1 are found in the pancreatic β -cell plasma membrane. The receptor belongs to the glucagon subfamily of G protein-coupled receptors. Following binding and subsequent activation of the receptor, several intracellular pathways are initiated [32, 33], which ultimately results in intracellular accumulation of cyclic adenosine monophosphate, closure of ATP-sensitive K^+ channels, elevation of cytosolic Ca^{2+} concentrations, and mobilization and exocytosis of insulin-containing granules. Importantly, GLP-1R activation in β cells leads only to insulin secretion when glucose concentrations are elevated above 4–5 mmol/l [34]. Thus, GLP-1 can be perceived to act as a β -cell sensitizer potentiating glucose-induced insulin secretion. In addition to its glucose-dependent insulinotropic effect, GLP-1 enhances all steps of insulin biosynthesis and insulin gene transcription. Furthermore, GLP-1 is involved in β -cell growth and differentiation and may protect cells from apoptosis [32, 33]. However, the role of these cell cycle regulatory mechanisms in relation to human physiology and pathophysiology and GLP-1RA treatment remains to be established.

In pancreatic cells, GLP-1 exerts glucagon-suppressive effects. As for its insulinotropic effect, this glucagonostatic effect is glucose dependent and is likewise only active when plasma glucose levels are elevated above 4–5 mmol/l [28]. The mechanisms by which GLP-1 reduces α -cell secretion of glucagon remain incompletely understood. Thus, it is controversial whether GLP-1-induced glucagon suppression is mediated via GLP-1Rs on pancreatic α cells (which have been shown to exist in small amounts in some studies, whereas other studies have not detected them) or whether indirect mechanisms (e.g. via glucagon-suppressive effects of β -cell secretory products and/or somatostatin from pancreatic δ cells) are at play; or perhaps most likely a combination of these effects.

Effects on the gastrointestinal tract

GLP-1 reduces gastrointestinal motility and intermittent GLP-1R activation has a pronounced effect on gastric emptying of both liquid and solid meals [35]. This phenomenon has been referred to

as the *ileal brake*; that is, GLP-1 secreted from enteroendocrine cells in the distal small intestine slows further delivery of nutrients to the small intestines from the stomach [36]. GLP-1-induced deceleration of gastric emptying translates into reduced post-prandial plasma glucose excursions [37]. By contrast, prolonged GLP-1R activation leads to tachyphylaxis of this effect [38], which most likely explains the sustained effect of short-acting GLP-1RAs on post-prandial plasma glucose excursions and the lesser effects seen with long-acting GLP-1RAs [39].

Effects on appetite and food intake

GLP-1Rs are found in both the peripheral nervous system and CNS, with GLP-1R-positive neurons in the hypothalamus and the brainstem. The pathways controlling modulation of food intake by GLP-1 are not fully understood, however activation of GLP-1Rs in the brain, specifically the circumventricular organs, is believed to be responsible for the reduced appetite and food intake observed after GLP-1 administration [33]. Nevertheless, modulation of food intake by GLP-1 may also involve vagal afferent neurons. The GLP-1 effect on food intake has been demonstrated in clinical studies, where infusion of GLP-1 in lean individuals and those with obesity with and without diabetes causes dose-dependent reductions in *ad libitum* food intake and increases satiety [40]. However, as GLP-1R knockout mice are not obese, GLP-1R activation is not likely to be a prerequisite for body weight regulation in normal physiology [41]. Nevertheless, GLP-1R activation and its related effects on appetite and food intake constitute an important part of the body weight-lowering effect of pharmaceutical GLP-1RAs [42].

Effects on the cardiovascular system

The effect of GLP-1 on the cardiovascular system has attracted much attention and is amplified by the beneficial effect of GLP-1RAs on cardiovascular disease progression in clinical studies. The GLP-1R is expressed in both the heart atria and ventricles as well as the sinoatrial node [33]. Since most studies have applied supra-physiological GLP-1 doses, the physiological role of the GLP-1R in the heart remains unclear [43]. However, mice lacking the GLP-1R exhibit impaired left ventricular contractility and diastolic function, and also impaired responses to exogenous epinephrine, indicating a role for GLP-1 in cardiac structure and function [44]. Infusion of GLP-1 and GLP-RAs induces an increase in heart rate, which is mediated through both the autonomic nervous system as well as GLP-1R located at the sinoatrial node [45]. Furthermore, some studies have shown that GLP-1 protects the ischaemic and reperfused myocardium in rats [46], improves the ejection fraction in individuals treated with angioplasty after acute myocardial infarction [47], and improves left ventricular function and systemic haemodynamics in dogs with induced dilated cardiomyopathy [48]. GLP-1 reduces the post-prandial rise in triglycerides and lowers free fatty acid concentrations in healthy individuals [49], and improves endothelial dysfunction in individuals with type 2 diabetes and coronary heart disease [50]. Lastly, GLP-1 may exert a beneficial effect on the cardiovascular system through decreased inflammation and oxidative stress [51].

Effects on renal function

GLP-1 increases natriuresis through inhibition of the Na^+/H^+ exchanger in the proximal tubules, which may in part explain why GLP-1RAs have subtle antihypertensive effects [52, 53]. Additionally, GLP-1RA reduces glomerular hyperfiltration and albuminuria in individuals with type 2 diabetes [54]. The exact

localization of the GLP-1R in the kidney remains controversial; however, current evidence suggests that it is expressed in preglomerular afferent arterioles, whereas its presence in tubular and juxtaglomerular cells is uncertain [33]. Whether the natriuretic effect of GLP-1 is exerted directly through renal GLP1-Rs, modulation of the atrial natriuretic peptide or the renin–angiotensin system, or a neural pathway remains unclear.

Neuroprotective effects

Finally, GLP-1 has been associated with improved learning in rats and has also displayed neuroprotective effects, but again human studies have not established GLP-1 as a neuroprotective hormone so far or provided convincing evidence for significant effects of GLP-1R agonism on neurodegenerative diseases [55].

Most of what is known about GLP-1's pleiotropic physiological effects stems from studies of pancreatic islet function, particularly β -cell function. It is well acknowledged that GLP-1-induced insulinotropic and glucagonostatic effects represent the main mediators of the normalization of fasting plasma glucose and diurnal plasma glucose excursions and also improved glycaemic levels observed in studies utilizing native GLP-1 in people with type 2 diabetes [56–59]. Such studies have been of great importance to the development of GLP-1RAs.

GLP-1 receptor agonists for the treatment of diabetes

In 2005, the GLP-1RAs were introduced into clinical practice, and since 2009 they have been included in the joint position statements on the treatment of type 2 diabetes by the European Association for the Study of Diabetes (EASD) and the American Diabetes Association (ADA). Recently GLP-1RAs have been

recommended as the first injectable therapy before insulin [60]. The GLP-1RAs, which exert the pleiotropic effects of the native gut hormone GLP-1, target a broad spectrum of the multifaceted pathophysiology of type 2 diabetes, and improve glucose homeostasis with a low risk of hypoglycaemia combined with body weight loss [61, 62]. Furthermore, they reduce cardiovascular events [63]. The introduction of the GLP-1RAs has generated substantial clinical interest and they are increasingly prescribed by clinicians worldwide. Until recently, all GLP-1RAs were administered by subcutaneous injection; however, one GLP-1RA, semaglutide, is now available as an oral formulation, which may facilitate use of this class earlier in the treatment cascade owing to wider acceptance from the individual with type 2 diabetes and healthcare professionals [64].

As several GLP-1RAs have emerged, it has become apparent that there are clinically relevant differences between them, making the therapeutic field challenging to navigate. Currently, seven GLP-1RAs are approved for treating people with type 2 diabetes (Table 36.1) [61, 62]. The challenge in developing a GLP-1RA is that native GLP-1 is rapidly degraded by the enzyme DPP-4, resulting in a short half-life (1–2 min) [65]. To overcome this, GLP-1RAs resistant to degradation by DPP-4 have been developed using two different strategies. The first strategy is based on the naturally occurring polypeptide exendin-4, which was originally isolated from the saliva of the lizard *Heloderma suspectum*. Exendin-4 is DPP-4 resistant, but activates the GLP-1R with equal efficacy to native GLP-1. The other strategy is based on the structure of native GLP-1, with a few amino acid alterations that protect the molecule from being degraded by DPP-4. The main difference between the GLP-1RAs resides in the pharmacokinetic profiles that largely divide them into short-acting and long-acting GLP-1RAs (Table 36.1). The differences in similarity to native GLP-1, pharmacokinetics, and molecular size of the GLP-1R agonists are important, as the efficacy and tolerability seem to depend on these differences.

Table 36.1 Pharmacokinetic properties of approved GLP-1RAs.

GLP-1 RAs		Approval year		Reference amino acid	Pharmacokinetics (single-dose administration)				Antibody development (% of individuals)
Compound	Category	FDA	EMA		Time to peak	Half-life	Elimination		
Exenatide twice daily	Short acting	2005	2006	Exendin-4 (53% homology with native GLP-1)	2.1–2.2 h	2.4 h	Mainly renal	35	
Lixisenatide	Short acting	2016	2013	Exendin-4 (53% homology with native GLP-1)	~2 h	3 h	Mainly renal	56–70	
Liraglutide	Long acting	2010	2009	GLP-1 (97% homology with native GLP-1)	11.0–13.8 h	13 h	Peptide hydrolysis, renal (6%) and faecal (5%)	8.6	
Exenatide once weekly	Long acting	2012	2011	Exendin-4 (53% homology with native GLP-1)	NA	2.4 h	Mainly renal	57	
Dulaglutide	Long acting	2014	2014	GLP-1 (~90% homology with native GLP-1)	48 h	4.7 d	Peptidases and renal	1.6	
Semaglutide	Long acting	2017	2019	GLP-1 (94% homology to native GLP-1)	24 h	7 d	Peptidases and renal	0.01–3.50	
Oral semaglutide	Long acting	2019	2020	GLP-1 (94% homology to native GLP-1)	<1–4 h	7 d	Peptidases and renal	0.5	

EMA, European Medicines Agency; FDA, US Food and Drug Administration; GLP-1, glucagon-like peptide 1; GLP-1RA, glucagon-like peptide 1 receptor agonist.

Short-acting GLP-1RAs

The short-acting GLP-1RAs are readily absorbed after subcutaneous injection and are resistant to degradation by DPP-4, but are still subject to renal elimination, which confers a plasma half-life of ~2–4 h [66,67]. They are administered twice daily (exenatide) or once daily (lixisenatide), which results in relatively large fluctuations in plasma concentrations during the day, and intermittent activation of GLP-1Rs.

Exenatide twice daily

Exenatide was introduced in 2005 (Byetta[®], AstraZeneca, Cambridge, UK) and is a synthetic version of exendin-4, which shares only 53% amino acid sequence homology with human GLP-1 [68,69]. Exenatide is primarily cleared in the kidneys by glomerular filtration [67], and the half-life after subcutaneous injection is ~2.4 h, with detectable plasma concentrations up to 10 h after injection [68]. Exenatide is recommended for twice-daily administration starting at 5 µg twice daily, which may be increased to 10 µg twice daily after one month if well tolerated. To obtain the maximum effect, exenatide should be injected within 60 minutes before the two main meals. The clinical effects of exenatide twice daily were investigated in the AC2993 diabetes Management for Improving Glucose Outcome (AMIGO) trials [69–71]. These trials showed significant reductions in HbA_{1c} versus placebo, and a modest reduction in fasting plasma glucose versus placebo. Post-prandial plasma glucose excursions are blunted in the exenatide-treated participants versus placebo, presumably driven primarily by a substantial deceleration in gastric emptying. Importantly, the effect on post-prandial plasma glucose was only evident during meals with concomitant drug administration; that is, not during lunch where no drug was administered [72]. The average weight loss amounted to 1–4 kg in the exenatide-treated groups versus comparators [73]. The main side effects of exenatide are mild to moderate nausea, diarrhoea, and vomiting [74]. The risk of hypoglycaemia is low with exenatide unless combined with sulphonylurea and insulin.

Lixisenatide once daily

Lixisenatide was approved in 2013 in Europe (Lyxumia[®], Sanofi, Paris, France) and in the USA in 2016 (Adlyxin[®], Sanofi, Bridgewater, NJ, USA) [75]. As with exenatide, lixisenatide is based on exendin-4, but with a deletion of a proline and an addition of six lysine amino acids at the C-terminus [76]. Clinical trials have demonstrated efficacy and tolerability with a once-daily dose of 20 µg, as evaluated in the clinical trial programme GetGoal [67,77,78]. These trials showed that lixisenatide lowered HbA_{1c} and resulted in moderate reductions of fasting plasma glucose versus placebo. Lixisenatide showed effects on post-prandial plasma glucose during a standardized meal test versus placebo, but only when the drug was administered immediately before food ingestion [74]. A dose-dependent decrease in body weight was seen with the 20 µg once-daily lixisenatide, but in some studies the weight reductions were not superior to placebo [79,80]. The most common side effects of lixisenatide treatment are of gastrointestinal origin (nausea and diarrhoea), consistent with other GLP-1RAs. A head-to-head trial of lixisenatide versus exenatide twice daily reported non-inferiority of lixisenatide regarding HbA_{1c} reduction, slightly better tolerability with nausea, diarrhoea, and vomiting, and fewer episodes of symptomatic hypoglycaemia with lixisenatide. However, lixisenatide treatment was inferior regarding weight loss [77].

Continuous-acting GLP-1RA

Several continuous-acting GLP-RA peptides are available. Different modifications have been applied to prolong the receptor activation. These modifications include:

- Incorporation of the GLP-RA in injectable depot-forming microspheres (exenatide once weekly).
- Attachment of a fatty acid side-chain, which allows reversible binding to albumin (liraglutide and semaglutide).
- Fusion with the Fc fragment of immunoglobulin G (dulaglutide, efglantide).

The longer half-lives of these compounds allow administration with longer intervals, while at the same time reducing fluctuations of plasma peptide levels, resulting in continuous activation of GLP-1Rs [61,62]. Recently, oral semaglutide reached the market, a combination of semaglutide and an absorption enhancer, which protects semaglutide of degradation and facilitates the absorption of semaglutide across the gastric mucosa [81].

Exenatide once weekly

Exenatide was developed as an extended-release formulation approved in Europe in 2011 and in the USA at the beginning of 2012 (Bydureon[®], AstraZeneca, Cambridge, UK) [82]. Exenatide once weekly contains exendin-4 encased in microspheres made of biodegradable polymer [83]. The pharmacokinetic profile depends almost solely on the absorption, and over time the biologically active exenatide given as a weekly injection is derived from multiple previous injections undergoing different phases of microsphere dissolution. The extended-release formulation of exenatide once weekly was examined in the phase III clinical trial program Diabetes therapy utilization: researching changes in HbA_{1c} weight and other factors through intervention with exenatide once weekly (DURATION) [84–89]. In two head-to-head studies, it was demonstrated that once-weekly (2 mg) exenatide was superior with regard to glucose lowering to the twice-daily (10 µg) formulation of exenatide, but with similar reductions in body weight [86,88]. Both formulations of exenatide were generally well tolerated; the most frequent adverse event, nausea, was less common with the once-weekly than the twice-daily compound [87]. Once-weekly exenatide 2 mg was also compared in a head-to-head trial with once-daily (1.8 mg) liraglutide [87], with greater reductions in HbA_{1c} and weight loss in the liraglutide-treated group, but once-weekly exenatide was better tolerated [87].

Liraglutide once daily

Liraglutide was approved for clinical use in Europe in 2009 and in the USA in 2010 (Victoza[®], Novo Nordisk) [90]. The structure of liraglutide is based on native GLP-1 with an Arg34Lys substitution and the addition of a 16-carbon fatty acid chain at Lys26, leaving liraglutide with a 97% homology with native GLP-1 (Table 36.1). The effects of liraglutide in doses uptitrated to 1.8 mg daily have been investigated in the phase III clinical trial programme Liraglutide Effect and Action in Diabetes (LEAD) [91–97]. Liraglutide significantly lowered HbA_{1c}, fasting plasma glucose, and weight compared with the placebo-treated group. Liraglutide also reduced post-prandial plasma glucose excursions compared with placebo; this effect was, however, primarily mediated by a decrease in pre-prandial (e.g. fasting) glucose values, which is consistent with the observation that liraglutide has small to moderate effects on gastric emptying [97]. The LEAD studies reported significant reductions in systolic blood pressure of up to 6 mmHg, but also a small increase in heart rate of 2–4 beats per minute in the

liraglutide-treated group [95,97]. The most frequently reported adverse events were gastrointestinal (nausea; mild and less persistent compared with treatment with exenatide twice daily) [98]. Compared with exenatide twice daily, liraglutide demonstrated greater reduction in fasting plasma glucose, but weight reductions were equal between the two groups [98]. In a head-to-head trial liraglutide reduced both fasting plasma glucose reductions, HbA_{1c}, and weight more than lixisenatide [99]. Another head-to-head trial with once-daily (1.8 mg) liraglutide demonstrated superiority compared with once-weekly (1.5 mg) dulaglutide with respect to body weight reduction [100].

Dulaglutide once weekly

Dulaglutide (Trulicity[®], Eli Lilly and Company, Indianapolis, IN, USA) was approved in 2014 by the FDA and 2015 by the EMA [101]. It comprises two GLP-1 moieties covalently linked to a human immunoglobulin G (IgG) 4-Fc heavy chain, which acts as an inert plasma carrier. Dulaglutide, used as a 1.5 mg once-weekly dose, has been examined in the phase III clinical trial programme Assessment of weekly administration of LY2189265 in diabetes (AWARD), and has also been compared head to head with exenatide twice daily, sitagliptin, and liraglutide [102–104]. Clinical trials showed dose-dependent reductions of HbA_{1c}, fasting plasma glucose, and weight reductions. Safety data indicate a low incidence of hypoglycaemia and the most frequently reported adverse events were gastrointestinal, primarily nausea, which seemed to reduce over time. Dulaglutide 1.5 mg once weekly showed non-inferiority to liraglutide 1.8 mg once daily for HbA_{1c} reduction after 26 weeks, but a greater weight loss was seen in the liraglutide-treated group [100]. As with other GLP-1RA, the most common adverse events are mild to moderate and transient nausea and diarrhoea. Recently, escalation of dulaglutide from 1.5 mg to 3.0 mg or 4.5 mg demonstrated clinically relevant, dose-related reductions in HbA_{1c} and body weight with similar safety profiles, and all three doses are now available for the treatment of type 2 diabetes [105].

Semaglutide once weekly (injection)

Semaglutide once weekly (Ozempic[®], Novo Nordisk [106]) was approved in 2018 by the FDA and EMA as a subcutaneously administered GLP-1RA that is structurally closely related to liraglutide, but with the attachment of a C-18 fatty acid chain (instead of the C-16 fatty acid chain in liraglutide) for improved albumin binding. There is also an alanine to α-aminoisobutyric acid substitution at position 8, which decreases degradation by DDP-4. The efficacy and safety of semaglutide in doses up titrated to 1 mg once weekly were investigated in the phase III clinical trial programme Semaglutide unabated sustainability in treatment of type 2 diabetes (SUSTAIN). Results from the trials support the superiority of semaglutide for reduction of HbA_{1c} and weight loss versus placebo as well as active comparators, including sitagliptin, canagliflozin, exenatide once weekly, dulaglutide, liraglutide, and insulin glargine [107–113]. Interestingly, exposure-response analyses showed a clear relationship reflecting plasma levels of semaglutide obtained after subcutaneous semaglutide and subsequent reductions in HbA_{1c} and body weight [114]. Consistent with these findings, the proportions of people reporting nausea or vomiting with semaglutide subcutaneously were also related to the plasma concentration [114]. The prevalence of gastrointestinal adverse events with once-weekly semaglutide and dulaglutide was similar at a full dose.

Semaglutide once daily (oral)

Oral semaglutide (Rybelsus [115]) was approved in 2019 by the FDA and in 2020 by the EMA. Oral semaglutide is a combination of semaglutide and the absorption enhancer sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC), which protects semaglutide from degradation in the stomach and facilitates the absorption of semaglutide across the gastric mucosa [64,81]. The efficacy and safety of daily oral semaglutide (3, 7, and 14 mg) were investigated in the phase III clinical trial programme Peptide innovation for early diabetes treatment (PIONEER), which included 10 multinational studies [116–122]. Individuals recruited for this programme were people with type 2 diabetes from across a broad range of disease durations and background therapies, and were representative of many individuals typically encountered in clinical practice. Oral semaglutide 14 mg was superior in reducing HbA_{1c} versus empagliflozin (25 mg) when used as second-line treatment in individuals not reaching their target on metformin [117], and superiority was also seen versus sitagliptin (100 mg) [118]. Oral semaglutide (up titrated to 14 mg) was non-inferior to subcutaneous liraglutide (1.8 mg once daily) in decreasing HbA_{1c} [119]. Body weight reductions were similar for oral semaglutide compared with empagliflozin [117], but with greater reductions than sitagliptin [118] and liraglutide [119]. These observations suggest that oral semaglutide may provide some weight management benefits versus other commonly prescribed subcutaneous GLP-1RAs. Overall, oral semaglutide is well tolerated, with a safety profile consistent with the GLP-1RA drug class. The risk of hypoglycaemia was low, and the most common adverse events were gastrointestinal, with nausea and diarrhoea generally being the most frequently reported manifestations [64]. Currently higher doses (up to 50 mg) of oral semaglutide are being investigation for the treatment of type 2 diabetes and obesity [123–126].

Albiglutide once weekly

Albiglutide was a once-weekly GLP-1RA for subcutaneous administration approved in 2014 in both the USA (Tanzeum[®], GlaxoSmithKline, Durham, NC, USA) and Europe (Eperzan[®], GlaxoSmithKline, Brentford, UK), but in 2018 it was withdrawn from the market for commercial reasons.

Efpeglenatide once weekly

Efpeglenatide is a once-weekly exendin-4-based subcutaneously administrated GLP-1RA under development. The modified exendin-4 has been conjugated with an IgG4 Fc fragment to avoid DPP-4 degeneration and renal clearance [127,128]. Efpeglenatide has not yet been approved by the FDA.

Cardiovascular outcome trials with GLP-1RA in diabetes

The cardiovascular safety of all approved GLP-1RAs has been investigated in large-scale cardiovascular outcome trials, except for the short-acting exenatide twice daily, which was approved before cardiovascular outcome trials were mandated by the FDA and EMA (Table 36.2). The cardiovascular outcome trials are international, multicentre, double-blinded, randomized trials, which have compared the cardiovascular effect of GLP-1RAs with placebo when added to standard therapy. All trials have applied the same composite primary endpoint of major adverse cardiovascular events comprising cardiovascular death, non-fatal myocardial infarction, and non-fatal stroke, except for the Evaluation of Lixisenatide in Acute Coronary

Table 36.2 Overview of currently published cardiovascular outcome trials including baseline characteristics and outcomes.

Cardiovascular outcome trials of GLP-1RAs									
Trial drug	Trial name	Year of completion	Number of individuals	Median follow-up (years)	Age (years)	HbA _{1c} (%)	CVD	Exposure to trial drug	MACE (HR [95% CI])
Lixisenatide	ELIXA	Feb 2015	6068	2.1	60	7.7	100%	91%	1.02 (0.89–1.17)
Liraglutide	LEADER	Dec 2015	9340	3.8	64	8.7	81.3%	84%	0.89 (0.78–0.97)
Semaglutide	SUSTAIN 6	Mar 2016	3297	2.1	65	8.7	83.0%	87%	0.74 (0.58–0.95)
Exenatide once weekly	EXSCEL	May 2017	14752	3.2	62	8.1	73.1%	76%	0.91 (0.83–1.00)
Albiglutide	HARMONY Outcomes	Nov 2017	9463	1.6	64	8.7	100%	87%	0.78 (0.68–0.90)
Dulaglutide	REWIND	Aug 2018	9901	5.4	66	7.3	31.5%	82%	0.88 (0.79–0.99)
Semaglutide (oral)	PIONEER-6	Sep 2018	3183	1.3	66	8.2	84.7%	75%	0.79 (0.57–1.11)
Efpeglenatide	AMPLITUDE-O	Dec 2020	4076	1.8	65	8.9	89.6%	89%	0.73 (0.58–0.92)

CI, confidence interval; CVD, cardiovascular disease; GLP-1RA, glucagon-like peptide 1 receptor agonist; HbA_{1c}, glycated haemoglobin; HR, hazard ratio; MACE, major adverse cardiovascular event.

Syndrome (ELIXA) trial, in which the primary composite endpoint also included hospitalization for unstable angina [61–63].

The ELIXA trial, which investigated the cardiovascular safety of lixisenatide, was the first cardiovascular outcome trial to provide data for a GLP-1RA and the only cardiovascular outcome trial to provide data for a short-acting GLP-1RA [129]. The trial included individuals with type 2 diabetes and recent acute coronary syndrome, and showed that lixisenatide was non-inferior to placebo in reducing the primary composite endpoint. Hence, the available data are currently not supporting any beneficial cardiovascular effect of short-acting GLP-1RAs.

Several continuous-acting GLP-1RAs have proved to reduce major adverse cardiovascular events. The first cardiovascular outcome trials to provide data for continuous-acting GLP1-RAs were the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial and the SUSTAIN 6 trial, which investigated the cardiovascular safety of liraglutide and semaglutide, respectively [130, 131]. These trials included individuals with type 2 diabetes and established cardiovascular disease or high risk of cardiovascular disease. Both liraglutide and semaglutide proved superior to placebo in reducing major adverse cardiovascular events, thereby being the first GLP-1RAs with a proven effect on the prevention of cardiovascular events.

The next cardiovascular outcome trial to present data on the cardiovascular safety of a GLP-1RA was the Exenatide Study of Cardiovascular Event Lowering (EXSCEL) trial, which also was the largest of the cardiovascular outcome trials with >14 000 participants [132]. The trial was designed to have 70% individuals with pre-existing cardiovascular disease and 30% without cardiovascular disease. In this trial, exenatide once weekly was non-inferior to placebo, but superiority was not proved. The participants in EXSCEL were younger and had a lower HbA_{1c}, a lower prevalence of cardiovascular disease, and a lower time on active treatment during the trial than previous cardiovascular outcome trials, which may partly explain the inability of exenatide once weekly to obtain superiority. Both dulaglutide and albiglutide subsequently were shown to reduce major adverse cardiovascular events in their respective cardiovascular outcome trials [133, 134]. In the

Dulaglutide and cardiovascular outcomes in type 2 diabetes (REWIND) trial, dulaglutide reduced major adverse cardiovascular events in a population with a markedly lower level of established cardiovascular disease at baseline when compared to any of the other cardiovascular outcome trials, which predominantly included individuals with established cardiovascular disease [133]. This finding supports a role for dulaglutide and potentially the other continuous-acting GLP-1RAs in the primary prevention of cardiovascular disease in type 2 diabetes.

The PIONEER-6 trial investigating the cardiovascular safety of oral semaglutide included the smallest population and had the shortest follow-up time of the completed cardiovascular outcome trials [135]. Oral semaglutide demonstrated non-inferiority, but not superiority, compared with placebo. The estimated hazard ratio of major adverse cardiovascular events was roughly like that of subcutaneous semaglutide, but with a markedly wider confidence interval, and hence the study was likely underpowered to detect any significant effect. Whether oral semaglutide has a beneficial cardiovascular effect remains to be explored in the ongoing Heart Disease Study of Semaglutide in Patients with Type 2 Diabetes (SOUL) trial [136]. The last of the cardiovascular outcome trials to be completed was the Effect of Efpeglenatide on Cardiovascular Outcomes (AMPLITUDE-O) trial, which investigated the cardiovascular safety of efpeglenatide and included individuals with type 2 diabetes and established cardiovascular disease or current kidney disease plus a least one cardiovascular risk factor [128]. This was the first trial to demonstrate a significant reduction in major adverse cardiovascular events for an exendin-4-based GLP-1RA.

Whereas the currently conducted cardiovascular outcome trials support a class effect for continuous-acting GLP-1RAs on the risk of cardiovascular disease, the trials have revealed an inconsistent effect on the individual major adverse cardiovascular event components. However, in a meta-analysis of the currently published cardiovascular outcome trials including >60 000 individuals, a significant effect on each of the components (cardiovascular death, fatal or non-fatal myocardial infarction, and fatal or non-fatal stroke) was found [63]. The meta-analysis also found that treatment with a GLP-1RA reduced the risk of hospitalization for heart failure.

It is important to recognize that the populations in the cardiovascular outcome trials are different and results from the different trials cannot be directly compared. The prevalence of established cardiovascular disease varied from 32% to 100%, which affected the incidence of major adverse cardiovascular events and thereby the number needed to treat. However, in a meta-analysis, the number needed to treat to prevent one incident major adverse cardiovascular event over a weighted average median follow-up period of three years was 65 individuals [63].

In addition to investigating the effect of GLP-1RAs on cardiovascular disease, most cardiovascular outcome trials have included renal secondary endpoints. Treatment with GLP-1RA reduced a broad composite renal outcome comprising development of macroalbuminuria, doubling of serum creatinine, or at least 40% decline in estimated glomerular filtration rate (eGFR), kidney replacement therapy, or death due to kidney disease [137]. However, this effect was mainly driven by a decrease in macroalbuminuria, and whether GLP-1RAs reduce worsening in kidney function and delay progression to dialysis is still to be determined. Nevertheless, in a sensitivity analysis excluding data from the ELIXA trial, which stands out as the only cardiovascular outcome trial investigating a short-acting GLP-1RA, treatment with GLP-1RAs led to a significant reduction of 18% in worsening of kidney function, defined as either doubling of serum creatinine or $\geq 40\%$ decline in eGFR [63].

Safety Issues

The safety of GLP-1RAs has been extensively studied in pre-clinical studies, the large clinical trial programmes, as well as the cardiovascular outcome trials. The most common adverse events observed in clinical trials of GLP-1RAs involve the gastrointestinal system and are mainly nausea, vomiting, and diarrhoea. These events are dose dependent and diminish over time. Differences exist in the reported occurrence of these gastrointestinal effects between each GLP-1RA. Other identified potential safety issues include hypoglycaemia, pancreatic adverse events, thyroid neoplasms, immunogenicity issues, and interactions with other medicinal products [68, 75, 82, 90, 101, 106, 115].

Hypoglycaemia

GLP-1RAs generally confer a low risk of severe hypoglycaemia, as the clinical insulin-stimulatory effects are only present at plasma glucose levels >4 mmol/l (72 mg/dl) [138]. In monotherapy or combination with other anti-diabetes agents that have a low risk of hypoglycaemia (e.g. metformin), the GLP-1RAs uncommonly cause hypoglycaemia [68, 75, 82, 90, 101, 106, 115]. In trials in which the GLP-1RAs were combined with a hypoglycaemic agent, such as a sulfonylurea or insulin, the incidence of non-severe hypoglycaemia was significantly higher (up to one-third of participants), depending on trial duration, study population, and the dose of insulin and/or sulfonylurea. When a GLP-1RA has been combined with insulin treatment in clinical trials, symptomatic hypoglycaemic events have been reported in ~25% of individuals, and slightly more with short-acting than continuous-acting GLP-1RAs [139].

Pancreatic adverse events

Since the introduction of GLP-1-based therapy, pancreatic adverse effects, in particular pancreatitis and pancreatic cancer, have been a major concern. The concern for pancreatic safety was spurred by

post-marketing reports of pancreatitis during GLP-1RA treatment. According to an analysis based on the FDA adverse event reporting database for the years 2005–2009 [140], pancreatitis was reported as an adverse event more than six times as frequently for individuals administered exenatide compared with other (non-GLP-1-based) therapies for type 2 diabetes. This may have been a so-called Weber effect, which constitutes a peak in adverse event reporting at the end of the second year after regulatory approval of a drug followed by a continuous decline thereafter [141]. In 2013–2014, the EMA and FDA undertook an extensive appraisal of the existing pre-clinical and clinical safety data together with the observational evidence. They concluded that data were too inconsistent to establish a certain connection between GLP-1RA administration and pancreatic adverse effects, but owing to the uncertainty of the estimates, a causal role could not be completely excluded [142]. A major issue in relation to the spontaneous reports of pancreatic adverse events is the fact that people with type 2 diabetes generally have an up to four times higher risk of pancreatitis than those without diabetes [143]. In contrast to early increases in spontaneously reported events, acute pancreatitis and pancreatic cancer events have been extremely rare in the randomized clinical trials with the GLP-1RAs [144]. Data from cardiovascular outcome trials with adjudicated pancreatic events showed that the incidence of pancreatitis was similar (~0.3%) in GLP-1RA- and placebo-treated individuals with type 2 diabetes [130, 144, 145]. It is important for the interpretation that individuals with a high risk of pancreatitis (e.g. previous pancreatitis) were excluded from participating in most of these trials. Reassuringly, a recent meta-analysis of 22 population-based observational studies did not identify an association with GLP-1RA use and any pancreatic pathology [146]. Nonetheless, acute pancreatitis is still listed as an adverse event for all GLP-1RAs [68, 75, 82, 90, 101, 106, 115]. So far there are no data to suggest differences in adverse pancreatic effects between the GLP-1RAs (e.g. between short- and continuous-acting agents [147]). Individuals started on treatment with any of the GLP-1RAs should be informed of the potential risk and characteristic symptoms of acute pancreatitis; and caution is advised when prescribing GLP-1RAs to those with a risk of or a history of pancreatitis [68, 75, 82, 90, 101, 106, 115].

Thyroid adverse events

The pre-clinical development programme of several GLP-1RAs exposed significant increases in medullary thyroid carcinoma (thyroid C-cell neoplasm) in rodents [68, 75, 82, 90, 101, 106, 115]. The fact that these C-cell neoplasms were not detected in monkeys [148] suggests important species differences. Accordingly, in comparison with rodent thyroid glands, C cells are much less abundant in human thyroid tissue and, equally importantly, GLP-1Rs are present in much lower amounts per C cell [148]. Thyroid events and medullary thyroid carcinoma were closely monitored in the clinical trial programmes of all GLP-1RAs, including their cardiovascular outcome studies and in post-marketing surveillance. The collective evidence does not suggest that GLP-1RA treatment causes a higher risk of thyroid cancers in humans [144, 146, 149].

Immunogenicity issues

The GLP-1RAs are large molecules that can raise an immune response. This is evidenced by measurable levels of antibodies directed against epitopes on the GLP-1RA in some individuals. Generally, the exendin-4-based GLP-1RAs (exenatide, lixisenatide, and efpeglenatide) raise more antibodies (~25–74% of treated

individuals) than the GLP-1RAs with higher peptide sequence homology to native human GLP-1 (liraglutide, semaglutide, albiglutide, and dulaglutide), where antibodies can be detected in 1–9% of those treated. There is conflicting evidence on the clinical relevance of these antibodies [150–152]. However, the presence of high levels of neutralizing antibodies may limit the clinical effects of at least some of the GLP-1RAs (as is evident with exenatide, where high levels are present in 1–6% of individuals, associated with a lower clinical efficacy [151, 153]). Hypersensitivity reactions and local injection-site reactions are inconsistently reported in the trials, but may also depend on immunogenicity. Injection-site reactions include local nodule formation, redness, or itching that occurs in 0–22% of individuals treated with a GLP-1RA for up to a year. Interestingly, injection-site reactions are more frequent in individuals who develop antibodies [82]. However, other excipients in the drug formulation (e.g. the prolonged-release delivery systems in the GLP-1RA for once-weekly administration or fatty acid side-chains to the GLP-1-moecity) may also be important factors in the development of injection-site reactions. Thus, exenatide once weekly caused much more injection site pruritus than exenatide twice daily (18% vs 1%) [88] and injection-site reactions occurred in more individuals given albiglutide than in those given liraglutide (13% vs 5%) [154].

Interactions with other medical products

None of the GLP-1RAs interacts with the hepatic metabolism of other medicinal products; specific interactions with acetaminophen, digoxin, oral contraceptives, lisinopril, metformin, hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, and warfarin have been studied in clinical trials [68, 75, 82, 90, 101, 106, 115]. However, all the GLP-1RAs delay gastric emptying with acute dosing, and therefore have the potential to prolong the absorption of concomitantly administered oral medicinal products. Importantly, the effect on gastric emptying diminishes with time for the continuous-acting GLP-1RAs owing to rapid tachyphylaxis, already evident from the first day of treatment [38]. Therefore, the interaction through delayed gastric emptying is mainly of clinical relevance with the short-acting GLP-1RAs and in a situation with concomitant administration of medicinal products with a narrow therapeutic-toxic ratio that require careful clinical or biochemical monitoring. The interaction can be alleviated by administration of the other medicinal product one hour before or four hours after the administration of the short-acting GLP-1RA [68, 75].

Amylin and amylin analogues

Historical overview

Amyloid deposits were discovered a century ago and are described as a pathological feature of people with diabetes and those with insulinomas. In 1987, amylin was isolated from amyloid deposits and there was speculation on whether it had important endocrine effects [155, 156]. Amylin is stored and secreted with insulin from the β cells [157] and type 1 diabetes is considered an amylin-deficient state owing to β -cell destruction, and the hormones exhibiting complementary roles in the regulation of plasma glucose [158]. The physiological actions of amylin involve inhibition of appetite and gastric emptying, and may also involve suppression of glucagon

secretion in relation to meal intake [158]. The development of amylin analogues focuses on the clinically beneficial effects on glycaemic levels, especially post-prandially, and body weight in the treatment of diabetes.

Amylin physiology

Amylin release, metabolism, regulation of secretion and receptor

Amylin and insulin are stored together in secretory granules and are co-released from the pancreatic β cells [159]. The release of amylin is stimulated by nutrient ingestion and gut-derived incretin hormones (GLP-1 and GIP) and through neural signalling. Amylin is released during meals and together with insulin in a corresponding high-frequency pulsatile pattern, but at a 1:100 ratio [159]. Deviation from this secretion pattern has been observed in several conditions, including diabetes and obesity, but the mechanisms of the altered amylin secretion pattern and its potential implications are unknown [160]. In contrast to insulin, which is eliminated primarily in the liver, amylin is eliminated mainly through renal metabolism [158]. Amylin acts on a composite receptor with two parts. The *core* part comprises a calcitonin receptor, which is a transmembrane class B G protein-coupled receptor [161, 162]. Two splice variants of the calcitonin receptor (a and b) exist, and they are complexed with one of three receptor activity-modifying proteins (RAMP1, RAMP2, and RAMP3), creating diverse amylin receptors (AMY1, AMY2, and AMY3) [163]. Amylin appears to bind with high affinity to six different emerging receptors [162].

Amylin's effect on gastric emptying and central effects on appetite and food intake

Amylin and GLP-1 share overlapping physiological properties. Both peptide hormones slow nutrient delivery to the small intestine by decelerating gastric emptying, suppress post-prandial glucagon secretion, and reduce appetite, albeit through seemingly different pathways [164]. Dose-response studies performed in rats investigating the influence on gastric emptying exerted by several different subcutaneously injected gastrointestinal hormones (amylin, cholecystokinin octapeptide [CCK-8], GIP, GLP-1, glucagon, and pancreatic peptide) showed that amylin was the most potent inhibitor of these [165]. Correspondingly, subcutaneous injection of a selective amylin receptor antagonist in rats revealed an acceleration of gastric emptying [166, 167]. Importantly, the ability of amylin to inhibit gastric emptying is overridden by the occurrence of hypoglycaemia [168]. Whether amylin's decelerating effect on gastric emptying contributes to its anorectic effects remain uncertain. Nevertheless, exogenous amylin reduces meal size and, furthermore, peripherally or centrally infused amylin receptor antagonist produces an opposite effect, suggesting that amylin is a physiological regulator of food intake [169].

Amylin exerts its anorectic actions via direct effects on the CNS [164, 169, 170]. c-Fos expression (a marker of neuronal activity) is induced by amylin in target neurons in different brain regions involved with metabolic regulation [171]. The area postrema located in the hindbrain is the primary and most important site of amylin action. This assumption is based on studies of rodents undergoing area postrema ablation, which demonstrated a complete abrogation of amylin's anorexigenic effects [172, 173]. After area postrema activation, the amylin signal is conveyed to the

forebrain via distinct relay stations and to regions of hypothalamus known to be involved in feeding behaviour. Within the lateral hypothalamic area, amylin diminishes the expression of orexigenic neuropeptides such as orexin and melanin-concentrating hormone [160,171,173]. The area postrema is favourably located as a target of central hormone action owing to the permeable blood-brain barrier in this region. Other brain sites suggested to be important contributors to amylin's anorexic effects include the subfornical organ, the nucleus accumbens, and the dorsal raphe of the brain-stem [172,173]. Amylin's anorectic effect relies on both satiety-promoting effects and attenuation in feeding reward neurocircuits [174]. Whether amylin also exerts peripheral actions has been investigated in muscle, liver, and adipose tissue of mice and adipose tissue of humans [175,176], and physiological effects were clearly evident with stimulation of distinct signalling pathways after application of amylin. However, the presence of amylin receptors in these peripheral tissues remains uncertain.

Amylin analogues for the treatment of diabetes

The discovery of amylin's glucose and body weight-lowering effects makes it attractive for therapeutic purposes. However, the instability and propensity to self-aggregate complicated the clinical development of drugs based on native sequence human amylin [157]. The problem was solved by substituting a few amino acids in the rat sequence of amylin with proline residues [164]. This enhanced the solubility and markedly reduced amyloid fibril formation of the bioactive peptide [177]. The actions and pharmacokinetic and pharmacodynamic properties of a synthetic amylin analogue, pramlintide, are very similar to those of native amylin [157]. Numerous clinical trials tested the efficacy and safety of pramlintide ahead of its approval by the FDA in 2005. Currently, this sole available amylin analogue is marketed in the USA as Symlin® (Amylin Pharmaceuticals, San Diego, CA, USA). The drug is approved for adjunct treatment of type 1 diabetes and type 2 diabetes, when optimal glucose levels are not achieved with insulin administration alone or combined with other glucose-lowering drugs [178]. Pramlintide is administered in conjunction with meal-time insulin therapy [177]. The plasma elimination half-life is ~48 min when injected subcutaneously in the thigh or the abdomen. The drug is primarily eliminated by the kidneys, like native amylin [179]. The most common adverse events related to pramlintide treatment are of gastrointestinal origin, including decreased appetite, vomiting, and stomach pain, with mild-to-moderate nausea being most frequent. However, these effects are generally transient and can be minimized by slow uptitration. No clear correlation between gastrointestinal symptoms and therapy-induced weight loss has been found [180]. Although pramlintide is well tolerated overall, it is associated with an increased risk of insulin-induced severe hypoglycaemia, particularly in people with type 1 diabetes [181].

Clinical studies investigating the acute and short-term effects of pramlintide have demonstrated reductions in post-prandial glucose excursions and 24 h glucose profile [182]. These glycaemic improvements were observed in acute studies and with continued dosing for 2–4 weeks and are likely due to decreased gastric emptying. Whether amylin-induced attenuation of post-prandial glucagon release contributes remains uncertain. Several larger long-term trials with pramlintide have also been conducted. Hollander et al. investigated HbA_{1c} and weight management with adjuvant pramlintide therapy in 656 individuals with type

2 diabetes with HbA_{1c} ≥8% (64 mmol/mol) who were requiring insulin treatment either alone or combined with oral anti-diabetes medications at baseline [158]. Participants were randomized to receive pramlintide at different doses or placebo for 52 weeks. Treatment with pramlintide twice daily led to a reduction from baseline in HbA_{1c} of −0.62% (7 mmol/mol) at week 52 (vs −0.25% [3 mmol/mol] with placebo). Body weight change at week 52 from baseline was sustained in individuals receiving 120 µg twice daily (−1.4 kg) versus 90 µg twice daily (−0.5 kg) or placebo (+0.7 kg) [158]. The 1155 participants with type 2 diabetes and body mass index >25 kg/m², who received pramlintide 120 µg twice daily in the study, were included in a pooled *post hoc* analysis with corresponding participants from another large-scale trial [154,183]. Significant reductions in both HbA_{1c} (−0.43%; 5 mmol/mol) and body weight (−2.0 kg) from baseline to week 26 (compared with placebo) were found with adjunctive pramlintide therapy. These data indicate that pramlintide added to insulin therapy yields further reductions in HbA_{1c} and a concomitant weight loss in individuals with type 2 diabetes.

Perspectives for non-insulin parenteral therapies

Evidence from large-scale trials focusing on cardiovascular safety has established GLP-1RA as a cornerstone in type 2 diabetes treatment. In contrast to older anti-diabetes agents, several GLP-1RAs confer substantial body weight loss and prevent cardiovascular morbidity and death within few years of initiating therapy in type 2 diabetes. Based on these extraordinary results, the future use of the GLP-1RAs is likely to expand. Two GLP-1RAs (liraglutide and semaglutide) have been approved in higher doses for the treatment of obesity and new avenues for type 2 diabetes-associated conditions are also being specifically investigated. Thus, trials are ongoing in type 2 diabetes-associated chronic kidney disease [184], eye disease [185], and heart failure with preserved ejection fraction [186], but also type 1 diabetes [187] and non-alcoholic fatty liver disease and non-alcoholic steatohepatitis [188]. In addition, potential effects on neurological diseases such as Alzheimer disease [189], Parkinson disease [190], and depression [191] are also possible and are currently being investigated.

When treating complicated metabolic diseases, such type 2 diabetes, intervening with more than one regulatory pathway is often desirable due to additive effects. Along these lines, several dual and/or triple receptor agonists, where activation of the GLP-1R is combined with activity at other peptide hormone receptors, are in clinical development. The combined agonism of GLP-1R and the GIP, glucagon, or amylin receptors is particularly promising and several unimolecular multiagonist treatment compounds simultaneously activating two or more of these receptors, besides the GLP-1R, are in late clinical development for the treatment of type 2 diabetes, obesity, and/or non-alcoholic steatohepatitis [192,193]. Major caveats for the success of these compounds include the unclear translation to clinical efficacy and safety in humans, and an aggravated risk of untoward immunological reactions and unforeseen off-target effects, which have to compare favourably to the well-established clinical efficacy and safety of optimally dosed GLP-1RAs.

How to Use Type 2 Diabetes Treatments in Clinical Practice

Thomas Karagiannis^{1,2}, Aris Liakos^{1,2}, and Apostolos Tsapas^{1,2,3}

¹ Diabetes Centre, Second Medical Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

² Clinical Research and Evidence-Based Medicine Unit, Second Medical Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

³ Harris Manchester College, University of Oxford, Oxford, UK

Key points

- Numerous pharmacological options for the management of type 2 diabetes are available.
- The choice of appropriate anti-diabetes therapy is guided by the presence of clinically important comorbidities and underlying cardiovascular risk.
- Sodium–glucose cotransporter-2 (SGLT-2) inhibitors are the treatment of choice in people with heart failure or chronic kidney disease.
- Specific SGLT-2 inhibitors or glucagon-like peptide-1 receptor agonists (GLP-1RAs) are prioritized in people with established or at high risk of developing atherosclerotic cardiovascular disease.
- In those with low absolute cardiovascular risk, therapeutic decisions should consider the efficacy and safety profile of potential agents and avoid increased treatment burden.
- In the presence of obesity, GLP-1RAs or SGLT-2 inhibitors are preferred.

- In those with non-alcoholic steatohepatitis (NASH), pioglitazone and some GLP-1RAs are recommended.
- For treatment of hyperglycaemia, metformin remains the initial choice in most people, including those with newly diagnosed type 2 diabetes, due to the extensive experience with its use, overall efficacy and safety profile, and affordability.
- Additional important considerations affect real-life therapeutic decisions and the likelihood that people will take their medication as prescribed, including the values and preferences of the informed individual, tolerability issues, practical matters, and drug availability and affordability.
- Clinicians should continually update their knowledge of the pharmacological management of type 2 diabetes and avoid clinical inertia by regularly reassessing the overall clinical profile of those they treat.

In recent years, pharmacotherapy for type 2 diabetes has departed from focusing solely on the management of hyperglycaemia to mitigation of cardiovascular risk [1–3]. The changing landscape in the management of type 2 diabetes was largely imposed by findings from cardiovascular outcomes trials, which suggest a beneficial effect on hard clinical endpoints for certain classes of anti-diabetes agents, namely sodium–glucose cotransporter 2 inhibitors (SGLT-2) and glucagon-like peptide 1 receptor agonists (GLP-1RAs). In this context, clinicians should consider indicators of high risk of, or established, atherosclerotic cardiovascular disease, chronic kidney disease, or heart failure when choosing the optimal treatment. In this chapter, we review the main glucose-lowering drug classes in terms of their benefits and harms, and their current place in the management of type 2 diabetes.

to follow (Chapters 35 and 36; Table 37.1). Medications approved for the treatment of type 2 diabetes fall into the following main categories:

- Insulin-sensitizing agents, which include biguanides represented solely by metformin, as well as thiazolidinediones represented by pioglitazone; the use of rosiglitazone has practically ceased due to concerns about an increased risk of myocardial infarction [4].
- Insulin secretagogues (sulfonylureas, meglitinides).
- Incretin mimetics (dipeptidyl-peptidase 4 [DPP-4] inhibitors, GLP-1RAs, dual glucose-dependent insulinotropic polypeptide [GIP] and GLP-1RAs).
- Agents that induce glycosuria (SGLT-2 inhibitors).
- Agents that block intestinal absorption of carbohydrates (α -glucosidase inhibitors).
- Insulin.

There are also other medications with glucose-lowering properties (e.g. bile acid sequestrants, dopamine-2 agonists, and amylin mimetics) that are either licensed for the treatment of type 2 diabetes only in specific regions or whose use in clinical practice is very limited.

Therapeutic options

The number of diabetes drugs has expanded substantially over the preceding years and evidence from cardiorenal outcomes trials is rapidly accruing at a pace that practising clinicians might find hard

Table 37.1 Characteristics of agents used for the treatment of type 2 diabetes in the USA or Europe.

Class	Medications	Primary physiological action(s)	Main advantages	Main disadvantages
Biguanides	Metformin	↓ Hepatic glucose production ↑ Glucose uptake in peripheral tissues	Extensive experience No hypoglycaemia Weight neutral (potential for modest loss) ? Reduction in CV events or all-cause mortality Low cost	Gastrointestinal adverse events Vitamin B ₁₂ deficiency Contraindicated with eGFR <30 ml/min/1.73 m ² Lactic acidosis (rare)
Sulfonylureas	Glibenclamide (or glyburide) Glidiazide Glipizide Glimepiride	↑ Insulin secretion	Extensive experience ↓ Microvascular complications Low cost	Hypoglycaemia ↑ Weight Dose adjustment/avoidance in CKD ? Cardiovascular safety 'Pancreatic exhaustion'
Meglitinides (or glinides)	Nateglinide Repaglinide	↑ Insulin secretion	↓ Post-prandial glucose excursions Dosing flexibility Relatively safe in advanced CKD	Hypoglycaemia ↑ Weight ? Cardiovascular safety
Thiazolidinediones (or glitazones)	Pioglitazone	↑ Insulin sensitivity	No hypoglycaemia ↓ Cardiovascular events ↓ Liver steatosis	↑ Weight ↑ Fractures Oedema/heart failure Bladder cancer
DPP-4 inhibitors (or gliptins)	Alogliptin Linagliptin Saxagliptin Sitagliptin Vildagliptin	Glucose dependent: ↑ Insulin secretion ↓ Glucagon secretion	No hypoglycaemia Weight neutral Well tolerated	Modest glycaemic efficacy Skin reactions ↑ Hospitalizations for heart failure (saxagliptin) Dose adjustment in CKD (except for linagliptin) ? Pancreatitis, pancreatic neoplasms ? Arthralgia
GLP-1 receptor agonists	Dulaglutide Exenatide Exenatide LAR Liraglutide Lixisenatide Subcutaneous semaglutide Oral semaglutide	Glucose dependent: ↑ Insulin secretion ↓ Glucagon secretion Delay gastric emptying ↑ Satiety	No hypoglycaemia ↓ Weight ↓ Post-prandial glucose excursions ↓ CV events Prevent progression of albuminuria ↓ Liver steatosis ↓ Mortality	Injectable (except oral semaglutide), local site reactions, require training Gastrointestinal adverse events ? Pancreatitis, pancreatic neoplasms Gallbladder disease ? Medullary carcinoma ↑ Heart rate High cost
GIP/GLP-1 receptor agonists	Tirzepatide	Glucose dependent: ↑ Insulin secretion ↓ Glucagon secretion Delay gastric emptying ↑ Satiety Improve lipid homeostasis ↑ Insulin sensitivity	No hypoglycaemia ↓ Weight	Injectable Gastrointestinal adverse events High cost Currently in development
SGLT-2 inhibitors (or gliflozins)	Canagliflozin Dapagliflozin Empagliflozin Ertugliflozin	Insulin independent inhibition of glucose reabsorption in the proximal convoluted tubule → glucosuria	No hypoglycaemia ↓ Weight ↓ Blood pressure ↓ CV events in high-risk individuals ↓ Hospitalizations for heart failure Prevent progression of CKD ↓ Mortality	Genitourinary tract infections Volume depletion (dizziness, orthostatic hypotension, syncope) esp. in older people, CKD, or those on diuretics Dose adjustment in CKD (see labels of individual agents for renal dose considerations) Lower glycaemic efficacy at low eGFR ↑ Risk for amputation (canagliflozin) ↑ Risk for fracture (canagliflozin) Euglycaemic ketoacidosis (rare) High cost

(continued)

Table 37.1 (Continued)

Class	Medications	Primary physiological action(s)	Main advantages	Main disadvantages
Insulins	<ul style="list-style-type: none"> Basal <ul style="list-style-type: none"> • Human NPH • Detemir • Degludec (U-100 and U-200) • Glargin (U-100, U-300, and biosimilars) Prandial <ul style="list-style-type: none"> • Human regular • Aspart (including faster acting) • Glulisine • Lispro (U-100, U-200, and ultra-rapid) Premixed 	<ul style="list-style-type: none"> ↑ Glucose disposal ↓ Hepatic glucose production 	<ul style="list-style-type: none"> Nearly universal response Theoretically unlimited efficacy ↓ Microvascular complications 	<ul style="list-style-type: none"> Hypoglycaemia ↑ Weight Injectable, require training Frequent self-monitoring and dose adjustment High cost (insulin analogues) Treatment burden may lead to reluctance to take insulin

CKD, chronic kidney disease; CV, cardiovascular; DPP-4, dipeptidyl-peptidase 4; eGFR, estimated glomerular filtration rate; GIP, glucose-dependent insulinotropic polypeptide; GLP-1, glucagon-like peptide 1; LAR, long-acting release; NPH, neutral protamine Hagedorn; SGLT-2, sodium–glucose cotransporter 2.

Metformin

Metformin is an oral biguanide that first received marketing approval in Europe in 1957 and the USA in 1994; it has the advantage of targeting insulin resistance, which is considered an early feature of type 2 diabetes. It acts mainly by suppressing gluconeogenesis in the liver, thereby reducing hepatic glucose production. Moreover, it leads to increased peripheral glucose uptake mainly in skeletal muscles, possibly by enhancing the binding of insulin to its receptors. It appears to be ineffective in tissues that are insensitive to insulin such as the brain [5]. Several other physiological effects have also been described, such as decreased fatty acid oxidation and increased intestinal glucose use, potentially mediated by release of intestinal GLP-1. About 90% of the drug is eliminated in the urine.

The maximal daily dose of metformin is 3000 mg in Europe or 2550 mg in the USA and the drug is usually administered in 2–3 divided doses that are taken with meals. To improve gastric tolerance the drug should be introduced at a dose of 500 or 850 mg twice daily, which should be adjusted slowly in biweekly intervals. Given the rising rates of obesity and the associated prevalent cases of type 2 diabetes among younger individuals, use of metformin is now allowed in children from 10 years of age, but the maximum recommended dose for the paediatric population is 2000 mg. Extended-release formulations for once-daily dosing and fixed-dose combinations with other oral anti-diabetes agents are available.

Metformin is contraindicated in severe renal impairment with an estimated glomerular filtration rate (eGFR) <30 ml/min/1.73 m². In Europe, the daily dose of metformin should not exceed 2000 mg for those with stage 3A chronic kidney disease (eGFR 45–59 ml/min/1.73 m²), whereas for individuals with stage 3B chronic kidney disease (eGFR 30–44 ml/min/1.73 m²) the maximal daily metformin dose is 1000 mg. In the USA, initiation of metformin is not recommended with an eGFR between 30 and 45 ml/min/1.73 m². Annual monitoring of serum creatinine is required and people with moderate renal impairment should be educated to withhold metformin during acute illness or if the administration of iodinated contrast media is planned.

Experience with metformin is extensive and no major safety concerns have arisen to date. Metformin does not increase the risk of hypoglycaemia and can have a small effect to reduce body weight [6]. Because of its favourable efficacy, safety profile, and low cost, it is generally considered as first-line therapy for most people with type 2 diabetes unless contraindicated or not tolerated. Intensive treatment with metformin was also associated with a lower incidence of all-cause mortality compared to diet in people with overweight and newly diagnosed type 2 diabetes in a substudy of the UK Prospective Diabetes Study (UKPDS) [7,8]. However, in another substudy that was also performed within the UKPDS, addition of metformin to sulfonylurea resulted in increased mortality compared with sulfonylurea alone [7]. No firm explanation could be given for this controversial finding, and based on later follow-up data it was attributed to chance [9]. A meta-analysis incorporating data from both UKPDS substudies and additional smaller randomized controlled trials found a neutral effect of metformin on all-cause mortality [10]. Consistently, metformin had no effect on major cardiovascular events over a 21-year median follow-up of participants in the Diabetes Prevention Program (DPP) and Diabetes Prevention Program Outcomes Study (DPPOS) [11].

Metformin is commonly associated with gastrointestinal side effects including metallic taste, bloating, abdominal discomfort, and soft bowel movements or diarrhoea. These symptoms may improve over time and can be mitigated by gradual dose titration. The most concerning safety issue is metformin-associated lactic acidosis. This extremely uncommon but potentially life-threatening condition usually develops in the setting of critical illness that predisposes to hypoperfusion or hypoxaemia, including renal insufficiency, liver disease, and shock, or as a result of drug overdose. Finally, metformin reduces vitamin B₁₂ absorption in the small intestine, which might present as peripheral neuropathy, although the drug rarely causes megaloblastic anaemia. Clinicians might offer periodic monitoring of serum vitamin B₁₂ concentrations, especially for high-risk people such as those on a vegan diet or after bariatric surgery [12].

Sulfonylureas

Sulfonylureas are the oldest class of oral anti-diabetes compounds. They bind to sulfonylurea receptors in pancreatic β cells and stimulate insulin release by inhibiting adenosine triphosphate (ATP)-sensitive potassium channels, leading to depolarization of the cell membrane, which in turn results in calcium influx and consequent exocytosis of insulin. Because they constantly stimulate insulin secretion, sulfonylureas are very effective in terms of glycated haemoglobin (HbA_{1c}) lowering, especially at early stages of the disease in people with residual β -cell function. Nevertheless, sulfonylureas are associated with a lack of a durable effect on glucose lowering, which is related to the declining insulin-producing capacity of β cells, a phenomenon known as *pancreatic exhaustion*. First-generation agents are no longer used in clinical practice and have been replaced by second-generation sulfonylureas including glipizide (also available as a modified-release formulation), glipizide, glibenclamide (also known as glyburide), and glimepiride (also classified as a third-generation sulfonylurea), which have a prolonged duration of action and more convenient dosing scheme [13].

Hypoglycaemia is a major limitation of this class, because sulfonylureas increase insulin release irrespective of blood glucose concentrations. Hypoglycaemia might be prolonged and require hospitalization. It is more likely to occur after exercise or in the fasting state. Because sulfonylurea metabolites are renally excreted, the risk of hypoglycaemia is higher in people with chronic kidney disease. Hence, the drugs should be initiated at the lower end of the approved dose range and carefully titrated, especially in older individuals or those with chronic kidney disease.

Sulfonylureas should also be given with caution or avoided in people in whom severe hypoglycaemia can be fatal, such as those with coronary artery disease. Concomitant use of sulfonylureas with intensified insulin regimens should generally be avoided. People should be educated regarding the recognition and management of hypoglycaemia. Weight gain is another undesirable effect of sulfonylureas and is attributed to the anabolic effects of insulin. On the other hand, the drugs are relatively inexpensive and remain a reasonable choice when cost is the primary consideration in treatment decisions [3].

Evaluation of cardiovascular safety for newly approved anti-diabetes agents has become a regulatory requirement since 2008 [14], but large-scale cardiovascular outcomes trials have not been mandated for older agents, including metformin and sulfonylureas. Observational studies and randomized controlled trials comparing second-generation sulfonylureas against various anti-diabetes agents suggest the possibility of an increased risk for cardiovascular events relative to metformin, which might be secondary to potential cardioprotection with metformin [15]. However, dedicated cardiovascular outcomes trials comparing mostly glimepiride either with pioglitazone or the DPP-4 inhibitor linagliptin did not identify a detrimental effect [16, 17].

Meglitinides

Meglitinides (or glinides) including nateglinide and repaglinide are secretagogues that have a similar mechanism of action to sulfonylureas, although they act via different pancreatic β -cell receptors. They have a rapid onset but short duration of action, thereby controlling post-prandial glucose excursions. These agents need frequent dosing and might be considered in people with erratic meal schedules. Meglitinides have a similar risk for weight gain as sulfonylureas, but possibly a lower risk for hypoglycaemia. Repaglinide is principally metabolized by the liver and can be used

safely in people with mild to moderate renal impairment, although meglitinides should be titrated slowly based on blood glucose levels to minimize the risk of hypoglycaemia [18].

Pioglitazone

Pioglitazone belongs to the thiazolidinediones class, also known as glitazones, which act by activating peroxisome proliferator-activated receptors (PPAR), especially PPAR- γ [19]. These nuclear receptors are expressed predominantly in adipocytes and skeletal muscles and regulate the transcription of specific genes involved in glucose and lipid metabolism. As a result of PPAR- γ activation, cells become more dependent on the oxidation of glucose to yield energy for cellular processes. Pioglitazone has a delayed onset of action, but provides durable reduction in HbA_{1c} and could offer an advantage in certain clinical settings, such as individuals with severe insulin resistance or non-alcoholic steatohepatitis (NASH) [20]. It does not cause hypoglycaemia, but is associated with weight gain as well as fluid retention due to increased sodium reabsorption in the collecting tubules, especially if used concomitantly with insulin [20]. Consequently, the drug may precipitate or worsen heart failure. In addition, pioglitazone use has been linked to an increased risk of bladder cancer and fractures [21, 22]. Finally, pioglitazone may decrease the incidence of cardiovascular events [23–25].

α -Glucosidase inhibitors

α -Glucosidase inhibitors (acarbose, miglitol, voglibose) inhibit the absorption of carbohydrates from the small intestine. They modestly decrease HbA_{1c} [26], but can be useful for reducing post-prandial hyperglycaemia [27]. Since α -glucosidase inhibitors prevent the degradation of complex carbohydrates into glucose, some carbohydrates will remain in the intestine and be delivered to the colon, causing gastrointestinal side effects such as flatulence and diarrhoea. As such, α -glucosidase inhibitors are contraindicated in individuals who have chronic intestinal diseases and in those who have conditions that may deteriorate as a result of increased gas formation in the intestine [27]. Moreover, hypoglycaemia in people treated with these agents can only be effectively improved with the ingestion of glucose. Acarbose is the most commonly used drug of this class, and also the most widely studied. In particular, in the Study to Prevent Non-Insulin Dependent Diabetes Mellitus (STOP-NIDDM) trial, acarbose significantly increased reversion of impaired glucose tolerance (IGT) to normal glucose tolerance and was associated with a 49% relative risk reduction in the development of cardiovascular events [28, 29]. The Acarbose Cardiovascular Evaluation (ACE) trial, however, which randomized 6522 people with coronary heart disease and IGT to acarbose or placebo and had a follow-up of a median of five years, showed no reduction in the risk of major cardiovascular events with acarbose, although progression to diabetes was reduced [30].

Dipeptidyl-peptidase 4 inhibitors

DPP-4 inhibitors, also referred to as gliptins, are a class of oral anti-diabetes agents that target the enzyme DPP-4, which deactivates endogenous incretins including GIP and GLP-1. Incretins are gut-derived hormones that stimulate glucose-dependent insulin release from the pancreatic islets while suppressing glucagon secretion, and are responsible for the incretin effect, defined as an enhanced insulin secretion following oral glucose administration compared with an isoglycaemic intravenous challenge [31]. In people with type 2 diabetes the incretin effect is substantially reduced or even lost.

DPP-4 inhibitors have a modest effect on lowering blood glucose and a neutral effect on body weight, but carry a minimal risk for hypoglycaemia in the absence of therapies that may otherwise cause hypoglycaemia [6, 32]. They can be used as add-on therapy to metformin or as monotherapy in people with type 2 diabetes for whom metformin is not well tolerated or is contraindicated. Licensed DPP-4 inhibitors across Europe and the USA include alogliptin, linagliptin, saxagliptin, and sitagliptin. Vildagliptin is licensed in Europe but has not received marketing authorization by the US Food and Drug Administration (FDA). The dose of DPP-4 inhibitors should be adjusted based on renal function, with the exception of linagliptin, which is primarily eliminated via the enterohepatic system and can therefore be used in people with end-stage kidney disease.

DPP-4 inhibitors were historically the first anti-diabetes agents evaluated in the context of dedicated cardiovascular outcomes imposed by drug regulators [14]. These trials recruited people at high cardiovascular risk and showed that DPP-4 inhibitors do not increase the risk for major cardiovascular events, including non-fatal myocardial infarction, stroke, and cardiovascular death [33–37]. Nevertheless, an increased risk of hospitalization from worsening heart failure was observed following treatment with saxagliptin.

DPP-4 inhibitors are generally well tolerated. An increased risk of pancreatic adverse events including acute pancreatitis and pancreatic cancer was initially postulated among people treated with incretin mimetics, based primarily on data from post-marketing surveillance systems and animal studies, which suggested higher rates of pancreatic intraepithelial neoplasia with incretin therapies. However, these safety signals have been subsequently alleviated [38]. A potential association of DPP-4 inhibitors with respiratory and urinary tract infections has also been reported. The association of DPP-4 inhibitors with infections has been largely refuted, although it remains questionable whether cases of nasopharyngitis are more common with sitagliptin [39]. Other adverse effects with DPP-4 inhibitors include elevated liver enzymes, skin lesions, inflammatory bowel disease, and joint pain [40]. The favourable safety profile of DPP-4 inhibitors taken together with their modest effect on glycaemia suggests that these agents might be an attractive treatment option for frail individuals in whom intensive glycaemic management and ensuing harms should be avoided.

Glucagon-like peptide 1 receptor agonists

GLP-1 is an incretin produced by the enteroendocrine L cells that enhances peripheral insulin action, slows gastric emptying, and inhibits glucagon secretion. Endogenous GLP-1 has a short half-life and is rapidly deactivated by DPP-4. As such, pharmaceutical efforts have led to the development of synthetic, degradation-resistant GLP-1RAs with favourable pharmacokinetic properties. The first licensed GLP-1RA was exenatide, a synthetic exendin-4 that was discovered in lizard saliva [31]. Licensed GLP-1RAs also include liraglutide and lixisenatide, which are administered once daily by subcutaneous injection, as well as dulaglutide, exenatide extended release, and semaglutide, which are administered once weekly. An oral formulation of semaglutide administered once daily has also received marketing authorization.

GLP-1RAs are effective in improving glycaemic levels, although intraclass variations are noted. Subcutaneous semaglutide is probably the most potent agent in terms of HbA_{1c} lowering, whereas shorter-acting agents such as lixisenatide exhibit less pronounced glycaemic benefits [26]. Because the effects of GLP-1RAs on insulin

secretion are glucose dependent, while the counter-regulatory release of glucagon in response to low blood glucose is fully preserved, the risk of hypoglycaemia is minimal. However, dose adjustments of other anti-diabetes medications known to cause hypoglycaemia, such as insulin, sulfonylureas, or meglitinides, might be necessary on initiation of GLP-1RAs. Weight loss is a further advantage of therapy with GLP-1RAs. Besides slowing gastric emptying, thereby inducing nausea and vomiting as side effects, it has been proposed that GLP-1RAs promote satiety by directly acting on appetite centres in the hypothalamus. Of note is that liraglutide 3.0 mg daily and semaglutide 2.4 mg once weekly have received marketing authorization for weight management as an adjunct to a reduced-calorie diet and increased physical activity for adults with obesity (body mass index [BMI] $\geq 30 \text{ kg/m}^2$) or overweight (BMI $\geq 27 \text{ kg/m}^2$) with at least one comorbidity irrespective of the presence of type 2 diabetes.

Cardiovascular outcomes trials have shown that dulaglutide, liraglutide, and subcutaneous semaglutide reduce the composite cardiovascular endpoint of non-fatal myocardial infarction, stroke, and cardiovascular death [41–43]. Oral semaglutide reduced cardiovascular death [44], whereas exenatide extended release and lixisenatide had a neutral effect on cardiovascular endpoints [45, 46]. Moreover, dulaglutide and subcutaneous semaglutide decreased incidence of stroke, while extended-release exenatide, liraglutide, and oral semaglutide reduced all-cause mortality [26]. The cardiovascular benefits of GLP-1RAs cannot be attributed to improved glycaemic levels alone and might be related to effects on other important risk factors such as body weight, blood pressure, and cholesterol profile [6]. Emerging evidence suggests that these drugs might independently attenuate the progression of atherosclerosis. Based on the aforementioned findings, GLP-1RAs are now recommended in people with type 2 diabetes and established cardiovascular disease or multiple cardiovascular risk factors [1]. This recommendation is not contingent on HbA_{1c}, in recognition of the glucose-independent cardiovascular benefits of these agents [1, 2]. These recommendations are also reflected in the revised labelling of dulaglutide, liraglutide, and subcutaneous semaglutide, for which the indication has been expanded beyond glycaemic management to include the reduction of major cardiovascular events.

GLP-1RAs are generally effective and safe in people with declining kidney function. Dulaglutide, liraglutide, and semaglutide can be used without dose adjustments, even in severe renal impairment for which treatment options beyond insulin therapy are limited. Based on data from cardiovascular outcomes trials, GLP-1RAs ameliorate the progression of albuminuria, although no long-term benefit was observed with respect to decline in eGFR [47].

The main side effects of therapy with GLP-1RAs are nausea and to some extent vomiting and diarrhoea, which are related to slowing of gastric emptying. These symptoms are dose dependent and usually wane during the course of treatment. Slow dose escalation to minimize these side effects is suggested. GLP-1RAs should be avoided in people with gastroparesis. Local site reactions appear more common with GLP-1RAs compared with insulin injections. Similar to DPP-4 inhibitors, early concerns about an increased risk of acute pancreatitis or pancreatic cancer have largely abated [38]. Animal studies have also suggested a potential association of certain GLP-1RAs with thyroid C-cell neoplasms and as a precaution these agents should be avoided in people with a history of medullary cancer or multiple endocrine neoplasia 2. GLP-1RAs could possibly increase risk for gallbladder adverse events including acute cholecystitis [42], although it remains unclear whether these side effects are caused by

rapid weight loss or other underlying mechanisms. Finally, an increased incidence of diabetic retinopathy complications was observed with subcutaneous semaglutide, but it is unclear whether this effect was mediated by a rapid decline of HbA_{1c} [43]. Therefore, frequent retinal screening to detect progression of retinopathy might be prudent for individuals treated with semaglutide.

Sodium–glucose cotransporter 2 inhibitors

SGLT-2 is expressed in the proximal convoluted tubule and is responsible for the reabsorption of ~90% of the filtered glucose load. SGLT-2 inhibitors, also called gliflozins, are a recent addition to the therapeutic armamentarium for type 2 diabetes. They lead to increased urinary glucose excretion, thereby lowering plasma glucose levels. Because of this insulin-independent mode of action, SGLT-2 inhibitors do not increase the risk of hypoglycaemia. Nevertheless, the glycaemic efficacy of SGLT-2 inhibitors is relatively modest and limited by any decline in renal function. Other benefits include weight loss and modest blood pressure reduction as a result of osmotic diuresis [48]. Currently, four SGLT-2 inhibitors have been approved by regulatory authorities in Europe and the USA, namely canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin.

The SGLT-2 inhibitor cardiovascular outcomes trials have changed the landscape in the management of type 2 diabetes [49–52]. Empagliflozin and canagliflozin reduced major cardiovascular events, whereas empagliflozin also showed a benefit for all-cause mortality. The cardiovascular benefits of SGLT-2 inhibitors generally occur early in the course of treatment and are probably multidimensional in nature. The underlying mechanisms could involve glycaemic levels, weight loss, blood pressure reduction, lowering of uric acid levels, or changes in arterial stiffness. All SGLT-2 inhibitors consistently lowered hospitalizations for heart failure, an observation that can partly be explained by natriuresis. Risk reduction of worsening heart failure is a class effect that has been corroborated in people who received empagliflozin or dapagliflozin even in the absence of type 2 diabetes [53–55]. As such, dapagliflozin and empagliflozin are now indicated for chronic heart failure.

SGLT-2 inhibitors also reduce the risk of end-stage kidney disease [56–58]. The FDA has updated the indications for most SGLT-2 inhibitors to reflect cardiorenal protection. The drugs stabilize kidney function and alleviate the progression of albuminuria, possibly through activation of tubuloglomerular feedback, which leads to a reduction of intraglomerular pressure and prevents hyperfiltration. Initiation of SGLT-2 inhibitors is associated with a temporary decrease in eGFR, which stabilizes over time, a pattern that is also observed with renin–angiotensin system blockade. Assessment of renal function is recommended before initiation of SGLT-2 inhibitors and periodically thereafter (at least yearly). Dose adjustments are necessary for canagliflozin and empagliflozin in people with moderate renal impairment (eGFR <60 ml/min/1.73 m²).

The most common adverse effects of therapy with SGLT-2 inhibitors are genital mycotic infections, which are related to glucosuria and include mainly cases of balanoposthitis in men and vulvovaginal candidiasis in women. They are generally of mild to moderate intensity, respond well to standard therapy, and do not tend to reoccur. Urinary tract infections are less common and reports of pyelonephritis, urosepsis, or Fournier's gangrene are extremely rare. A numerical imbalance of bladder cancer cases was also noted in the clinical development programme of dapagliflozin, but early detection after short exposure and potential detection bias due to frequent urinalysis point against causality. Volume depletion-related adverse events including dizziness, orthostatic hypotension,

and syncope may also be precipitated by SGLT-2 inhibitors in older individuals, people with renal impairment, and in cases of concomitant therapy with thiazides or loop diuretics. The risk of acute kidney injury does not appear to be increased. Thrombosis due to haemoconcentration is another theoretical concern. The incidence of fractures was higher among those taking canagliflozin, but was likely related to falls resulting from volume depletion. For canagliflozin an increased risk of amputations was also reported and, as such, consideration may be given to stopping treatment in people who develop events that may precede amputation, such as lower-extremity skin ulcer, infection, osteomyelitis, or gangrene [26, 48]. Finally, people treated with SGLT-2 inhibitors might be prone to the development of diabetic euglycaemic ketoacidosis in the setting of intercurrent illness [59]. In these individuals the absence of marked hyperglycaemia might delay the recognition and treatment of this rare complication. People should be advised to withhold treatment with SGLT-2 inhibitors during acute illness or in the perioperative period, and the drugs should be avoided in people predisposed to diabetic ketoacidosis (e.g. pancreatic insufficiency or alcohol abuse).

Dual glucose-dependent insulinotropic polypeptide/glucagon-like peptide 1 receptor agonists

Combined GLP-1 and GIP receptor activation has also been examined as a promising therapeutic option, based on the rationale that the two incretins can have synergistic and complementary actions [60]. Tirzepatide is the first dual GIP and GLP-1 receptor agonist that has received marketing approval by the FDA for the treatment of type 2 diabetes. It has greater affinity to the GIP, rather than GLP-1, receptor and is administered subcutaneously once weekly. Meta-analysis has shown that tirzepatide is more efficacious in lowering HbA_{1c} than once-weekly GLP-1RAs (semaglutide and dulaglutide) and basal insulin analogues [61]. Treatment with tirzepatide also induced greater body weight reduction compared with GLP-1RAs, but was associated with an increased incidence of gastrointestinal adverse events, mostly nausea [61]. Limited cardiovascular data, derived mostly from one trial, suggest that tirzepatide does not increase the risk of major cardiovascular events [62].

Insulin

Due to the progressive nature of the disease, many people with type 2 diabetes will eventually require insulin therapy. Insulin might also be the sole therapeutic option for certain populations such as people with advanced kidney disease or cirrhosis. Insulin has theoretically unlimited efficacy with respect to HbA_{1c} lowering that is constrained only by the development of hypoglycaemia. However, insulin therapy is associated with weight gain and requires considerable self-management skills and adequate support, because of the need for more frequent blood glucose monitoring and dose adjustment. People should also receive training in the recognition and management of hypoglycaemic episodes.

Human insulin has largely been replaced by insulin analogues, which are produced by modifications to the amino acid sequence of insulin that alter its pharmacokinetic properties (Chapter 31). The following formulations of insulin are available in the USA or Europe:

- Human insulins:
 - Short-acting regular insulin.
 - Concentrated regular insulin U-500.
 - Intermediate acting neutral protamine Hagedorn (NPH), also called isophane insulin.
 - Premixed combinations of these.

- Basal insulin analogues:
 - Insulin glargine U-100 and biosimilars.
 - Insulin detemir.
 - Ultra-long-acting insulin degludec.
 - Concentrated forms of insulin glargine U-300 and insulin degludec U-200.
- Prandial insulin analogues:
 - Short- and rapid-acting insulins aspart, glulisine, and lispro.
 - Faster-acting insulin aspart.
 - Ultra-rapid lispro.
- Premixed basal/prandial regimens.

Basal insulin is meant to cover the basic metabolic requirements, whereas prandial insulin regulates mealtime glucose excursions. People with type 2 diabetes progressing to insulin therapy usually start with once-daily bedtime administration of basal insulin, although NPH and insulin detemir may also be dosed twice daily. The starting dose of basal insulin is 10 units or 0.1–0.2 units/kg and titration is based on fasting glucose levels. The differences in glycaemic efficacy among basal insulin analogues are likely minimal and of limited clinical significance. Newer agents including insulin degludec and glargin U300 have longer duration of action and lower rates of nocturnal hypoglycaemia, whereas insulin detemir might have a more favourable profile with respect to weight gain [63]. Concentrated preparations such as degludec U-200 and glargin U-300 allow injection of a reduced volume and might be more convenient for people with higher requirements because of insulin resistance. Basal insulin analogues are considerably more costly than NPH, although cheaper biosimilars have become available. Finally, data from cardiovascular safety trials are reassuring for insulin glargin and degludec [64,65].

Once basal insulin dose has exceeded 0.5 units/kg or if the fasting glucose target is met but the desired HbA_{1c} target has not been achieved, insulin therapy should be intensified by adding doses of prandial to basal insulin. A starting dose of 4 units or 0.1 units/kg of prandial insulin (or 10% of the amount of basal insulin) is initially administered at the largest meal of the day. Dose can be gradually increased by 1–2 units or 10–15% to meet post-prandial glucose targets. If the HbA_{1c} is still above target, this basal-plus scheme can then be advanced to a basal-bolus regimen with the stepwise addition of mealtime insulin injections. During this process decreasing doses of basal insulin might be required to avoid hypoglycaemia. Regular human insulin should be administered ~30 minutes before start of the meal to match post-prandial glucose excursions. The rapid-acting insulin analogues aspart, glulisine, and lispro have an onset of action within 15 minutes of injection and quicker return to baseline concentrations. Finally, the newly approved faster-acting insulin aspart and ultra-rapid lispro have accelerated absorption and even earlier onset of action, but also earlier offset of exposure. In this regard, they resemble more closely physiological mealtime insulin secretion and could therefore offer better post-prandial glucose regulation while minimizing the risk of post-prandial hypoglycaemia [66].

Alternatively, for individuals using basal insulin for whom prandial coverage is required, the regimen can be converted to two doses of premixed basal/prandial insulin by splitting the total insulin dose. Premixed regimens might be more practical for people with frailty for whom tight glycaemic levels are not desirable, whereas basal-bolus regimens allow greater flexibility for people with irregular eating habits [3].

Clinicians and people with diabetes sometimes are reluctant to start insulin, which may delay timely intensification of therapy

(therapeutic inertia). People with diabetes might find it difficult to accept insulin therapy because of fear of injections, life restrictions, or risk of hypoglycaemia. Moreover, starting insulin therapy could be felt as a personal failure in the management of the disease. Healthcare providers should address these misconceptions during the clinical encounter and avoid using insulin therapy as a threat to motivate people [67]. Notably, modern, prefilled pen devices have appreciably simplified insulin administration.

Rationale for treatment selection

Glycaemic management

Management of hyperglycaemia has traditionally guided the initiation and escalation of glucose-lowering therapy in people with type 2 diabetes. Indeed, landmark trials have corroborated the beneficial effects of tight glycaemic levels, mainly for the reduction of microvascular complications. In contrast, the impact of intensive glucose lowering on incident macrovascular events is less certain [8,68,69]. Measurement of HbA_{1c} remains the primary tool for assessment of glycaemia. The test reflects average glucose levels over ~3 months and is strongly predictive of diabetes-related complications. Observational studies suggest that each 1% (11 mmol/mol) reduction in HbA_{1c} is associated with risk reductions of 37% for microvascular complications, 14% for myocardial infarction, and 21% for diabetes-related mortality [70]. Nevertheless, as HbA_{1c} decreases, a U-shaped relationship with all-cause mortality and cardiac events is observed [71], especially in older individuals and people with frailty or established cardiovascular disease, for whom hypoglycaemia is a limiting factor for intensifying treatment. The HbA_{1c} target for most people with type 2 diabetes is <7% (53 mmol/mol), but it may be lower for well-motivated individuals, while higher HbA_{1c} goals such as <8% (64 mmol/mol) might be more appropriate for people with limited life expectancy [72]. If prevention of hypoglycaemia is a therapeutic priority, the use of sulfonylureas or insulin is discouraged. The vast majority of studies for medications for type 2 diabetes have utilized HbA_{1c} as the primary outcome measure for glycaemic efficacy. Anti-diabetes drugs have variable glucose-lowering effects, with insulin regimens and specific GLP-1RAs producing the greatest HbA_{1c} reduction [26]. The newly approved dual GIP/GLP-1 receptor agonist tirzepatide offers an even more pronounced HbA_{1c} reduction, as high as 2% (22 mmol/mol) [61].

The standard approach to glycaemic management has been to initiate metformin monotherapy followed by the stepwise addition of anti-diabetes agents until the individualized HbA_{1c} target is reached. The Vildagliptin Efficacy in combination with metformin For early treatment of type 2 diabetes (VERIFY) trial showed that upfront combination therapy with metformin plus a DPP-4 inhibitor improves the durability of the glycaemic effect compared with sequential addition of anti-diabetes drugs [73]. Combination therapy can target multiple physiological derangements simultaneously and could also decrease medication burden and improve medication taking. GLP-1RAs are considered first-line injectable therapy in type 2 diabetes and should be prioritized over basal insulin, because they have comparable glycaemic efficacy, induce weight loss, and confer a low risk of hypoglycaemia [74]. For people with catabolic symptoms including weight loss, hypertriglyceridaemia, and ketosis or severe hyperglycaemia (i.e. HbA_{1c}>10% [86 mmol/mol] or blood glucose levels ≥300 mg/dl [16.7 mmol/l]), introduction of insulin should be considered. After resolution of glucose

toxicity, the therapeutic regimen may be simplified [1]. Fixed ratio combinations of GLP-1RAs with basal insulin allowing co-administration through a single injection are also commercially available. These co-formulations provide further improvements in glycaemia while balancing out weight gain and risk of hypoglycaemia [75].

The HbA_{1c} test has limitations, as it does not capture hypoglycaemic episodes or glucose variability and results might be unreliable under circumstances that alter red blood cell turnover (anaemia, haemoglobinopathies, or end-stage renal disease with erythropoietin therapy). In these situations, capillary glucose measurements may supplement treatment decisions. Beyond people receiving insulin therapy for whom frequent measurements are required for dose titration, self-monitoring of blood glucose has limited clinical value in terms of glycaemic management and is associated with higher treatment cost without evidently improving quality of life [76]. In recent years, continuous glucose monitoring (CGM) has been fully incorporated into the management of type 1 diabetes, although evidence supporting its use in type 2 diabetes remains limited. Time in range (TIR) and the glucose management indicator (GMI) derived from CGM are useful metrics of glucose levels that correlate well with HbA_{1c}. The ambulatory glucose profile (AGP), which includes time below and above target range, can be used to develop a more personalized treatment plan, especially for people receiving insulin therapy [77]. Remote access to CGM data will also potentially transform healthcare encounters. In the near future, it is expected that more trials in type 2 diabetes will evaluate the effect of anti-diabetes agents on TIR instead of HbA_{1c} as the primary glycaemic endpoint.

Management for prevention of complications

Evidence from cardiovascular outcomes trials

In the past, regulatory bodies approved new medications for diabetes solely on the basis of their glucose-lowering potential, even though it was recognized that regulation of hyperglycaemia is a surrogate for reducing the microvascular, and to a lesser extent the macrovascular, complications of diabetes. Evidence on the potential benefit of glucose-lowering drugs on specific cardiovascular outcomes first became available for metformin in a substudy of the UKPDS; UKPDS 34 was a randomized controlled trial that assessed whether intensive treatment with metformin reduced the risk of diabetes-related complications compared to conventional treatment policy (diet alone) in 753 individuals with overweight and newly diagnosed type 2 diabetes [7]. After a median follow-up of 10.7 years, participants allocated to metformin had risk reductions of 32% for any diabetes-related endpoint (a composite of mortality and vascular outcomes) and 36% for all-cause mortality [7].

Following a similar rationale to that of the UKPDS, and also based on trial data suggesting a beneficial effect of thiazolidinediones on multiple cardiovascular risk factors, the PROspective pioglitAzone Clinical Trial In macroVascular Events (PROactive) and the Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycaemia in Diabetes (RECORD) studies evaluated the cardiovascular effects of pioglitazone and rosiglitazone, respectively [23, 78]. The PROactive study (5238 participants) found that, over an average period of 34.5 months, pioglitazone reduced the composite of all-cause mortality, or myocardial infarction, or stroke versus placebo (hazard ratio [HR] 0.84; 95% confidence interval [CI] 0.72 to 0.98). However, the effect of pioglitazone on the primary outcome (composite of all-cause mortality, non-fatal myocardial

infarction including silent myocardial infarction, stroke, acute coronary syndrome, endovascular or surgical intervention in the coronary or leg arteries, and amputation above the ankle) was not significant [23]. The RECORD trial (4447 participants) found that rosiglitazone in combination with metformin or sulfonylurea was non-inferior to metformin and sulfonylurea dual therapy in terms of the composite outcome of cardiovascular death, myocardial infarction, or stroke (three-component major adverse cardiovascular events, MACE) [78]. Notably, in both trials thiazolidinediones considerably increased the risk of heart failure compared to control.

In 2008 the FDA, and later the European Medicines Agency, required that a dedicated cardiovascular outcomes trial be conducted as a prerequisite for the regulatory approval of new anti-diabetes drugs [14]. This change in policy was probably influenced by an earlier FDA decision to reject the approval of muraglitazar following the publication of a relevant meta-analysis of cardiovascular outcomes [79], but was mainly triggered by the findings of a meta-analysis for rosiglitazone [4]. This meta-analysis suggested that rosiglitazone, which was widely used in the USA and Europe at that time, increased the risk of myocardial infarction compared to placebo and other anti-diabetes regimens [4]. Subsequently, several cardiovascular outcomes trials have been completed, mainly for DPP-4 inhibitors, GLP-1RAs, and SGLT-2 inhibitors.

To achieve feasible and adequate power, cardiovascular outcomes trials typically have assessed the composite endpoint of MACE as primary outcome and have recruited people with type 2 diabetes and increased cardiovascular risk, defined as history of atherosclerotic disease or presence of multiple cardiovascular risk factors. The main findings of cardiovascular outcomes trials in type 2 diabetes for anti-diabetes drugs approved in the USA or Europe are presented in Table 37.2. In summary, trials of DPP-4 inhibitors have demonstrated a neutral effect on cardiovascular outcomes. Similarly, in the Outcome Reduction with Initial Glargine Intervention (ORIGIN) trial, insulin glargine had a neutral effect on cardiovascular outcomes [64], while in the Trial comparing cardiovascular safety of insulin degludec versus insulin glargine in subjects with type 2 diabetes at high risk of cardiovascular events (DEVOTE), insulin degludec was non-inferior to insulin glargine with respect to major cardiovascular events [65]. Notable favourable effects on MACE and mortality outcomes were evident in cardiovascular outcomes trials of specific GLP-1RAs and SGLT-2 inhibitors. Moreover, both drug classes have demonstrated benefits in kidney outcomes, while SGLT-2 inhibitors also improved heart failure endpoints. Consequently, the effect of specific SGLT-2 inhibitors on these outcomes has also been assessed in dedicated trials focusing on people with chronic kidney disease or heart failure irrespective of history of diabetes. As such, current guidance in the pharmacological management of type 2 diabetes advocates that choice of therapeutic options should be primarily based on atherosclerotic cardiovascular risk profile and presence of chronic kidney disease, heart failure, or obesity-related morbidities [1, 80].

Among cardiovascular outcomes trials with GLP-1RAs, the Evaluation of Lixisenatide in Acute Coronary Syndrome (ELIXA) trial was the first to be reported. Over a median follow-up of 24 months, ELIXA compared once-daily lixisenatide (at a maximum daily dose of 20 µg) with placebo in 6068 people with type 2 diabetes and a recent (within 180 days) acute coronary event [46]. Lixisenatide was non-inferior, but not superior, to placebo for the primary composite endpoint of cardiovascular death, myocardial infarction, stroke, or hospitalization for unstable angina (four-component MACE), with an HR of 1.02 (95% CI 0.89 to 1.17) [46].

Table 37.2 Findings from major cardiovascular outcome trials for pharmaceutical agents approved for the treatment of type 2 diabetes in Europe or the USA.

Anti-diabetes agent	Trial ^a	Major adverse cardiovascular events ^b	Hospitalization for heart failure	All-cause mortality
Pioglitazone	PROACTIVE [23]	0.82 (0.70 to 0.97)	1.41 (1.10 to 1.80)	0.96 (0.78 to 1.18)
	TOSCA.IT [16]	0.96 (0.74 to 1.26)	1.57 (0.76 to 3.24)	1.08 (0.71 to 1.65)
DPP-4 inhibitors				
Alogliptin	EXAMINE [33, 34]	0.96 (≤ 1.16) ^c	1.07 (0.79 to 1.46)	0.88 (0.71 to 1.09)
Linagliptin	CARMELINA [35]	1.02 (0.89 to 1.17)	0.90 (0.74 to 1.08)	0.98 (0.84 to 1.13)
	CAROLINA [17]	0.98 (0.84 to 1.14)	1.00 (0.84 to 1.20)	0.91 (0.78 to 1.06)
Saxagliptin	SAVOR-TIMI 53 [36]	1.00 (0.89 to 1.12)	1.27 (1.07 to 1.51)	1.11 (0.96 to 1.27)
Sitagliptin	TECOS [37]	0.99 (0.89 to 1.10)	1.00 (0.83 to 1.20)	1.01 (0.90 to 1.14)
GLP-1 receptor agonists				
Dulaglutide	REWIND [41]	0.88 (0.79 to 0.99)	0.93 (0.77 to 1.12)	0.90 (0.90 to 1.01)
Exenatide LAR	EXSCEL [45]	0.91 (0.89 to 1.00)	0.94 (0.78 to 1.13)	0.86 (0.77 to 0.97)
Lixisenatide	ELIXA [46]	1.02 (0.89 to 1.17)	0.96 (0.75 to 1.23)	0.94 (0.78 to 1.13)
Liraglutide	LEADER [42]	0.87 (0.78 to 0.97)	0.87 (0.73 to 1.05)	0.85 (0.74 to 0.97)
Subcutaneous semaglutide	SUSTAIN-6 [43]	0.74 (0.58 to 0.95)	1.11 (0.77 to 1.61)	1.05 (0.74 to 1.50)
Oral semaglutide	PIONEER 6 [44]	0.79 (0.57 to 1.11)	0.86 (0.48 to 1.55)	0.51 (0.31 to 0.84)
SGLT-2 inhibitors				
Canagliflozin	CANVAS PROGRAM [49]	0.86 (0.75 to 0.97)	0.67 (0.52 to 0.87)	0.87 (0.74 to 1.01)
Dapagliflozin	DECLARE-TIMI 58 [51]	0.93 (0.84 to 1.03)	0.73 (0.61 to 0.88)	0.93 (0.82 to 1.04)
Empagliflozin	EMPA-REG OUTCOME [52]	0.86 (0.74 to 0.99)	0.65 (0.50 to 0.85)	0.68 (0.57 to 0.82)
Ertugliflozin	VERTIS CV [50]	0.97 (0.85 to 1.11)	0.70 (0.54 to 0.90)	0.93 (0.80 to 1.08)
Basal insulin analogues				
Degludec	DEVOTE [65]	0.91 (0.78 to 1.06)	0.88 (0.72 to 1.08)	0.91 (0.76 to 1.11)
Glargine U-100	ORIGIN [64]	1.02 (0.94 to 1.11)	0.90 (0.77 to 1.05)	0.98 (0.90 to 1.08)

Results are expressed as hazard ratios and 95% confidence intervals. Green indicates a favourable effect, yellow indicates a neutral effect, and red indicates a detrimental effect. DPP-4, dipeptidyl-peptidase 4; GLP-1, glucagon-like peptide 1; LAR, long-acting release; SGLT-2, sodium-glucose cotransporter 2.

^a Comparisons against placebo except for the TOSCA-IT trial, in which pioglitazone was compared with sulfonylureas; the CAROLINA trial, in which linagliptin was compared with glimepiride; and the DEVOTE trial, in which insulin degludec was compared with glargine U-100.

^b Composite of cardiovascular death, non-fatal myocardial infarction, and non-fatal stroke (including also urgent coronary revascularization in the TOSCA.IT trial for pioglitazone and hospitalization for unstable angina in the ELIXA trial for lixisenatide).

^c Upper boundary of the one-side repeated confidence interval.

In the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial, 9340 participants with type 2 diabetes were randomized to either once-daily 1.8 mg (or the maximum tolerated dose) liraglutide or placebo in addition to their standard care and were followed over a median of 3.8 years [42]. All participants were at increased cardiovascular risk, defined as either an age of more than 50 years with a history of a cardiovascular condition (coronary heart disease, cerebrovascular disease, peripheral vascular disease, chronic kidney disease, or heart failure) or an age of more than 60 years with at least one cardiovascular risk factor (including microalbuminuria, hypertension, left ventricular dysfunction, or an ankle-brachial index of less than 0.9). Most participants (81.3%) had established cardiovascular disease, chronic kidney disease of stage 3 or higher, or both. Treatment with liraglutide reduced the incidence of the primary outcome of first occurrence of cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke (three-component MACE) with an HR of 0.87 (95% CI

0.78 to 0.97). This effect was mainly driven by a reduction in cardiovascular mortality (HR 0.78; 95% CI 0.66 to 0.93), whereas the effects on non-fatal myocardial infarction and on non-fatal stroke did not significantly differ between liraglutide and placebo. Treatment with liraglutide also reduced the incidence of all-cause mortality (HR 0.85; 95% CI 0.74 to 0.97) and of the composite kidney outcome (HR 0.78; 95% CI 0.67 to 0.92), the latter being primarily driven by the effect on new-onset macroalbuminuria [42, 81].

The Exenatide Study of Cardiovascular Event Lowering (EXSCEL) assessed the cardiovascular effects of once-weekly exenatide versus placebo in 14 752 people with type 2 diabetes over a median of 3.2 years [45]. As per the trial design, ~70% of enrolled participants had a previous cardiovascular event prior to randomization, defined as a history of major clinical manifestation of coronary artery disease, ischaemic cerebrovascular disease, or atherosclerotic peripheral artery disease. The primary outcome of three-component MACE occurred in fewer participants in the exenatide arm

compared with the placebo arm, yielding a marginally non-significant HR of 0.91 (95% CI 0.83 to 1.00). Incidence of all-cause mortality was lower in the exenatide arm (HR 0.86; 95% CI 0.77 to 0.97); however, this effect was not deemed significant on the basis of the hierarchical testing plan that was implemented [45].

The cardiovascular profile of once-weekly subcutaneous semaglutide was evaluated in the Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes (SUSTAIN-6), in which 3297 participants were randomized in a 1:1:1:1 ratio to semaglutide 0.5 mg, or 1 mg, or two volume-matched placebo arms [43]. The eligibility criteria regarding participants' cardiovascular risk profile at baseline were identical to those in the LEADER trial [42], and the percentage of enrolled individuals with established vascular disease (83%) was also similar to the LEADER trial. SUSTAIN-6 was not event driven but had a predefined 104-week treatment period. Both doses of semaglutide were superior to placebo in reducing the three-component MACE (HR 0.74; 95% CI 0.58 to 0.95) and the outcome of new or worsening nephropathy comprising macroalbuminuria, doubling of serum creatinine, or the need for renal-replacement therapy (HR 0.64; 95% CI 0.46 to 0.88). However, diabetic retinopathy complications were more frequent with semaglutide in comparison to placebo (HR 1.76; 95% CI 1.11 to 2.78) [43].

The once-daily oral formulation of semaglutide was assessed in the Peptide Innovation for Early Diabetes Treatment (PIONEER 6) trial [44]. Although it was event driven, PIONEER 6 was designed to assess the non-inferiority, and not the superiority, of oral semaglutide versus placebo. It followed 3183 participants over a median of 15.9 months, 2695 (84.7%) of whom had established cardiovascular disease or chronic kidney disease, while the remainder had cardiovascular risk factors only. The primary outcome of MACE occurred in 3.8% of participants receiving semaglutide (at a target daily dose of 14 mg) and in 4.8% of participants allocated to placebo, thus confirming the non-inferiority of oral semaglutide compared with placebo. Treatment with oral semaglutide was also associated with reduced all-cause mortality (HR 0.51; 95% CI 0.31 to 0.84) and cardiovascular mortality (HR 0.49; 95% CI 0.27 to 0.92); however, the trial was neither designed nor adequately powered to assess the superiority of semaglutide over placebo on any of these outcomes [44].

The effect of once-weekly dulaglutide on cardiovascular endpoints was assessed in the Researching Cardiovascular Events with a Weekly Incretin in Diabetes (REWIND) trial [41]. As opposed to the other cardiovascular outcomes trials with GLP-1RAs, only 31.5% of the 9091 participants in the REWIND trial had previous cardiovascular disease. The remainder were either older than 60 years with at least two risk factors (tobacco use, dyslipidaemia, hypertension, or obesity) or older than 55 years with myocardial ischaemia, coronary, carotid, or lower-extremity stenosis exceeding 50%, left ventricular hypertrophy, eGFR <60 ml/min/1.73 m², or albuminuria. During a median follow-up of 5.4 years, MACE occurred in fewer participants assigned to dulaglutide than those assigned to placebo (HR 0.88; 95% CI 0.79 to 0.99). In terms of individual MACE components, dulaglutide versus placebo significantly reduced non-fatal stroke (HR 0.76; 95% CI 0.61 to 0.95), but not non-fatal myocardial infarction or cardiovascular death [41]. Moreover, dulaglutide was superior to placebo in reducing a composite kidney outcome comprising the development of macroalbuminuria, a sustained 30% or greater decline in eGFR, or renal replacement therapy (HR 0.85; 95% CI 0.77 to 0.93) [41]. As was

also the case with the LEADER trial, this effect was mainly driven by the favourable effect on new-onset macroalbuminuria.

Once-weekly albiglutide was compared with placebo in the Harmony Outcomes trial, which included 9463 people with type 2 diabetes and established coronary, cardiovascular, or peripheral artery disease [82]. During a median follow-up of 1.6 years, albiglutide was superior to placebo in reducing MACE (HR 0.78; 95% CI 0.68 to 0.90). Interestingly, albiglutide was the only GLP-1RA that achieved statistical significance versus placebo in terms of reducing the incidence of myocardial infarction (HR 0.75; 95% CI 0.61 to 0.90) [82]. Albiglutide has been withdrawn from the market by the manufacturer in both the USA and Europe for economic reasons.

More recently, the cardiovascular and renal effects of once-weekly efpeglenatide were assessed in the Effect of efpeglenatide on cardiovascular outcomes (AMPLITUDE-O) trial [83]. Of the 4076 participants, ~90% had a history of coronary artery disease, stroke, or peripheral artery disease, while the remaining participants had kidney disease and at least one cardiovascular risk factor. Over a median follow-up of 1.81 years, compared to placebo, efpeglenatide (at a maintenance dose of 4 mg or 6 mg per week) reduced MACE (HR 0.73; 95% CI 0.58 to 0.92) and the composite kidney outcome of macroalbuminuria plus a decrease in kidney function (HR 0.68; 95% CI 0.57 to 0.79). An interesting finding of a subgroup analysis in AMPLITUDE-O was that the beneficial cardiovascular effects of efpeglenatide did not seem to be affected by the concomitant use of an SGLT-2 inhibitor (15% of trial participants) [83]. Efpeglenatide is not available for clinical use.

The dual GIP/GLP-1 receptor agonist tirzepatide was not associated with an increased incidence of MACE with insulin glargine in the Tirzepatide versus insulin glargine in type 2 diabetes and increased cardiovascular risk (SURPASS-4) trial over one year of treatment [84]. However, SURPASS-4 was not designed to assess cardiovascular outcomes; the ongoing SURPASS-CVOT trial (NCT04255433) is expected to elucidate the cardiovascular profile of tirzepatide.

A meta-analysis synthesizing data from eight cardiovascular outcomes trials found that GLP-1RAs as a drug class reduced MACE by 14% (HR 0.86; 95% CI 0.80 to 0.93) in comparison to placebo, corresponding to a number needed to treat (NNT) of 65 (95% CI 45 to 130) for a period of three years [85]. Across trials, the point estimate of each individual trial, albeit not always statistically significant, was consistently in favour of the GLP-1RA arm, except for lixisenatide in the ELIXA trial. It has been speculated that this may be partly attributed to the shorter half-life of lixisenatide (2–3 h) than other GLP-1RAs, suggesting that exposure to lixisenatide in ELIXA might have been lower than optimal in view of its once-daily dosing [85]. When ELIXA was excluded from the meta-analysis, heterogeneity was reduced, leading to the certainty of evidence regarding the overall effect of GLP-1RAs on MACE to be classified as high [85] according to Grading of Recommendations, Assessment, Development and Evaluation (GRADE) criteria [86]. In terms of individual MACE components, meta-analysis results suggested that GLP-1RAs, compared with placebo, significantly reduced the risk of cardiovascular mortality, myocardial infarction, and stroke by 13%, 10%, and 17%, respectively. All-cause mortality was also reduced with GLP-1RAs, with an HR of 0.88 (95% CI 0.82 to 0.94) corresponding to an NNT of 114 (95% CI 76 to 228) for a period of three years. Treatment with a GLP-1RA was associated with an 11% lower risk of hospitalization for heart failure and a 21% lower risk of a broad composite kidney outcome [85]. These findings have been corroborated in an additional

meta-analysis [87]; however, their clinical interpretation should take into consideration that, across GLP-1RA trials, details about heart failure were often incomplete and not standardized, while the effect on the composite kidney outcome was primarily driven by the reduction in the macroalbuminuria component (HR 0.74; 95% CI 0.67 to 0.82) [87].

One question of particular clinical relevance is whether the overall cardiovascular benefits of GLP-1RAs are equally applicable both to people with established atherosclerotic disease and to people with cardiovascular risk factors only. In this regard, the majority of participants in individual cardiovascular outcomes trials had established cardiovascular disease (ranging between 70% and 100%), the only exception being the REWIND trial, in which ~70% of participants had a combination of cardiovascular risk factors but not established vascular disease. An earlier meta-analysis of five trials suggested that the overall beneficial effect of GLP-1RAs on MACE was evident solely in individuals with a history of cardiovascular disease, based on the statistically significant value of the test for interaction between subgroups (P for interaction) [88]. However, subsequent meta-analyses incorporating data from all eight trials found no significant interaction between the two subgroups of people with and without established cardiovascular disease in terms of the overall effect estimate on MACE, even though the subgroup estimate was greater in those with known cardiovascular disease [85,89]. Nevertheless, the credibility and clinical interpretation of these meta-analyses of subgroups should not be based solely on the value of a statistical test for interaction between subgroups, but additional aspects should also be taken into consideration [90].

Among cardiovascular outcomes trials with SGLT-2 inhibitors, the Empagliflozin cardiovascular outcome event trial in type 2 diabetes mellitus patients (EMPA-REG OUTCOME) was the first to be reported. EMPA-REG OUTCOME assessed the effects of empagliflozin (at a dose of either 10 mg or 25 mg) on cardiovascular events versus placebo in 7020 adults with type 2 diabetes and established cardiovascular disease (history of myocardial infarction, stroke, single- or multi-vessel coronary artery disease, or occlusive peripheral artery disease) [52]. Over a median follow-up of 3.1 years, participants who received empagliflozin had a lower rate of the primary outcome of three-component MACE (HR 0.86; 95% CI 0.74 to 0.99), cardiovascular mortality (HR 0.62; 95% CI 0.49 to 0.77), and all-cause mortality (HR 0.68; 95% CI 0.57 to 0.82). Treatment with empagliflozin also reduced hospitalization for heart failure by 35% and the composite kidney outcome of incident or worsening nephropathy by 39% [52,56]. This beneficial effect was evident in each individual component of the composite kidney outcome, comprising macroalbuminuria, doubling of serum creatinine, and initiation of renal-replacement therapy [56].

The cardiovascular effects of canagliflozin (100 mg or 300 mg) were examined in 10 142 people with type 2 diabetes in the CANVAS Program, which integrated data from the Canagliflozin Cardiovascular Assessment Study (CANVAS) and CANVAS-Renal (CANVAS-R) [49]. CANVAS was designed with the aim of meeting the 2008 FDA cardiovascular safety (non-inferiority) requirements, and as such was insufficient to enable a test of a positive cardiovascular effect (superiority) of canagliflozin over placebo [49]. On this ground, CANVAS-R was undertaken with a similar design to CANVAS to jointly achieve statistical power to detect plausible favourable effects of canagliflozin on cardiovascular and kidney outcomes [91]. Participants' eligibility criteria were identical in both trials, with ~65% of the CANVAS Program population having

a history of cardiovascular disease, and the remaining being 50 years or older with two or more cardiovascular risk factors. During a median follow-up of 126 weeks in the overall CANVAS Program, MACE occurred in fewer participants assigned to canagliflozin than those assigned to placebo, with an HR of 0.86 (95% CI 0.75 to 0.97). In addition, fewer participants in the canagliflozin group were hospitalized for heart failure (HR 0.67; 95% CI 0.52 to 0.87) and had the composite kidney outcome of sustained reduction in eGFR, need for renal-replacement therapy, or renal death (HR 0.60; 95% CI 0.47 to 0.77) [49].

In the Dapagliflozin Effect on Cardiovascular Events-Thrombolysis in Myocardial Infarction 58 (DECLARE-TIMI 58) trial, 17 160 people with type 2 diabetes who had or were at risk for atherosclerotic cardiovascular disease were randomized to either dapagliflozin 10 mg or placebo and were followed for a median of 4.2 years [51]. A notable characteristic differentiating DECLARE-TIMI 58 from other cardiovascular outcomes trials with SGLT-2 inhibitors was that this trial included more than 10 000 individuals (~60% of the trial population) without evident cardiovascular disease but with multiple risk factors. MACE was originally the sole primary outcome, but the study protocol was amended to include the composite of cardiovascular death or hospitalization of heart failure as a second primary outcome. The rate of MACE was similar between dapagliflozin and placebo (HR 0.93; 95% CI 0.84 to 1.03), while dapagliflozin was superior to placebo in reducing the composite of cardiovascular death or hospitalization for heart failure (HR 0.83; 95% CI 0.73 to 0.95). The latter finding, however, was due to the lower rate of hospitalization for heart failure in the dapagliflozin group (HR 0.73; 95% CI 0.61 to 0.88) and not due to an effect on cardiovascular mortality. Dapagliflozin significantly reduced by 24% the incidence of the composite kidney outcome of more than 40% reduction in eGFR, new end-stage renal disease, or death from renal or cardiovascular causes [51].

The Evaluation of Ertugliflozin Efficacy and Safety Cardiovascular Outcomes Trial (VERTIS CV) examined the cardiovascular effects of ertugliflozin (5 mg or 15 mg) compared to placebo in 8246 people with type 2 diabetes and established atherosclerotic cardiovascular disease involving the coronary, cerebrovascular, or peripheral artery systems [50]. During a median follow-up of 3.0 years, ertugliflozin was non-inferior, but not superior, to placebo in terms of MACE (HR 0.97; 95% CI 0.85 to 1.11), its individual components, and the composite kidney outcome of death from renal causes, renal replacement therapy, or doubling of serum creatinine. Consistent with other SGLT-2 inhibitors, ertugliflozin reduced the incidence of hospitalization for heart failure versus placebo with an HR of 0.70 (95% CI 0.54 to 0.90) [50].

Based on the results of individual cardiovascular outcomes trials, all four SGLT-2 inhibitors consistently reduced hospitalization for heart failure, all SGLT-2 inhibitors except ertugliflozin improved kidney outcomes, while empagliflozin and canagliflozin had a beneficial effect on MACE. These findings were synthesized in a meta-analysis that produced pooled estimates for all SGLT-2 inhibitors as a drug class and explored the heterogeneity of outcomes assessed by individual SGLT-2 inhibitors in the overall class [92]. Results of this meta-analysis showed that the predominant beneficial effect of SGLT-2 inhibitors was the reduction in hospitalization for heart failure compared to placebo, with an HR of 0.68 (95% CI 0.61 to 0.76). This estimate was highly consistent with no evidence of statistical heterogeneity across the class, given that a significant effect in favour of the SGLT-2 inhibitor arm was achieved in each individual trial. An overall beneficial effect of SGLT-2 inhibitors

was also shown on MACE (HR 0.90; 95% CI 0.85 to 0.95) and on cardiovascular mortality (HR 0.85; 95% CI 0.78 to 0.93); however, a significant degree of heterogeneity was observed in the analyses for both outcomes, especially cardiovascular mortality, reflecting possible differences between individual SGLT-2 inhibitors in terms of their effects on atherosclerotic events [92]. Some degree of heterogeneity was also present in the analysis for the composite kidney endpoint (HR 0.62; 95% CI 0.56 to 0.70), most likely due to VERTIS-CV trial, as ertugliflozin was the only SGLT-2 inhibitor without a demonstrated benefit on kidney outcomes. Another potential source of heterogeneity could be the fact that there were differences in the components of the composite kidney outcome across trials [92]. In this regard, a meta-analysis focusing on the renal effects of SGLT-2 inhibitors used more consistent definitions across trials with canagliflozin, dapagliflozin, and empagliflozin for clinically important kidney outcomes [93]; based on this meta-analysis, the three SGLT-2 inhibitors improved all kidney outcomes with no evidence of heterogeneity between trials [93].

As for GLP-1RAs, it is clinically relevant to establish whether the observed effects of SGLT-2 inhibitors in people with type 2 diabetes and increased cardiovascular risk are consistent regardless of history of established atherosclerotic disease. Meta-analyses of cardiovascular outcomes trials that assessed the effects of SGLT-2 inhibitors in two subgroups according to the presence of established atherosclerotic cardiovascular disease did not find evidence of a modification effect regarding the overall beneficial effect of SGLT-2 inhibitors versus placebo on MACE, cardiovascular mortality, hospitalization for heart failure, and a composite kidney outcome [92]. However, data for the subgroup of participants without atherosclerotic disease (individuals with multiple risk factors only) were available only for dapagliflozin and canagliflozin [92].

Although long-term head-to-head trials comparing GLP-1RAs with SGLT-2 inhibitors are lacking, indirect comparisons from network meta-analyses found that both classes confer comparable benefits on all-cause mortality, cardiovascular mortality, and MACE [26, 94, 95]. Moreover, GLP-1RAs might be more effective in preventing stroke, whereas SGLT-2 inhibitors reduce hospitalizations for heart failure [26, 94, 95]. Some intraclass differences between agents might also exist, but it is unclear whether these comparative estimates are clinically meaningful [26]. A complementary source of comparative effectiveness evidence is large registry-based cohort studies utilizing real-world data of new users of GLP-1RAs or SGLT-2 inhibitors. In particular, five cohort studies have corroborated the superiority of SGLT-2 inhibitors over GLP-1RAs in reducing heart failure hospitalizations [96–100], whereas two of these studies also found that SGLT-2 inhibitors were more effective in reducing a composite cardiovascular endpoint [96, 97]. Interestingly, emerging data suggest that, due to their different mechanisms of action, both drug classes may be considered as combination therapy to enhance their favourable effect on metabolic variables and possibly to provide complementary cardiovascular benefits [1, 101, 102].

Evidence from kidney outcomes trials

Secondary and exploratory analyses of type 2 diabetes cardiovascular outcomes trials suggested that SGLT-2 inhibitors can improve kidney outcomes; however, none of these trials was designed to assess kidney outcomes specifically in people with chronic kidney disease [49–52]. In this regard, the Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation

(CREDENCE) trial was the first large-scale randomized trial to assess the effects of canagliflozin on kidney outcomes in people with type 2 diabetes and albuminuric chronic kidney disease, the latter defined as an eGFR of 30 to <90 ml/min/1.73 m² and a urinary albumin-to-creatinine ratio of >300 [57]. The 4401 participants were randomized to either canagliflozin 100 mg or placebo, and were followed over a median period of 2.6 years. Stable treatment (for at least four weeks before randomization) with an angiotensin-converting enzyme inhibitor or an angiotensin-receptor blocker was a prerequisite for all eligible participants. The primary composite outcome of end-stage kidney disease, or doubling of serum creatinine level, or death from renal or cardiovascular causes occurred in significantly fewer participants receiving canagliflozin with an HR of 0.70 (95% CI 0.59 to 0.82). Additionally, treatment with canagliflozin reduced the risk for MACE by 20% and for the composite of cardiovascular death or hospitalization for heart failure by 31% [57].

The Dapagliflozin and Prevention of Adverse Outcomes in Chronic Kidney Disease (DAPA-CKD) trial was based on the same rationale, aiming to assess the kidney and cardiovascular effects of dapagliflozin in a dedicated chronic kidney disease population [58]. However, in contrast to CREDENCE, the primary hypothesis in DAPA-CKD was that the kidney effects of dapagliflozin occur in people with chronic kidney disease irrespective of the presence of type 2 diabetes. As such, DAPA-CKD included a considerable number of participants without type 2 diabetes at baseline (~32.5% of the 4304 participants). Moreover, in its eligibility criteria, DAPA-CKD used lower thresholds than CREDENCE both for eGFR (25–75 ml/min/1.73 m²) and for albuminuria (urinary albumin-to-creatinine ratio of >200) [58]. The primary composite kidney outcome was reduced by 39% (HR 0.61; 95% CI 0.51 to 0.72) in the dapagliflozin arm. Treatment with dapagliflozin was also associated with a lower incidence of all-cause mortality (HR 0.69; 95% CI 0.53 to 0.88) and of the composite of cardiovascular mortality or hospitalization for heart failure (HR 0.71; 95% CI 0.55 to 0.92) [58]. Subgroup analyses of DAPA-CKD indicated that these effects were consistent regardless of presence of type 2 diabetes [103].

Both CREDENCE and DAPA-CKD required the presence of macroalbuminuria for inclusion in addition to reduced eGFR. In contrast, the Effect of sotagliflozin on cardiovascular and renal events in patients with type 2 diabetes and moderate renal impairment who are at cardiovascular risk (SCORED) trial evaluated the dual SGLT-2 and SGLT-1 inhibitor sotagliflozin in people with type 2 diabetes and chronic kidney disease, regardless of the degree of albuminuria [104]. The original two primary outcomes in SCORED were MACE and the composite of cardiovascular mortality or hospitalization for heart failure; however, due to the trial's early cessation and the subsequent fewer than planned accrued number of events, the primary outcome was changed to the total number of cardiovascular deaths, hospitalizations for heart failure, and urgent visits for heart failure. During a median follow-up of 16 months, the primary outcome occurred in fewer people in the sotagliflozin arm, compared with placebo (HR 0.74; 95% CI 0.63 to 0.88) [104]. Sotagliflozin has not received marketing approval for type 2 diabetes.

Empagliflozin in patients with chronic kidney disease (EMPA-KIDNEY) is an event-driven randomized trial evaluating the effect of empagliflozin 10 mg against placebo on the primary outcome of kidney disease progression or cardiovascular death in people with chronic kidney disease [105]. Between May 2019 and April 2021,

6609 participants were randomized, of whom 44% had type 2 diabetes and 27% had a history of cardiovascular disease. Trial results are anticipated in the near future [105].

A meta-analysis has synthesized cardiovascular outcomes trials and kidney outcomes trials of SGLT-2 inhibitors, using data only for people who had both type 2 diabetes and chronic kidney disease across all trials [106]. In this population, SGLT-2 inhibitors, compared to placebo, reduced MACE by 17%, hospitalization for heart failure by 38%, and a kidney composite outcome by 34%. Individual MACE components and all-cause mortality were also significantly reduced with SGLT-2 inhibitors. In addition, beneficial effects of SGLT-2 inhibitors on MACE, hospitalization for heart failure, and kidney outcomes were evident even in the subgroup of participants with an eGFR of <45 ml/min/1.73 m² [106].

With regard to GLP-1RAs, no dedicated kidney outcomes trial is currently available. However, cardiovascular outcomes trials with GLP-1RAs have included people with an eGFR as low as 15 ml/min/1.73 m² [85]. A meta-analysis of eight cardiovascular outcomes trials found that the overall beneficial effect of GLP-1RAs on MACE (HR 0.85; 95% CI 0.78 to 0.93) was consistent between those with an eGFR of ≤60 ml/min/1.73 m² and the subgroup with an eGFR of >60 ml/min/1.73 m², as suggested by the non-significant value of the statistical test for subgroup differences [85]. More definitive evidence about the kidney and cardiovascular effects of GLP-1RAs in people with chronic kidney disease are expected on completion of the FLOW trial (NCT03819153), which is evaluating whether subcutaneous semaglutide can slow the progression of chronic kidney disease in people with type 2 diabetes and renal impairment [107].

Evidence from heart failure trials

People with type 2 diabetes have an increased risk of developing heart failure, which further increases morbidity, mortality, and occurrence of other adverse outcomes (Chapter 50). Therefore, careful consideration should be paid when choosing among pharmacological treatment options in those individuals with type 2 diabetes with established or high risk for developing heart failure. Pioglitazone should be avoided because it has been associated with an increased risk of heart failure [108]. Cardiovascular outcomes trials suggest that DPP-4 inhibitors have a neutral effect on heart failure outcomes, except for saxagliptin, which was associated with a higher rate of hospitalization for heart failure versus placebo (3.5% vs 2.8%) in the Saxagliptin Assessment of Vascular Outcomes Recorded in patients with diabetes mellitus–Thrombolysis in Myocardial Infarction (SAVOR-TIMI 53) trial [36]. Caution is therefore warranted if saxagliptin is used in people with a history of heart failure. Meta-analyses of cardiovascular outcomes trials have found a modest effect of GLP-1RAs in reducing hospitalization for heart failure that was marginally significant [85,89]. Although it is unclear whether this finding is clinically meaningful, it deserves to be further examined. The effect of the GIP/GLP-1 receptor agonist tirzepatide on heart failure endpoints in people with heart failure with preserved ejection fraction and obesity is being evaluated in the Study of tirzepatide in participants with heart failure with preserved ejection fraction and obesity (SUMMIT) trial (NCT04847557). A considerable beneficial effect on heart failure outcomes, in particular hospitalization for heart failure, has been shown consistently in all cardiovascular outcomes trials with SGLT-2 inhibitors. As a result, agents from this drug class have subsequently been evaluated in large-scale trials that focused on people with heart failure and assessed heart failure outcomes as their primary endpoint.

The Dapagliflozin and Prevention of Adverse Outcomes in Heart Failure (DAPA-HF) trial was the first dedicated heart failure trial with an SGLT-2 inhibitor. DAPA-HF randomized a total of 4744 participants with New York Heart Association (NYHA) class II, III, or IV heart failure and reduced ejection fraction (≤40%) to either dapagliflozin or placebo [55]. Over a median duration of 18.2 months, the primary composite outcome of worsening of heart failure (hospitalization or an urgent visit resulting in intravenous therapy for heart failure) or cardiovascular death occurred in fewer participants receiving dapagliflozin (HR 0.74; 95% CI 0.65 to 0.85). This beneficial effect was also evident in the subgroup of participants who had type 2 diabetes (42% of the trial population). Treatment with dapagliflozin significantly improved the individual components of the primary outcome and all-cause mortality [55]. The Empagliflozin outcome trial in people with chronic heart failure and a reduced ejection fraction (EMPEROR-Reduced) used the same key eligibility criteria (heart failure with reduced ejection fraction) and the same primary outcome as DAPA-HF [54]. During a median follow-up of 16 months, empagliflozin 10 mg reduced the risk of the primary outcome by 25% versus placebo, an effect that was consistent in the subgroup of participants with diabetes (~50% of the 3730 participants) [54]. A meta-analysis pooling data from both trials concluded that dapagliflozin and empagliflozin consistently reduced the composite of hospitalization for heart failure and cardiovascular death by ~25% in people with heart failure and reduced ejection fraction, regardless of the presence or absence of type 2 diabetes [109].

In the Empagliflozin outcome trial in patients with chronic heart failure and a preserved ejection fraction (EMPEROR-Preserved), empagliflozin was assessed in individuals with heart failure with preserved ejection fraction (>40%) [53]. The 5988 participants, 49% of whom had diabetes, were randomized to either empagliflozin 10 mg or placebo and were followed over a median of 26.2 months. The primary composite outcome of cardiovascular death or hospitalization for heart failure occurred in fewer participants assigned to empagliflozin compared with placebo (HR 0.79; 95% CI 0.69 to 0.90), an effect that was mainly related to a lower risk of hospitalization for heart failure (HR 0.73; 95% CI 0.61 to 0.88). In a subgroup analysis, these findings appeared consistent regardless of the presence of diabetes [53]. Individuals with heart failure with preserved ejection fraction are also the focus of the Dapagliflozin Evaluation to improve the Lives of patients with Preserved ejection fraction heart failure (DELIVER) trial, a randomized trial examining whether dapagliflozin is superior to placebo in reducing the composite of worsening heart failure or cardiovascular death [110]. Recruitment in DELIVER was completed in January 2021 with 6263 participants and an anticipated median follow-up of 27 months [110].

The Effect of sotagliflozin on cardiovascular events in patients with type 2 diabetes post worsening heart failure (SOLOIST-WHF) trial compared the dual SGLT-2 and SGLT-1 inhibitor sotagliflozin with placebo over a median of 9.0 months in 1222 people with heart failure with either reduced or preserved ejection fraction [111]. All participants had type 2 diabetes and were recently hospitalized for worsening heart failure. The rate of the primary outcome of the total number of cardiovascular deaths, hospitalizations, and urgent visits for heart failure (first and subsequent events) was significantly lower in the sotagliflozin group than in the placebo group (HR 0.67; 95% CI 0.52 to 0.85) and this benefit was consistent in the two prespecified subgroups of participants with an ejection fraction <50% and ≥50%. SOLOIST-WHF was originally designed to assess

the primary outcome of cardiovascular death or hospitalization for heart failure in ~4000 participants; however, its primary endpoint was changed because, similar to the SCORED trial, the trial ended early due to lack of funding [111].

Apart from these heart failure trials, additional evidence supporting the beneficial effects of SGLT-2 inhibitors in people with heart failure comes from subgroup analyses of the original cardiovascular outcomes trials that recruited people with type 2 diabetes and increased cardiovascular risk. In particular, a meta-analysis synthesized data from EMPAREG-OUTCOME, CANVAS Program, DECLARE-TIMI 58, and VERTIS CV and compared the cardiovascular effects of SGLT-2 inhibitors between the two subgroups of people with and without heart failure within the overall populations of all four trials [92]. The findings showed that SGLT-2 inhibitors reduce the composite of cardiovascular death or hospitalization for heart failure in both subgroups [92]. Based on the overall evidence both from cardiovascular outcomes trials and from heart failure trials, the SGLT-2 inhibitor class consistently confers clinically important benefits in heart failure endpoints in people who have either type 2 diabetes, or heart failure, or both.

Management of obesity and associated comorbidities

The obesity epidemic is paralleled not only by the increasing prevalence of type 2 diabetes, but also by other cardiometabolic adverse effects, including high blood pressure, elevated cholesterol and triglyceride levels, liver steatosis and fibrosis, obstructive sleep apnoea, and most importantly cardiovascular disease. Promoting weight loss through increased physical activity and energy restriction plays a key role in the management of type 2 diabetes, but behavioural changes are hard to implement. Sulfonylureas, pioglitazone, as well as basal insulin are associated with weight gain, while metformin and DPP-4 inhibitors have a neutral effect on body weight. By contrast, GLP-1RAs induce weight loss by slowing gastric emptying and by promoting satiety, while treatment with SGLT-2 inhibitors leads to urinary excretion of excess calories due to glucosuria. Use of agents from these two classes, in particular GLP-1RAs, results in sustainable weight reduction and, as such, people with type 2 diabetes for whom weight loss or maintenance is a therapeutic priority should be treated preferably with a GLP-1RA or an SGLT-2 inhibitor [1,6]. Certain GLP-1RAs including liraglutide and subcutaneous semaglutide have received marketing authorization at higher doses for chronic weight management irrespective of the presence of type 2 diabetes. Based on a network meta-analysis assessing pharmacological therapies for obesity, high-dose semaglutide is likely the most effective agent, achieving body weight reductions that could be as high as 10% [112]. In addition, currently available data from randomized controlled trials suggest that in people with type 2 diabetes the dual GIP/GLP-1 receptor agonist tirzepatide has an impressive weight-lowering potential, superior to that of subcutaneous semaglutide [61]. The effect of tirzepatide as an anti-obesity medication is being investigated in the ongoing Study of tirzepatide in participants with obesity or overweight (SURMOUNT) clinical trial programme.

People with type 2 diabetes who have overweight or obesity often have comorbid NASH, which currently represents the most common liver disorder in Western countries and has become the leading indication for liver transplantation in the USA. Insulin resistance is a shared characteristic of type 2 diabetes and obesity and is considered as a key pathogenic driver of NASH. Despite the

growing prevalence of the condition, management is largely based on lifestyle modification and treatment of individual components of the metabolic syndrome, due to lack of licensed disease-specific interventions that could prevent progression of hepatic steatosis to liver fibrosis and cirrhosis [113]. Nevertheless, emerging evidence suggests that certain anti-diabetes drugs including pioglitazone, GLP-1RAs, and to a lesser extent SGLT-2 inhibitors might have a favourable effect on NASH. Based on liver biopsy studies, pioglitazone was associated with reductions in hepatic steatosis and lobular inflammation, but not with improvement in fibrosis score [114]. Treatment with liraglutide and semaglutide resulted in histological resolution of NASH and halted progression of fibrosis [115,116]. Studies utilizing mostly magnetic resonance-based techniques for assessment of liver fat content have also suggested potential benefits for dulaglutide as well as several SGLT-2 inhibitors, including canagliflozin, dapagliflozin, empagliflozin, and ipragliflozin [117,118]. On the basis of this evidence, the American Association of Clinical Endocrinology advocates the use of pioglitazone or GLP-1RAs for people with type 2 diabetes and biopsy-proven NASH [113]. Both drug classes should be considered when there is an elevated probability of having NASH based on elevated plasma aminotransferase levels and non-invasive tests, while GLP-1RAs, pioglitazone, or SGLT2 inhibitors can probably be considered to offer cardiometabolic benefit in people with type 2 diabetes and non-alcoholic fatty liver disease (NAFLD) [113].

For people with type 2 diabetes and morbid obesity, bariatric surgery is a highly effective alternative for weight loss compared with lifestyle and medical interventions that confers superior glycaemic and other metabolic management, mitigates cardiovascular risk, and may even provide survival benefits. Metabolic surgery often reduces the number of anti-diabetes medications needed to restore euglycaemia and can induce remission of diabetes and clearance of NASH. The procedure is generally safe when performed in high-volume centres with experience in gastrointestinal surgery. Bariatric surgery is therefore recommended to treat type 2 diabetes in screened surgical candidates with $\text{BMI} \geq 40 \text{ kg/m}^2$, as well as in people with $\text{BMI} 35\text{--}40 \text{ kg/m}^2$ who do not achieve durable weight loss and improvement in comorbidities (including hyperglycaemia) with non-surgical methods. Bariatric surgery could also be considered in people with type 2 diabetes with $\text{BMI} 30\text{--}34 \text{ kg/m}^2$ [119].

Precision medicine-based approach

An alternative approach for choosing among anti-diabetes medications is in line with the concept of precision medicine and suggests that people with type 2 diabetes can be clustered into five distinct subgroups according to various clinical variables, such as age at onset of diabetes, HbA_{1c} , BMI, or measures of insulin resistance [120]. These subgroups have been reproduced in large-scale populations and have been associated with different risks of developing diabetes-related complications and responses to specific treatments. Based on this rationale, certain drugs can be more efficacious for specific clinical phenotypes of type 2 diabetes. In particular, it has been suggested that insulin and insulin secretagogues are likely the therapy of choice for the clusters of severe autoimmune diabetes (SAID) and severe insulin-deficient diabetes (SIDD), insulin sensitizers for people with severe insulin-resistant diabetes (SIRD), and metformin for mild obesity-related diabetes (MOD) [120]. A recent study aiming to validate these novel subtypes in the DEVOTE, LEADER, and SUSTAIN-6 cardiovascular outcomes trials found that the highest risk for cardiovascular events

was evident in participants with high HbA_{1c} and low BMI who most closely resembled the SIDD cluster [121]. Nevertheless, this suggested classification system of diabetes should not be considered final at present, as it is still evolving and requires further refinements to achieve better predictive power [120].

Therapeutic decision making in the clinical setting

Currently, choice of appropriate anti-diabetes therapy is primarily guided by the presence of clinically important comorbidities and underlying cardiovascular risk. For people with type 2 diabetes and chronic kidney disease, SGLT-2 inhibitors are most likely better suited due to their kidney and cardiovascular protection, whereas a long-acting GLP-1RA is recommended for individuals who cannot use an SGLT-2 inhibitor [122]. SGLT-2 inhibitors should also be prioritized in people with type 2 diabetes and heart failure [1, 80, 123]. Specific GLP-1RAs and SGLT-2 inhibitors are recommended for people with type 2 diabetes and with established atherosclerotic disease or with multiple cardiovascular risk factors [1, 2, 80]. The level of certainty in this recommendation is probably higher for the former subgroup, because some cardiovascular outcomes trials have focused exclusively on people with established cardiovascular disease, while in trials that recruited both subgroup populations fewer events were recorded for participants with multiple risk factors only. Although the definition used for multiple risk factors was not identical among these trials, in most cases it comprised a combination of at least three risk factors such as dyslipidaemia, obesity, smoking, age, or hypertension. The cardiovascular benefits of GLP-1RAs and SGLT-2 inhibitors appear to be independent of their glucose-lowering effect and of prior metformin use [124–126]; it is therefore reasonable to treat people who have type 2 diabetes and any of the cardiovascular comorbidities mentioned with these agents irrespective of baseline HbA_{1c} or metformin therapy [2].

It is unclear, however, whether the favourable cardiovascular effects of GLP-1RAs or SGLT-2 inhibitors are applicable to people with type 2 diabetes who have fewer than three risk factors. In this regard, a network meta-analysis of 298 randomized controlled trials found no clinically meaningful differences between anti-diabetes medications for mortality and vascular outcomes in people at low cardiovascular risk [26]. Another network meta-analysis estimated absolute effects of treatment with GLP-1RAs and SGLT-2 inhibitors on cardiovascular and kidney outcomes for different categories of baseline cardiovascular risk. In particular, relative effect estimates from pooled trial data, which were largely driven by cardiovascular outcomes trials, were combined with baseline risk estimates derived from epidemiological data [95]. The estimated absolute treatment effects were very low for people with few or no cardiovascular risk factors, leading to a weak recommendation regarding the use of either a GLP-1RA or an SGLT-2 inhibitor in this population [95, 127]. This underlines not only the importance of prudent use of finite resources, but also the need to consider and avoid increased treatment burden and potential side effects that might be associated with the use of agents for cardiorenal protection in people with very low absolute cardiovascular risk. As such, key drivers for therapeutic decisions in people with low underlying risk are management of glycaemia, body weight, or

associated morbidities such as NASH. Metformin remains the agent of choice for treatment of hyperglycaemia in most cases, including newly diagnosed type 2 diabetes, due to the extensive experience with its use, overall efficacy and safety profile, and affordability [1, 80]. In the presence of obesity or NASH, specific medications are preferable, such as GLP-1RAs or SGLT-2 inhibitors for the former, and pioglitazone and some GLP-1RAs for the latter condition.

Additional important considerations can affect real-life therapeutic decisions and people's willingness to follow these decisions. For example, treatments with increased hypoglycaemic risk, such as sulfonylureas or intensive insulin regimens, should be avoided in individuals in whom hypoglycaemia can be life threatening. Moreover, agent- or class-specific adverse events, such as gastrointestinal adverse events with metformin or with GLP-1RAs, can limit the use of these medications in some people. Pharmacological treatment of older people with diabetes and frailty should also be given special attention; in particular, despite the cardiovascular benefits of GLP-1RAs or SGLT-2 inhibitors even in older populations [128], treatment with these agents is often not feasible due to practical concerns (e.g. need for subcutaneous administration of GLP-1RAs), susceptibility to dangerous side effects (e.g. falls due to volume depletion caused by SGLT-2 inhibitors), or drug availability and affordability issues. With respect to the latter, diabetes and the associated costs of managing the disease and its complications affect ethnic minorities and low-income populations disproportionately. Beyond novel therapies, increased emphasis on social determinants of health is even more necessary to tackle disparities and ensure humane and affordable care for all people with type 2 diabetes [129].

It is equally important that clinical decisions attend to the values and preferences of the informed individual with type 2 diabetes. This person-centred approach means that it is not the clinician who should exclusively make therapeutic decisions: it is an ethical imperative that the affected individual participates as an equal partner in decision making. Personal values and preferences may include experience of former and current related illnesses, other relevant life experiences, health habits, goals and expectations, social or family support, or personal beliefs about medical interventions. Depending on these factors, people may have polarized perceptions, ranging from no specific views to concrete predispositions, on how to proceed with their treatment. Research has suggested that considerable variation can also exist between the preferences of physicians and those of people with type 2 diabetes when it comes to weighting the merits and drawbacks of available medications [130]. Moreover, people's actions may also deviate from the preferences and views they themselves had previously expressed during the clinical consultation with their physician.

Keeping these in mind and given the complex and chronic nature of type 2 diabetes, as well as the constantly evolving diabetes research informing guidelines formulation, clinicians should not only continually update their knowledge on the pharmacological management of the disease, but also regularly reassess the overall health profile, relevant comorbidities, and personal perceptions of those they treat. By doing so, meaningful deliberations between caregivers and individuals affected by type 2 diabetes can be achieved, leading to well-informed decisions with minimal treatment burden that motivate both parties to mutually collaborate in a holistic management plan.

Weight Management and Metabolic Surgery

Alexis Sudlow¹, Dimitri J. Pournaras¹, and Carel W. le Roux²

¹Department of Bariatric Surgery, Southmead Hospital, Bristol, UK

²Diabetes Complications Research Centre, University College Dublin, Dublin, Ireland

Key points

- Weight loss in its own right is increasingly being recognized as an important therapeutic target for people with obesity and type 2 diabetes, which can be achieved using several different modalities. The key to the success of any treatment is weight loss that is maintained.
- Lifestyle modification including caloric restriction can produce clinically significant weight loss; however, sustaining this long term is challenging. Evidence to demonstrate a resultant improvement in cardiovascular risk factors or mortality is limited.
- Evidence from more than 13 randomized controlled trials has consistently demonstrated that, irrespective of the procedure performed, bariatric surgery is more effective than medical therapy for the treatment of obesity and type 2 diabetes.
- The recent development of a number of medications producing clinically significant weight loss may present new treatment options to a wider demographic of people than surgery.

Weight loss in itself and weight management in people with type 2 diabetes allow for the alteration of the primary disease process, obesity. In those with impaired glucose tolerance or early diabetes it may prevent disease progression or induce remission, whereas for those with established disease it may improve glycaemic levels while reducing treatment burden. Additionally, for those with complications of type 2 diabetes, such as macrovascular complications, sustained weight loss may actually prevent progression or reversal of established complications, including diabetic kidney disease [1]. Like any intervention, the individual benefit of weight loss to those with type 2 diabetes will vary and may be of most value in those primarily with insulin resistance, while those with β -cell dysfunction will likely benefit to a lesser degree.

In addition to improving glycaemic levels, the treatment of hypertension and dyslipidaemia, in their own right, is critical in reducing the risk of cardiovascular death. It is also recognized that weight-based therapeutic goals have a place in the management of individuals with obesity and type 2 diabetes. Weight reduction not only presents the opportunity to modify the underlying disease process, but has further metabolic benefits, including a reduction in the systemic inflammatory response, and improved blood pressure, dyslipidaemia, and quality of life. Although there are many therapeutic interventions available to aid weight loss, it is important to recognize that sustained long-term weight loss is critical to improving clinically relevant outcomes. The heterogeneous nature of both type 2 diabetes and obesity means there will be a degree of inter-individual variation in response to any single treatment. The availability of different treatment modalities presents the opportunity to implement an individualized approach to weight management as well as the potential to combine treatments, which may act by complementary but distinct mechanisms.

Diet, lifestyle, and psychological support

Owing in part to the perceived simplicity and relatively low cost, diet and lifestyle interventions have long been favoured as a means of promoting weight loss in individuals with obesity and type 2 diabetes, with the aim of reducing glycaemic levels, inflammatory markers, as well as cardiovascular risk factors. Although several studies have demonstrated that weight loss through diet or exercise-based interventions resulted in improved glycaemic levels and cardiovascular risk factors, including lipids and blood pressure, questions remained regarding the impact of these interventions on the risk of cardiovascular morbidity and mortality [2–4]. The Look AHEAD (Action for Health in Diabetes) trial demonstrated that an intensive lifestyle modification programme achieved clinically significant weight loss with a concomitant improvement in glycated haemoglobin (HbA_{1c}) and cardiovascular risk factors aside from low-density lipoproteins (LDL). In spite of this, the trial was stopped early on the basis of futility, as it did not result in a reduction in the primary endpoint of decreased rates of cardiovascular events [5]. A *post hoc* analysis of the results, however, showed a relationship between the magnitude of weight loss and improved cardiovascular risk. In individuals who lost >10% of their body weight in the first year, there was a 21% reduction in the risk of fatal and non-fatal cardiovascular events [6].

More recently, the implementation of a very low-calorie diet (VLCD) or total meal replacement has garnered increasing attention, in part due to the results of the Diabetes Remission Clinical Trial (DiRECT). The primary care-led intervention comprised a strict 12–20-week period of 800 kcal/d weight loss phase, during which the individuals had only formula diet, followed by food

reintroduction and structured support for weight loss maintenance. Of the individuals in the intervention arm, 46% and 36% were in remission from type 2 diabetes after one and two years, respectively, with sustained weight loss being linked to the maintenance of remission [7]. Although this study demonstrated promising results with regard to diabetes remission following significant weight loss, it also highlighted the critical issue surrounding dietary or lifestyle interventions as a means of treating type 2 diabetes, namely the sustainability of the intervention and resultant ability to maintain weight loss. At one year, nearly 25% of the participants demonstrated a 15 kg weight loss, which fell to just 11% after two years, which in part likely represents a proportion of individuals who were no longer able to follow the diet as prescribed.

With all dietary or lifestyle interventions, the aim of inducing weight loss through a caloric deficit remains valid and in most cases is effective in the short term in producing volitional weight loss. However, they are unsustainable for many individuals in the long term, with subsequent weight regain. Critically, VLCD and total meal replacement, in particular, do not address the underlying disease process of obesity and may only exacerbate hunger, which reduces the likelihood of long-term weight loss maintenance. In spite of this, dietary interventions may be effective in a small subgroup of individuals and may have a role for those who have not previously been on supervised weight loss programmes, as they are a low-risk intervention. Clinicians should be mindful that the majority of individuals will require treatment intensification with the addition of alternative modalities to produce clinically relevant and sustained weight loss.

Prior to undergoing bariatric surgery, people with obesity are typically advised to engage in a supervised weight loss programme; however, the duration and exact structure are variable. Preoperative weight loss is positively correlated in some studies with increased postoperative weight loss, fewer complications, as well as a reduction in liver volume, which facilitates surgical access [8, 9]. Dietary changes are required in the postoperative period and generally involve modifying eating patterns to include regular, small meals, high in protein, while following supplementation guidelines, which vary according to the type of surgery. In the postoperative period there is no evidence to support that participation in a supervised exercise programme alone results in significant additional weight loss or preservation of lean mass [10, 11]. In spite of this, studies have demonstrated that engagement with a regular exercise programme following bariatric surgery can increase cardiorespiratory fitness, strength, and physical function and people undergoing surgery are generally advised to engage in regular physical activity [11–13].

Psychological support is a central element in the multidisciplinary management of people with obesity, particularly those undergoing bariatric surgery in both the preoperative and postoperative periods. As such, bariatric surgery should only be provided in units where psychological support is available [14]. People with obesity are more likely to suffer from psychological issues including anxiety, depression, poor self-image, prior trauma, and disordered eating, which all have implications for quality of life [15, 16]. The identification of maladaptive eating behaviours preoperatively, including binge eating and emotional eating, is important as they are unlikely to be improved following surgery and are associated with poorer weight loss outcomes [17].

The British Obesity Metabolic Surgery Society guidelines have broken the psychological support pathway into a pre- and postoperative stepped model involving three levels: online support, group workshops, and individualized support delivered by a trained

psychologist [18]. During the preoperative period, the role of psychological support is not to screen out those who are unsuitable for surgery, but rather to identify potential barriers to weight loss or success with bariatric surgery and implement support where possible. Psychological support is critical to helping those undergoing surgery to identify the means of setting realistic expectations, as well as strategies for how they will adapt and manage the challenges in the postoperative period [18]. Some people with previously well-managed mental health issues may experience a period of destabilization, including those with substance misuse disorders.

Pharmacotherapy

The ideal anti-obesity pharmacotherapy is theoretically one that is more effective than dietary or lifestyle intervention, while being less invasive and potentially available to a wider demographic than bariatric surgery. Until recently no such agent existed, with many of the previously available drugs being either ineffective, dangerous, or both. Widespread media coverage of serious side effects linked to the use of now recalled medications such as sibutramine and phentermine/fenfluramine has contributed to a general reluctance from both clinicians and individuals with obesity to consider their use. In recent years, there has been remarkable progress made in the development of novel agents, which show excellent tolerability and safety while promoting clinically significant weight loss. These may further broaden the availability of therapeutic options for those with obesity and type 2 diabetes. Broadly speaking, these novel agents can be divided into two main subclasses: anti-obesity medications that are specifically targeting weight loss; and diabetes medications that are primarily licensed for treating hyperglycaemia but also promote weight loss.

Anti-obesity medications

Orlistat is a gastric and pancreatic lipase inhibitor, which works primarily by reducing the absorption of dietary fat. Randomized controlled trials (RCTs) have shown that orlistat can result in a 5–10% weight loss associated with an improvement in glycaemic levels and cardiovascular risk factors [19, 20]. It is associated with gastrointestinal symptoms, particularly diarrhoea, and is often poorly tolerated, largely limiting its long-term use.

More recently developed anti-obesity medications largely act centrally to produce appetite suppression, which may in part be responsible for the decreased incidence of gastrointestinal side effects and greater tolerability. The combination of naltrexone and bupropion acts in a synergistic manner, with bupropion activating proopiomelanocortin (POMC) receptor neurons in the arcuate nucleus to decrease appetite and naltrexone further enhancing this effect. The COR-II trial demonstrated its efficacy in promoting weight loss in individuals with obesity, with nearly one-third of participants achieving >10% weight loss after 56 weeks of treatment [21].

Another combined anti-obesity medication, phentermine and topiramate, produces appetite suppression and also alters energy balance, resulting in weight loss and concomitant improvements in glycaemic levels. The CONQUER study demonstrated that in those with type 2 diabetes, there was a mean weight loss of 9.4% after a 56-week period of treatment associated with 37% of the individuals achieving an HbA_{1c}<6.5% (48 mmol/mol) despite a reduced need for diabetes medications [22].

Coming from the same drug class as fenfluramine, which has been withdrawn, lorcaserin is a selective 5-HT_{2c} agonist that produces appetite suppression through activation of POMC neurons. In the Behavioral Modification and Lorcaserin for Obesity and Overweight Management in Diabetes Mellitus (BLOOM-DM) 52-week placebo-controlled trial, lorcaserin produced a >5% weight reduction from baseline in 44.7% of people with type 2 diabetes [23]. A reduction in HbA_{1c} was also seen, with 52% of participants achieving a level of <7% (53 mmol/mol) at one year. Lorcaserin use is not associated with the valvular defects seen with fenfluramine, which were thought to be secondary to increased mitotic activity mediated via its effect on 5-HT_{2B} receptors [24]. The market approval for lorcaserin, however, was withdrawn because of an increased occurrence of cancer during a safety clinical trial.

Although none of these drugs in themselves directly mediates changes in glycaemic levels, the weight loss they produce may modify the underlying disease process of type 2 diabetes and improve glucose metabolism.

Anti-diabetes medications

Several medications that were initially licensed to treat type 2 diabetes induce significant weight loss and there is increasing interest in how indications for their use can be expanded (Table 38.1). Mimicking some of the neurohormonal changes induced by bariatric surgery, glucagon-like peptide-1 (GLP-1) receptor agonists, including semaglutide, liraglutide, and dulaglutide, produce not only improved glycaemic levels, but clinically significant reductions in body weight and cardiovascular risk factors, including blood pressure and lipids. These medications act in a glucose-dependent manner to stimulate insulin secretion while inhibiting glucagon production and therefore have a low risk of hypoglycaemia [25]. They also act to modulate hunger within the gastrointestinal tract by slowing gastric emptying as well as centrally, promoting satiety

by activating receptors in the arcuate nucleus of the hypothalamus. Clinical trials involving both liraglutide and semaglutide have demonstrated that 33% and 13% of the individuals achieve 10% weight loss, respectively [26, 27]. Critically, in people with type 2 diabetes, the use of GLP-1 receptor agonists reduces the risk of fatal and non-fatal cardiovascular events.

Sodium-glucose cotransporter 2 (SGLT-2) inhibitors act by decreasing the renal reabsorption of glucose, which not only improves glycaemia but results in clinically significant weight loss through an obligate calorie loss in the urine. A pooled analysis of outcomes of phase three trials comparing canagliflozin to placebo demonstrated that 25% of the individuals had >5% weight loss [28]. There were also weight-dependent improvements in HbA_{1c} and systolic blood pressure, with weight loss accounting for 15% and 42% of changes in each, respectively. The use of both canagliflozin, dapagliflozin, and empagliflozin reduces fatal and non-fatal cardiac events, with the EMPA-REG OUTCOME trial demonstrating a 38% relative risk reduction in fatal cardiovascular events with empagliflozin compared to placebo in people with type 2 diabetes [29, 30].

When considering the use of weight loss pharmacotherapy, there remain questions regarding timing and indications for initiation and stopping. Anti-obesity medications remain an underutilized treatment modality for individuals with obesity and type 2 diabetes, in part because of perceptions regarding efficacy and safety. These concerns are not reflective of the currently available medications and diabetes drugs that promote weight loss are increasingly being used.

Anti-obesity medications may be useful in the pre- and postoperative periods for individuals undergoing bariatric surgery [31]. It is well recognized that a proportion of people will experience weight gain or a plateau of weight loss following bariatric surgery for a variety of reasons, and in these circumstances the addition of

Table 38.1 Drugs used to manage obesity.

Drug name	Dosing	Mechanism of action	Expected weight loss	Common side effects
Semaglutide	2.4 mg weekly via SC injection	GLP-1 analogue ↑ Glucose sensitivity, satiety ↓ Gluconeogenesis, gastric emptying	-15.8% mean body weight change >10% weight loss in 70% of recipients	Nausea Diarrhoea
Liraglutide	3 mg OD via SC injection	GLP-1 analogue ↑ Glucose sensitivity, satiety ↓ Gluconeogenesis, gastric emptying	-6.4% mean body weight change >10% weight loss in 26% of recipients	Nausea Diarrhoea
Orlistat	120 mg TDS	Lipase inhibitor ↓ Absorption of dietary fat	-5% to 10% mean weight loss ->5% weight loss in 52% of recipients	Diarrhoea Steatorrhoea
Naltrexone/bupropion	16 mg naltrexone /180 mg bupropion BD	Naltrexone: μ opioid receptor antagonist Bupropion: norepinephrine and dopamine reuptake inhibitor	-6.4% mean weight loss >10% weight loss in 28% of recipients	Nausea Headache Constipation
Phentermine/topiramate	7.5 mg phentermine/46 mg topiramate or 15/92 mg	Phentermine: centrally acting sympathomimetic Topiramate: anti-convulsant ↓ Appetite via hypothalamus	-10.9% weight loss from baseline >10% weight loss in 48% of recipients on high dose	Paraesthesia Dizziness Dry mouth Insomnia Constipation

BD, twice daily; GLP-1, glucagon-like peptide-1; OD, daily; SC, subcutaneous; TDS, thrice daily.

pharmacotherapy may be beneficial. The GRAVITAS study demonstrated the benefits of combining liraglutide with Roux-en-Y gastric bypass (RYGB) or sleeve gastrectomy (SG) for individuals with persistent or recurrent type 2 diabetes. Over the 26-week study period, 46% of the individuals in the liraglutide group lost >5% of their baseline body weight compared to 9% in the placebo group. Weight loss was also accompanied by improved HbA_{1c}, with 42% of the individuals in the treatment group reaching an HbA_{1c} <6.5% (48 mmol/mol) compared to 13% in the control group [32]. Although evidence for the use of pharmacotherapy in the postoperative period is limited to a relatively small number of studies, one study reported a greater response to the initiation of medications in those with a weight loss plateau rather than those who had regained weight [33].

Treatment cessation guidance is clearer for most newly approved anti-obesity medications in Europe and the USA. The European Medicines Agency (EMA) and US Food and Drug Administration (FDA) have provided *stopping rules* to identify individuals who are likely to be *responders* to any specific treatment [34]. Although there is some variability between different drugs, it is generally advisable that individuals should not continue to take anti-obesity medications if they have lost <5% weight after 12 weeks at the full treatment dose. These guidelines are derived from studies that reported that early weight loss following initiation of a dietary or pharmacological intervention is strongly predictive of long-term outcomes [35,36].

Bariatric surgery

The initial development of bariatric surgery originally stemmed from the observation that individuals undergoing surgical resection for upper gastrointestinal cancers frequently experienced profound and often problematic weight loss. This prompted the recognition that these same procedures could be used for individuals with obesity, making weight loss the primary indication rather than an unintended side effect of surgery. Critically, bariatric surgery not only provided clinically significant weight loss for individuals with obesity, but resulted in sustained weight loss in the long term.

Types of bariatric surgery

Since the early adoption of bariatric procedures, there have been dramatic developments not only from a technical standpoint in developing safer and highly effective procedures and approaches, but also from a mechanistic view, gaining a better understanding of the weight loss-dependent and independent physiological changes evoked by bariatric surgery and their long-term impact on obesity and related complications. Worldwide, more than 99.1% of primary bariatric procedures are now performed laparoscopically according to the latest IFSO Global Registry Report [37]. Refinement of techniques and the development of bariatric surgery are seen as a specialist area of practice, with morbidity and mortality rates now on a par with laparoscopic cholecystectomy and hysterectomy [38]. Although there is a growing body of level 1 evidence to support the efficacy of bariatric surgery in producing sustained long-term weight loss and resolution of comorbidity, no RCTs have demonstrated the superiority of one procedure over another; however, there are ongoing trials that may provide some clarity on this matter. Determining

which procedure to perform should take into account individual comorbidities, the presence of obesity-related metabolic complications, potential short- and long-term risks of procedure-related complications, as well as the surgeon's experience.

Sleeve gastrectomy

Although a relatively new procedure, sleeve gastrectomy now accounts for 50% of all bariatric surgery, becoming the most commonly performed bariatric procedure worldwide [39]. Sleeve gastrectomy was originally one component of the two-stage duodenal switch procedure; however, once the substantial weight loss achieved was recognized, it was developed as a standalone procedure. The increased popularity of sleeve gastrectomy has been attributed in part to the perception that it is faster and less technically challenging to perform than traditional procedures, such as RYGB, while producing similar weight loss and resolution of comorbidity. Sleeve gastrectomy is associated with a significant reduction in ghrelin as a result of resection of the gastric fundus, along with post-prandial increases in GLP-1 and peptide tyrosine-tyrosine (PYY), which play important roles in appetite modulation and glucose homeostasis [39]. Sleeve gastrectomy may be associated with the development of new-onset or worsening of pre-existing reflux, which should be discussed preoperatively [40]. There is also concern regarding the development of Barrett's metaplasia as a result, and endoscopic surveillance in the postoperative period is now recommended one year postoperatively and every two to three years thereafter [41].

Adjustable gastric banding

There has been a dramatic reduction in the use of adjustable gastric banding, accounting for only 3.3% of all bariatric procedures in the 2021 IFSO Global Registry Report [37]. The fall in popularity is largely attributable to the view that it leads to a lesser degree of weight loss and resolution of obesity comorbidity compared to other widely available procedures, while being associated with a relatively high reintervention rate. Nevertheless, it can produce weight loss of ~20%, which is nearly equivalent to other bariatric procedures, although this requires close follow-up that may not be achievable in most healthcare settings [42,43]. It is a relatively low-risk and reversible procedure and may still be considered in certain scenarios. Adjustable gastric banding may contribute to weight loss by promoting satiety during periods of fasting, likely mediated by vagal afferents [44].

Roux-en-Y gastric bypass

RYGB is a procedure that provides reliable weight loss and amelioration of obesity-related complications, particularly type 2 diabetes, with several RCTs supporting its use. It has decreased in popularity in recent years, in part due to its relative technical difficulty compared to sleeve gastrectomy, requiring the formation of two anastomoses. The mechanisms by which RYGB acts have been extensively investigated; it produces similar neurohormonal changes to sleeve gastrectomy, although perhaps with a more exaggerated response, with an increase in postprandial GLP-1 and PYY [45]. These changes have important effects on modifying the gut-brain axis controlling hunger, appetite, and satiety as well as mediating changes in bile acid metabolism [46]. In contrast to sleeve gastrectomy, which may produce worsening of reflux symptoms, RYGB is a treatment for people with obesity and reflux in its own right, and thus may be a more appropriate choice than sleeve gastrectomy in this specific context [47].

One anastomosis gastric bypass

One anastomosis gastric bypass (OAGB) has emerged as a simplified version of RYGB, involving the formation of a small gastric pouch and the anastomosis of a loop of jejunum to the stomach, forming a gastro-jejunostomy. Similar to RYGB, this procedure results in the bypass of the proximal small bowel; however, it does not require the formation of a second jejuno-jejunal anastomosis. An RCT with two-year follow-up demonstrated that it resulted in weight loss and resolution of type 2 diabetes that was non-inferior to RYGB [48]. In comparison to RYGB, there was a higher rate of nutritional complications as well as steatorrhoea. Concerns have also been raised about the worsening of gastro-oesophageal reflux following OAGB in those with preoperative symptoms of reflux, as well as the development of *de novo* gastro-oesophageal reflux in people with a prior diagnosis of hiatus hernia [49]. Evidence to support its use is limited as it is a relatively new procedure, and longer-term studies are needed to determine if weight loss and metabolic improvements are sustained in the long term.

Biliopancreatic diversion and duodenal switch

Although biliopancreatic diversion and duodenal switch is recognized as the procedure that produces the greatest degree of weight loss and long-term remission of type 2 diabetes, it is infrequently performed. Following biliopancreatic diversion and duodenal switch, people may lose >70% excess weight, and a 10-year follow-up study has demonstrated a diabetes remission rate of 50% compared with 25% following RYGB [50,51]. In spite of these rather impressive outcomes, this procedure accounts for only a small fraction of all procedures due in part to the technical challenge, but also as a result of the increased risk of both short- and long-term complications. In comparison to all other bariatric procedures, biliopancreatic diversion and duodenal switch has the highest associated 30-day mortality and one-year complication rate, which are attributable to pulmonary embolism and anastomotic leak, respectively [52]. Much of the weight loss following biliopancreatic diversion and duodenal switch is secondary to the relatively long segment of small bowel bypassed and very short (80–100 cm) common channel; however, this is also responsible for many of the long-term complications of the procedure related to nutrient deficiencies. People need to have lifelong nutrient supplementation and close follow-up monitoring, but even despite this they may remain deficient. A proportion will be refractory to treatment and up to 10% require reoperation to correct the ongoing micronutrient deficiency [53,54]. Iron, vitamin B₁ and B₁₂, folate, and fat-soluble vitamin levels are particularly problematic. The importance of close follow-up should not be underestimated, as nutrient deficiency may lead to irreversible complications, including Wernicke's encephalopathy and neuropathy.

Efficacy of bariatric surgery

There is a strong evidence base supporting the efficacy of bariatric surgery. The Swedish Obese Subjects (SOS) study, a prospective cohort study, has demonstrated the remarkable durability of weight loss in individuals undergoing bariatric procedures. Over a follow-up period of 20 years, people undergoing bariatric surgery maintained a mean change in body weight of -18%, which showed only a minor increase from the lowest point of -23% at two years post-operatively [55,56]. When comparing the two most commonly performed procedures, sleeve gastrectomy and RYGB, RCTs have shown that although there was greater weight loss and change in body mass index (BMI) following RYGB, the difference was not

statistically different [57,58]. Looking beyond weight loss, in comparison to matched individuals with obesity receiving usual care, there was a reduction in all-cause mortality, including that from cardiovascular events as well as certain forms of cancer [56].

Early perceptions of bariatric surgery as a procedure limited to weight loss alone have shifted as mechanistic studies have demonstrated that bariatric surgery has multisystem effects. The ability to reliably induce and maintain weight loss has provided a model to gain greater insight into and understanding of the impact of weight loss on obesity-related diseases, particularly type 2 diabetes. Through weight loss-dependent and -independent pathways, bariatric surgery results in the modification of several pathological processes driving the development of obesity, as well as reducing the risk of obesity-related complications. The rapid, metabolic changes induced by bariatric surgery are in part mediated by neurohormonal changes that result in rapid improvements in glycaemia in people with type 2 diabetes that are independent of weight loss. The findings from these mechanistic studies have been supported by more than 13 RCTs, which have consistently demonstrated the positive effects on glucose levels following bariatric surgery, irrespective of the procedure performed compared to medical treatment for type 2 diabetes and prior to the onset of weight loss [42,51,59–69]. As such, the second Diabetes Surgery Summit (DSS-II) developed guidelines that saw bariatric surgery as a key element in the treatment for type 2 diabetes in individuals with obesity. These recommendations have been endorsed by international governing bodies including the American Diabetes Association and the International Diabetes Federation as a central part of their management algorithms [70,71].

The adoption of a diabetes-focused model of care with metabolic surgery saw treatment targets being largely driven by improved glycaemic levels, with weight loss viewed as a secondary goal of treatment of lesser consequence. This view ignores the role of obesity in the underlying pathophysiology of type 2 diabetes, and studies have shown that bariatric surgery can modify several pathways contributing to the development of obesity. The modification of the gut–brain axis following bariatric surgery, altering the release of several critical gastrointestinal hormones implicated in the regulation of appetite and satiety, has been highlighted as of particular importance in mediating long-term weight loss maintenance by decreasing the symptoms of hunger associated with obesity. GLP-1 and PYY are both secreted primarily by L cells in the terminal ileum, and increased levels in the postoperative period have been implicated in the sustained weight loss produced following sleeve gastrectomy and RYGB [72]. Increased secretion of GLP-1 in the postoperative period is directly linked to the rapid improvements in glucose metabolism, but it also plays a role in appetite regulation. This effect is enhanced by PYY, a hypothalamic regulator of satiety that mediates decreased gastric acid secretion and delayed gastric emptying, both of which counteract some of the orexigenic effects mediated by falling leptin levels following bariatric surgery [73]. The alterations in gut hormones may also be potentiated by the anatomical bypass of the proximal small bowel, resulting in elevated plasma bile acids. Following RYGB, terminal ileal L cells are stimulated by the passage of undiluted bile acids, which produces a subsequent further increase in postprandial GLP-1 levels, contributing to increased satiety and weight loss maintenance in the postoperative period [46].

The improved glycaemic levels following bariatric surgery are related to both weight-independent mechanisms, such as alterations in neurohormonal signalling, and weight-dependent mechanisms. Although changes in the early postoperative period allowing rapid

improvements in glycaemic levels occur in a weight-independent manner, it is important to recognize the importance of weight loss in long-term control and remission. In conjunction with additional factors such as the duration of diabetes, age, and insulin use, the amount of weight lost in the postoperative period is a predictive factor in determining which individuals will sustain diabetes remission in the long term [74].

Long-term complications of bariatric surgery

Although bariatric surgery has consistently been demonstrated to be associated with low morbidity and mortality, there are recognized long-term sequelae. The specific complications and the likelihood of each are largely dependent on the procedure performed and the resultant anatomical and physiological changes.

Nutritional deficiencies

Long-term nutritional supplementation and close micronutrient monitoring are important for all people undergoing bariatric surgery, but particularly after biliopancreatic diversion and duodenal switch, given the higher risk of iron, folate, and fat-soluble vitamin deficiencies. These can lead to severe, irreversible complications such as Wernicke's encephalopathy and peripheral neuropathy. Even with supplementation, some may remain refractory to treatment and up to 10% will require reoperation due to nutrient deficiencies [53].

Metabolic bone disease

Following bariatric surgery, increased bone turnover and decreased bone mineral density coupled with micronutrient deficiencies, including vitamin D, contribute to a recognized increased risk of fracture [75]. The risk of both hip and wrist fractures appears to be higher following RYGB compared to sleeve gastrectomy or adjustable gastric banding; however, there was no increased risk compared to individuals with obesity [76,77]. The increased risk following RYGB highlights the importance of ongoing nutrient supplementation and monitoring.

Internal hernia

Sudden, severe-onset abdominal pain, nausea, or vomiting following RYGB or OAGB merits urgent investigation given the risk of internal herniation. Although the hernial defects are typically closed during both procedures, the loss of mesenteric fat in the postoperative period can result in an enlargement of the previously closed defect. Computed tomography (CT) scanning tends to show a typical swirling pattern, although studies have demonstrated that imaging is often falsely reassuring and diagnostic laparoscopy is recommended to definitively diagnose or rule out internal hernia [78,79].

Gallstone disease

There is an increased risk of developing gallstones following bariatric surgery due to the significant weight loss and alterations in enterohepatic circulation [80]; however, strategies such as concomitant laparoscopic cholecystectomy at the time of bariatric surgery are now rarely employed because of the increased risk of perioperative complications and prolonged hospital stay [81]. An RCT examining the use of prophylactic ursodeoxycholic acid in people with asymptomatic gallstone disease demonstrated no reduction in symptomatic gallstones following bariatric surgery [82]. Owing to the anatomical changes limiting access to the remnant stomach and duodenum, the management of gallstone disease with endoscopic retrograde cholangiopancreatography is more challenging following RYGB, but is still possible with surgical assistance if required.

Slipped gastric band

A slipped gastric band typically presents with upper abdominal or chest pain, nausea, and intolerance of oral intake. The underlying pathology is herniation of the distal stomach through the band with resultant proximal pouch dilatation [83]. Diagnosis can be made with an erect chest X-ray to quickly establish the band position, but a CT scan or oral contrast study may be more helpful. The initial management is band deflation, which should be done promptly to prevent ischaemia and necrosis. If the band cannot be deflated or symptoms continue, urgent surgical removal is required [84].

Bariatric surgery referral pathways

The referral pathways for bariatric surgery are largely based on the National Institutes of Health (NIH) guidelines issued in 1991, which have since formed the basis of most treatment guidelines. These recommendations are primarily guided by BMI, which is increasingly being recognized as a poor measure of the potential implications of obesity; however, it remains central to the decision-making process, in part due to pragmatic reasons [85]. There is an increasing focus on offering early intervention in those with obesity-related complications, particularly type 2 diabetes, in recognition of their impact on mortality, morbidity, and quality of life. The National Institute for Health and Care Excellence (NICE) recommendations for bariatric surgery according to BMI are shown in Table 38.2.

Referral pathways to weight management services vary, but generally follow a tiered approach, involving multidisciplinary team care. The tier system presents a means of offering structured treatment intensification with an increased level of support from members of the multidisciplinary team, including psychologists, dieticians, specialist nurses, endocrinologists, and surgeons. Involvement of the multidisciplinary team with a specialist weight management service is central to the delivery of personalized care and improves weight loss outcomes [86]. The tier system used in the UK National Health Service (NHS) is shown in Figure 38.1.

- Tier 1: primary care with community advice on weight loss measures.
- Tier 2: primary care with community interventions including dietary and exercise advice. Services may be delivered in a group setting.
- Tier 3: clinician-led (physician or GP with specialist interest in weight loss) multidisciplinary team to provide intensive weight loss support and advice, including a specialist nurse, specialist dietician,

Table 38.2 National Institute for Health and Care Excellence (NICE) recommendations for bariatric surgery according to body mass index (BMI) thresholds.

BMI threshold	Recommendation
$>50 \text{ kg/m}^2$	Bariatric surgery should be considered as first-line treatment over lifestyle intervention or pharmacotherapy
$>40 \text{ kg/m}^2$ or $35\text{--}39.9 \text{ kg/m}^2$ (with obesity-related comorbidity)	Bariatric surgery should be considered if lifestyle intervention and pharmacotherapy ineffective
$30\text{--}34.9 \text{ kg/m}^2$	Bariatric surgery should be considered if there is a diagnosis of type 2 diabetes in the past 10 yr
$27.5\text{--}29.9 \text{ kg/m}^2$	Bariatric surgery should be considered in people of Asian origin with recent onset of type 2 diabetes

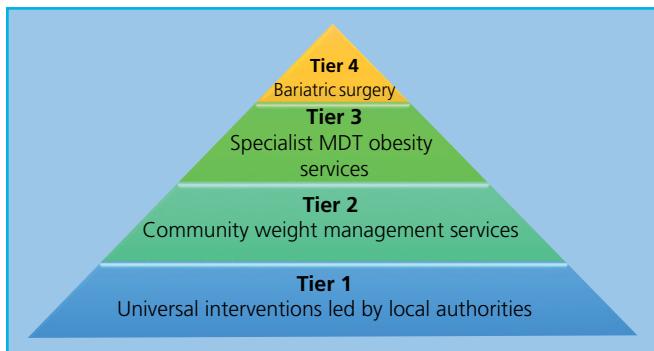

Figure 38.1 UK National Health Service tiered system for obesity care. MDT, multidisciplinary team.

psychologist, and physiotherapist. These services should be offered on a 1:1 basis.

- Tier 4: referral to obesity services for consideration for bariatric surgery.

Alternative pathways to manage obesity have been proposed to adopt a more flexible, personalized approach to care. Although the multidisciplinary team remains central to its delivery, a simplified two-tier system comprising a prevention and a treatment tier may

allow for the delivery of treatment most appropriate for the individual rather than requiring a mandatory stepped approach [87].

Conclusion

Although weight loss in itself presents a challenge for many individuals, what remains the most important element of obesity management for the purposes of health benefit is the period of weight loss maintenance. As illustrated by the Look AHEAD trial, this remains challenging with diet and lifestyle changes alone despite an initial period of weight loss. Weight loss interventions also tend to result in a lesser degree of weight loss in people with type 2 diabetes compared to those without, although the exact mechanisms responsible for this have not been elucidated. Having recognized the importance of glycaemic levels in individuals with type 2 diabetes, there has been a move away from weight-based treatment targets. It is increasingly acknowledged that weight loss is an important metric in its own right. Treatments aimed at weight loss and particularly those that mediate long-term weight loss maintenance modify the underlying disease processes related to obesity and may produce improvements in both morbidity and mortality associated with type 2 diabetes.

In-Hospital Treatment and Surgery in People with Diabetes

Ketan Dhatariya¹, Philip Newland-Jones², and Mayank Patel²

¹Norfolk and Norwich University Hospitals NHS Foundation Trust and University of East Anglia, Norwich, UK

²University Hospitals Southampton NHS Foundation Trust, Southampton, UK

Key points

- The number of people with diabetes in hospital continues to increase.
- Hyperglycaemia (particularly in those people not known to have diabetes prior to hospital admission or those experiencing stress hyperglycaemia) and hypoglycaemia are associated with increased levels of harm, defined using whatever measure is chosen.
- Levels of knowledge about diabetes among healthcare staff remain inadequate and levels of satisfaction about inpatient diabetes care remain low.
- The role and early involvement of a diabetes inpatient specialist team are stressed as an important factor in the education of people with diabetes and staff.
- Several national and international guidelines are now available to help teams manage this increasingly complex cohort of patients, and aim to achieve suitable glycaemic levels that avoid symptomatic hyperglycaemia or debilitating hypoglycaemia.
- The lack of robust data means that the target glucose concentrations for hospitalized individuals with diabetes have yet to be clearly determined.

Known diabetes in hospital

The prevalence of diabetes in the general population of Western Europe is approximately 6–7%, and is expected to rise significantly over the next 20–30 years [1]. The prevalence of diabetes in other parts of the world is much higher; in North America and the Caribbean it is reported to be between 10.5% and 11.1% overall, with some counties of the USA having a prevalence of 33% [1,2]. Having diabetes more than doubles the risk of being hospitalized for any given condition [3], which is reflected in the high prevalence of diabetes in hospitals. Data from the 2019 UK National Diabetes Inpatient Audit (NaDIA) showed that the prevalence of people with diabetes in hospital ranged from 8.3% to 31%, with a mean of 18.1% [4]. People with diabetes have a longer length of hospital stay and higher mortality rates than those without the condition [5]. This translates to greater costs; in the UK in 2010, it was estimated that diabetes accounted for over 10% of the entire budget of the National Health Service (NHS), with the excess costs of people with diabetes in hospital equating to between £573 million and £686 million per annum [6]. In the USA, data suggest that in 2017, 25% of the health budget was spent on diabetes, equating to \$327 billion, a rise of 25% (after adjusting for inflation) from 2012 [7,8].

Undiagnosed diabetes and stress hyperglycaemia in hospital

Aside from those with known diabetes prior to hospital admission, many people with hyperglycaemia are admitted without a prior diagnosis of diabetes. These include those with previously unknown diabetes but who continue to have hyperglycaemia after discharge. However, some people may develop transient hyperglycaemia during their inpatient stay that normalizes after discharge, so-called *stress hyperglycaemia* [9, 10]. The glucose values that represent stress hyperglycaemia vary, with some suggesting a fasting glucose level of $\geq 7.0 \text{ mmol/l}$ (126 mg/dl) or a random blood glucose level of $> 11.1 \text{ mmol/l}$ (200 mg/dl) [10], while the American Diabetes Association (ADA) and American Association of Clinical Endocrinologists (AACE) more recently defined it as any glucose level $> 7.8 \text{ mmol/l}$ (140 mg/dl) in an individual without a prior diagnosis of diabetes [3, 11]. Taken together, the number of people in hospital with either diabetes or transient hyperglycaemia is significant, with a prevalence of between 32% and 38% on general wards [12, 13] and between 28% and 80% of those with critical illness or undergoing cardiac surgery [13–17].

Pathophysiology of hyperglycaemia in acute illness

In fasting healthy individuals, glucose levels are usually maintained between 3.9 and 5.6 mmol/l (70 and 100 mg/dl). Glucose concentrations are finely controlled to match endogenous glucose production from the liver (with approximately 20% of the total coming from the kidneys) and glucose utilization by peripheral tissues [18–21]. The glucose concentrations are controlled by the balance of insulin and the counter-regulatory hormones, glucagon, catecholamines, growth hormone, and cortisol. At relatively low concentrations, insulin is a potent inhibitor of lipolysis, free fatty acid oxidation, and ketogenesis. As insulin concentrations increase, it lowers glucose concentrations, first by inhibiting hepatic gluconeogenesis and glycogenolysis, and then increasing peripheral glucose uptake and promoting glycogen synthesis. At even higher concentrations, insulin prevents protein breakdown and finally, at the highest concentrations, insulin acts to promote skeletal muscle formation [22,23].

Hyperglycaemia develops as a result of an imbalance between the glucose-lowering effect of insulin and the glucose-raising counter-regulatory response. Hyperglycaemia occurs as a result of (i) increased gluconeogenesis; (ii) accelerated glycogenolysis; and (iii) impaired glucose uptake and utilization in peripheral tissues [24]. The first two of these constitute the major contribution to hyperglycaemia. Skeletal muscle breakdown leads to an increased delivery of gluconeogenic precursors in the form of amino acids. Fat breakdown leads to an increased quantity of free fatty acids delivered to the liver. These effects may be exacerbated by prolonged starvation or during the fasting needed in the perioperative period [25]. In people without diabetes, a compensatory increase in insulin secretion helps to mediate against these catabolic effects. Without the glucose-lowering effects of insulin, the activity of gluconeogenic enzymes, in particular phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and pyruvate carboxylase, is increased [20,26]. During times of illness or stress, the increased concentrations of counter-regulatory hormones alter carbohydrate metabolism by inducing insulin resistance, increasing hepatic glucose production, and reducing peripheral glucose utilization [9,10]. A major consequence of severe hyperglycaemia is an osmotic diuresis that, if not countered, leads to dehydration and electrolyte disturbances, due to urinary loss of sodium, potassium, magnesium, and phosphate. The resulting increased plasma osmolality leads to a pro-coagulant state. In addition, hyperglycaemia results in raised concentrations of inflammatory cytokines and markers of oxidative stress such as tumour necrosis factor α , interleukin (IL)-6, IL-1 β , IL-8, and C-reactive protein [27–30]. These pro-inflammatory cytokines are associated with the development of insulin resistance by interfering with intracellular pathways downstream of the insulin receptor [27,29,31–34]. Furthermore, inflammatory cytokine concentrations fall when the glucose returns to normal [29].

There are other causes of hyperglycaemia that may be more specifically related to hospital admission [35]. These include co-administered medications such as enteral or parenteral nutrition, vasopressors, or corticosteroids. Almost 13% of all people in hospital were receiving corticosteroids, of whom 13% had a prior diagnosis of diabetes [36]. However, despite corticosteroid use being a cause of hyperglycaemia, which is associated with harm, only 20.8% of those on corticosteroids were having glucose monitoring [36]. In a recent study of people admitted with inflammatory

bowel disease and treated with steroids, 60% had a recorded episode of hyperglycaemia, including 57% who did not have a diagnosis of diabetes [37]. This issue is likely to become of greater concern with the evidence that corticosteroid use, in particular dexamethasone, reduces mortality in those admitted with moderate SARS-CoV-2 infection treated with oxygen therapy [38–42]. People with diabetes are at increased risk of being hospitalized with SARS-CoV-2 and their outcomes are worse than those without hyperglycaemia or diabetes [43–46]. Guidelines from the Joint British Diabetes Societies (JBDS) Inpatient Care Group in the UK and Diabetes UK are available to help tackle the management of hyperglycaemia and diabetes for those with or without Covid-19 infection [47,48].

Evidence of harm from in-hospital hyperglycaemia and effect of glucose lowering

Prior to the publication of large, randomized controlled trials in the 1990s, it had been well recognized that suboptimal diabetes management in ambulatory people with either type 1 diabetes or type 2 diabetes was associated with worse outcomes. The Diabetes Control and Complications Trial [49] and UK Prospective Diabetes Study [50] showed that interventions to improve glycaemic levels maintained over many years were associated with improved outcomes. In the world of hospitalized individuals with diabetes, there is compelling evidence that high blood glucose concentrations are associated with higher in-hospital morbidity and mortality, prolonged length of stay, unfavourable post-discharge outcomes, and significant excess healthcare costs in medical and surgical specialties [2,12,51–54]. Umpierrez et al. showed that individuals with new-onset hyperglycaemia had a striking 18-fold increase in in-hospital mortality, whereas people with known diabetes had a 2.7-fold increase in in-hospital mortality, compared with people with normoglycaemia [12]. In 2004, a joint position statement from the American College of Endocrinology (ACE) and the AACE on hospitalized individuals with diabetes and metabolic management concluded that hyperglycaemia in hospitalized individuals is a common, serious, and costly healthcare problem. There was a strong recommendation for early detection of hyperglycaemia and an aggressive management approach to improve outcomes [3]. In the UK, the JBDS has produced a series of guidelines on managing various aspects of diabetes care during hospital admission, which also recommend aggressive glucose management [48].

Hyperglycaemia, measured by glucose or glycated haemoglobin (HbA_{1c}), in the perioperative period is associated with poor outcomes in several surgical specialties, most often in those not previously known to have diabetes [53–59]. These poor outcomes include longer length of hospital stay and time in the intensive care unit (ICU), development of urinary tract and surgical site infections, and mortality. The reasons for these adverse outcomes are multifactorial, but include failure to identify those with diabetes and/or hyperglycaemia [60]; multiple comorbidities, including microvascular and macrovascular complications [61–67]; complex polypharmacy and insulin prescribing errors [68]; increased perioperative and post-operative infections [54,69,70]; associated hypoglycaemia and hyperglycaemia [54]; lack of or inadequate institutional guidelines for management of diabetes and/or hyperglycaemia during the admission [54,71]; and inadequate knowledge of diabetes and hyperglycaemia management among staff delivering care [72–74].

Having a diagnosis of diabetes prior to surgery is associated with a lowering of risk despite the hyperglycaemia [53, 54, 75], implying that the knowledge of diabetes is protective. It may be that people with diabetes have more attention paid to them, and thus have more contact with nursing and medical staff, which may mean that postoperative problems are picked up sooner [75]. What remains to be determined is whether it is the hyperglycaemia *per se* that causes the increased harm, or whether the high glucose is a marker for underlying disease severity.

While it is well established that perioperative hyperglycaemia is associated with harm, the association between high preoperative HbA_{1c} and outcomes is uncertain [76] because of a lack of high-quality prospective observational studies examining the relationship between HbA_{1c} and postoperative morbidity and mortality. The risks appear to increase when preoperative HbA_{1c} is >64 mmol/mol (8%), leading the UK JBDS guidelines to recommend a preoperative level of <69 mmol/mol (8.5%) [55].

There are increasing data, particularly from surgical specialties, to suggest that achieving optimal glycaemic levels during hospitalization is associated with improved outcomes [77, 78]. It was therefore surprising to see that the UK National Institute for Health and Care Excellence (NICE) suggest that there was little evidence to show that tight glucose management improves postsurgical outcomes in people with type 2 diabetes, or those not known to have diabetes, and that 'tight blood glucose control is not necessary for people in these two groups', although this likely represents the high level of evidence required by NICE to make solid recommendations [79]. For people with type 1 diabetes in the hospital, NICE recommends aiming for a blood glucose target of between 5.0 and 8.0 mmol/l [80]. Glycaemic targets are discussed in more detail in the next section.

Glycaemic targets for individuals with diabetes in hospital

The threshold for diagnosing hyperglycaemia during admission to hospital has been suggested as a random glucose >7.8 mmol/l (140 mg/dl) [11, 81]. In addition, it has been recognised that hypoglycaemia (i.e. blood glucose <4.0 mmol/l; 72 mg/dl) is associated with increased morbidity and mortality [82–84]. Hypoglycaemia is usually related to pre-existing comorbidities and the severity of intercurrent illness, rather than to medication use [85]. To reduce the impact of hypoglycaemia, there is a general consensus that glucose concentrations should not be allowed to fall below this threshold, although there are arguments that even 4.0 mmol/l is too low [86]. However, until recently the lack of robust data showing that aggressive glucose lowering reduces the excess morbidity and mortality associated with hyperglycaemia has meant that it has been difficult to reach an agreed consensus on what the target glucose concentrations should be in people with diabetes. Different targets have been suggested for different categories of inpatients, for instance those in the ICU compared with those on a general ward, or those due to undergo surgery.

Intensive care unit

A significant amount of work has been undertaken to establish the optimal glycaemic levels that are associated with the lowest morbidity and mortality since the first study published in 2001 on individuals in the surgical ICU in Belgium [17]. That study compared outcomes in over 1500 inpatients randomized to a group

given *usual care* – that is, glucose concentrations maintained between 10.0 and 11.1 mmol/l (180–200 mg/dl) – or treated with *intensive insulin therapy*, with glucose concentrations maintained between 4.4 and 6.1 mmol/l (80–110 mg/dl) and intravenous insulin given using an infusion pump. The mean glucose concentration in the usual care group was 8.5 mmol/l (153 mg/dl) and the mean concentration in the intensively treated arm was 5.7 mmol/l (103 mg/dl). Those randomized to the intensive insulin group did significantly better in all outcomes [17]. In particular, their mortality was reduced by 34%, but other outcome measures were also significantly improved, including less bacteraemia, less antibiotic use, shorter length of time on a ventilator, and fewer days in the ICU [17]. The authors then repeated the study in a medical ICU, with a mean glucose concentration in the intensively treated arm of 6.2 mmol/l (111 mg/dl), and showed that intensive insulin therapy was associated with a reduction in overall morbidity and a reduction in mortality if the stay on the ICU was over three days [83]. As a result of these two seminal studies, it had been suggested that the target for this cohort of inpatients should be between 4.4 and 6.1 mmol/l (80 and 110 mg/dl). However, subsequent attempts to reproduce these findings proved inconclusive, with most similar studies being unable to achieve similar reductions in morbidity or mortality [87–91]. Some of these subsequent studies were stopped early because of the significantly increased risk of harm due to the high frequency of severe hypoglycaemia [88–90].

In view of these and other findings, different recommendations have been published. A joint statement from the ADA and the AACE in 2014 recommended specific glycaemic targets in the ICU. They advocated for insulin initiation when glucose concentrations are persistently greater than 10.0 mmol/l (180 mg/dl), aiming for a glucose concentration between 7.8 and 10.0 mmol/l (140 and 180 mg/dl) [92]. They also suggested that in those centres with more experience in glucose management, a lower target of 6.1–7.8 mmol/l (110–140 mg/dl) may be appropriate provided that there is no increase in the incidence of severe hypoglycaemia [92]. By contrast, the Society of Critical Care Medicine in the USA recommends that glucose-lowering therapy is initiated once glucose levels rise above 8.3 mmol/l (150 mg/dl), and glucose concentrations should not be allowed to rise above 10.0 mmol/l (180 mg/dl) or drop below 3.9 mmol/l (70 mg/dl) [93]. Others have suggested that glycaemic targets vary according to a known or unknown diagnosis of diabetes [94], while there have been concerns that tight glycaemic management in critically ill individuals may do more harm than good [95].

A review of the literature on glucose levels in the ICU showed that there remained a wide variation in recommended targets, as well as methods to achieve them [96]. Of more concern, however, was a Chinese study reporting that many physicians did not know that hypoglycaemia in the people under their care was associated with harm, showing that more education was needed [97]. In summary, the issue of glycaemic targets in the ICU has yet to be resolved.

General wards

Studies from a variety of specialties show that hyperglycaemia in people in hospital is associated with negative outcomes [52, 98–101]; however, there is a paucity of good-quality data to inform the ideal targets for blood glucose in general wards. Until relatively recently, there were few data showing that optimizing glycaemic levels reduces the excess morbidity and mortality seen in hospital. Data are now emerging from surgical settings to show that achieving a glucose concentration of <8.3 mmol/l (150 mg/dl) is associated with

a lower risk of developing surgical site infection [78]. In the UK, the JBDS has published a series of consensus-based guidelines on several aspects of care for this increasingly large cohort [48]. It advocates that the target glucose concentration should be between 6.0 and 10.0 mmol/l (108 and 180 mg/dl), with a concentration of 4.0–12.0 mmol/l (72–216 mg/dl) being acceptable for medical patients and for conscious surgical patients, although the lower target of 4.0 mmol/l has recently been challenged [86]. The levels advocated by the JBDS are at slight variance with the USA, where the guidelines suggest targets for fasting glucose concentrations of <7.8 mmol/l (140 mg/dl) and a random glucose target of <10.0 mmol/l (180 mg/dl) [81]. Targets for those who are at the end of life are more relaxed (Chapter 73), aiming at avoiding symptomatic hypoglycaemia or hyperglycaemia, with concentrations of 6.0–15.0 mmol/l (108–270 mg/dl) being advocated in the UK [102] and similar but slightly lower levels in the USA [11].

Current recommended standards of hospital care for people with diabetes

Data from the USA in 2017 indicated that 38.7% of hospital bed days, accounting for an estimated 62.9 million days, were either attributable to or incurred by people with diabetes [7]. In the UK in 2019 people with diabetes occupied between 8.3% and 31% (mean 18.1%) of hospital beds [4]. Previous work from NaDIA and elsewhere has shown that the majority of people with diabetes were admitted for reasons other than diabetes, with ~90% admitted as an emergency [2, 103]. In addition, one in four people admitted with heart failure, heart attack, or stroke has diabetes [2].

Professional organizations from different countries publish recommended standards of hospital care. The International Diabetes Federation (IDF), an umbrella organization of more than 200 national diabetes associations in over 160 countries, offers a broad perspective on care relating to people with type 1 diabetes and type 2 diabetes during hospitalization, but acknowledges that not all countries have the infrastructure or resources to offer the same care standard for all. It therefore offers three care categories – recommended care, limited care, and comprehensive care – to which member organizations can benchmark [104, 105]:

- *Recommended care.* This is evidence-based care that is cost-effective in most nations with a well-developed service base, and with healthcare funding systems consuming a significant part of national wealth. Recommended care should be available to all people with diabetes and the aim of any healthcare system should be to achieve this level of care. However, as there are considerable variations in resources throughout the world, other levels of care are described that acknowledge low- and high-resource situations.
- *Limited care.* This is the lowest level of care that anyone with diabetes should receive, as standard medical resources and fully trained health professionals are often unavailable in poorly funded healthcare systems. However, even with limited and cost-effective resources, this level of care aims to achieve a high proportion of what can be achieved by recommended care. Only low-cost or high cost-effectiveness interventions are included at this level.
- *Comprehensive care.* This level of care includes the most up-to-date and complete range of health technologies that can be offered to people with diabetes, with the aim of achieving the best possible outcomes. However, the evidence base supporting the use of some of these expensive or new technologies is relatively weak.

Similar themes emerge when reviewing these documents relating to care, including the following:

- A diabetes diagnosis should be clearly identified in the hospital medical case records.
- All people with diabetes admitted to hospital should have their blood glucose level and HbA_{1c} measured, with results available to all members of the healthcare team.
- There should be an emphasis on insulin safety, particularly when using intravenous insulin infusion.
- Recommended blood glucose targets for people with diabetes in hospital should be stated, thereby reducing the risk of hypoglycaemia and hyperglycaemia.
- Discharge planning should be implemented on admission to hospital.
- Systems and policies should be in place that recognize the specific needs of people with diabetes in hospital.
- Each hospital should identify a clinical lead for inpatient care for people with diabetes.
- All people with diabetes should have access to a specialist inpatient multidisciplinary diabetes team.
- Staff caring for people with diabetes should be appropriately trained and competent in the management of inpatient diabetes.
- Diabetes self-management should be integrated into usual ward care.

Because of the ageing population, there are specific needs that also need to be considered. These are dealt with in more detail elsewhere [104, 106] (Chapter 72).

Minimizing length of stay

Reducing excess hospital length of stay is one of the principal aims of good care. Prolonged length of stay may occur for a multiplicity of reasons, but is often because of diabetes mismanagement secondary to inadequate staff knowledge and lack of education [72–74]. Insulin errors are associated with a longer hospital stay, and although it is recognized that certified diabetes educators (CDEs) and diabetes specialist nurses (DSNs) are effective in reducing length of stay, the majority of people with diabetes do not come into contact with these healthcare professionals during admission [107, 108]. The IDF and the ADA, as well as the JBDS in the UK, are among many organizations that have put discharge planning as a priority at the time of admission and not as an afterthought just prior to discharge [81, 109, 110]. Intervention by the diabetes inpatient team reduces the incidence of hypoglycaemia, reduces length of stay, and prevents 30-day readmission [111]. One systematic review and meta-analysis showed that reducing hypoglycaemia rates reduced length of stay by over four days [112].

Discharge planning defines the agreed management plan for that episode of care, including assessment and prompt referral to the specialist team if necessary, and can aid in anticipating and therefore preventing problems. When possible, this planning should be done in collaboration with the person with diabetes.

Patient safety

The issues surrounding inpatient safety focus predominantly on insulin and diabetes management errors, as well as the risks of infection or debilitation associated with extended length of hospital stay. Globally, insulin is one of the five highest-risk medications [113]. One-third of all hospital medical errors that cause death within 48 hours of the error involve insulin administration. Insulin medication errors can occur at any stage in the process of prescribing, preparing, and delivering the medication [114]. Errors

involving insulin infusion have been highlighted particularly in the last few years [103, 115]. In the UK, the 2019 NaDIA showed that 37.2% of those in hospital with type 1 diabetes and 40.3% of those with type 2 diabetes experienced an insulin-related drug error [4].

The UK National Patient Safety Agency reviews all medication errors, including those relating to insulin. In 2010, it published a six-year audit of reported insulin errors described as moderate and severe; 3881 reports were received and these included inpatient deaths [114]. It is well recognized that insulin errors occur because of the medication's complexity and its narrow therapeutic window. Initiatives to improve insulin prescribing and reduce these risks [116] include the introduction of electronic prescribing, while specialist diabetes pharmacists have been associated with lower error rates [117].

The use of sodium–glucose co transporter 2 (SGLT-2) inhibitors is beneficial for those with heart failure, and delays the progression of renal disease [118–124]. However, they increase the risk of dehydration, worsening renal function, and genital yeast infections. There is also a low but significant risk of developing euglycaemic or hyperglycaemic diabetic ketoacidosis (DKA). Although there are few data to support routine use of SGLT-2 inhibitors in the acute setting, if a person is already taking them prescribers should remain cautious, with a low threshold for temporarily discontinuing them [125].

Diabetes self-management

When not in hospital, people with diabetes are accustomed to managing their own condition. Traditionally, people with diabetes are disempowered in the management of their diabetes as soon as they are admitted, and for many this disempowerment is a negative experience [109, 126, 127]. The IDF has promoted the need for individuals to be enabled to self-manage their own condition [109]. Self-management includes the whole process of adjusting insulin treatment in response to self-measured glucose values [128]. The USA and UK have also set national standards defining the principles of self-management of diabetes, but there is general acceptance that there is no best practice education programme that meets the needs of all people with diabetes [129, 130].

Although this is an institutional decision, in principle individuals with diabetes in hospital should be given the opportunity to decide whether they wish to self-manage their condition during their admission, provided that they are well enough to do so. The key principle of self-management is that the person with diabetes has primary responsibility for making the decision about whether they should self-manage their own diabetes. Individuals suitable for self-management in hospital must be competent adults with a stable level of consciousness who successfully manage their diabetes at home. In addition, while in hospital it is advised that these people have the physical skills appropriate to self-administer insulin, be accustomed to performing glucose monitoring, and have adequate oral intake. In the event that self-care is deemed unsafe or impossible (e.g. critically ill, post-surgery, or unwillingness to self-manage), there must be a governance arrangement to assess their competency and, if necessary, supersede the individual's right to self-care. Hospitals should have a person-centred policy for diabetes self-management. Encouraging and supporting individuals to take as much responsibility for their diabetes management as they wish, and their clinical status allows, are likely to enhance the experience during a hospital stay [128, 131]. Part of this involves institutions providing written information for staff and patients to explain the responsibilities of self-management. For elective surgical patients, this written information may be provided at the time of

the pre-assessment clinic. In addition, for elective admissions, a care plan should be agreed at that time to establish whether the person with diabetes wishes to self-manage and the circumstances in which this may not be possible [128].

At the time of admission, the responsible nurse and the person with diabetes should again agree on the circumstances in which the individual with diabetes should or should not self-manage. Ideally, an agreement form should be signed by both the person with diabetes and the responsible nurse. People with diabetes should be able to monitor their glucose with their own glucose monitoring equipment, but results should be made available to hospital staff. For hospitals that utilize centrally uploaded glucose monitors, it is useful to maintain some monitoring on hospital equipment to allow system safety netting to continue. In addition, the technique for glucose testing and insulin administration should also be assessed. Once the person with diabetes has administered their own insulin, the dose self-administered should be recorded on the prescription chart, or an entry made on an electronic prescription by a member of staff.

To allow people with diabetes to keep and administer their own insulin, facilities should be available for safe storage of insulin and disposal of sharps in the ward environment. In addition, the institution should ensure that the timing and content of meals are suitable for people with diabetes; this is a common cause of unhappiness and dissatisfaction among those with diabetes [132].

It is important that clinical circumstances be regularly assessed during the admission to ensure that the individual's ability to self-manage has not been compromised by their clinical condition. If there are doubts or disagreements between the person with diabetes and the staff as to whether they can self-manage, then the diabetes specialist team may need to be involved.

Patient satisfaction

The experience of people with diabetes in hospital is important and plays a crucial role when developing local and national guidelines, but there is little in the worldwide literature evaluating experience during hospitalization. The UK has, however, gathered a large amount of information on patient satisfaction through two sources.

The Diabetes Inpatient Satisfaction Study was a cross-sectional study carried out in the UK measuring diabetes treatment satisfaction and its relationship to diabetes care in hospital by the validated Diabetes Treatment Satisfaction Questionnaire for Inpatients in over 1300 people with insulin-treated diabetes [132, 133]. Satisfaction with the general diabetes treatment was high, but there were high levels of extreme dissatisfaction with meal choices and quality, and lack of similarity of hospital meals to normal domestic choices: 23% would never or rarely have made similar meal choices at home.

Hyperglycaemia or hypoglycaemia was reported for much of the hospital stay (20% and 7%, respectively) and 26% reported at least one severe hypoglycaemic episode. More frequent hyperglycaemia or hypoglycaemia was associated with significantly poorer overall satisfaction scores and negative well-being scores and lower satisfaction with the timing of medication in relation to meals. Factors that were significantly associated with the highest levels of satisfaction were the amount of time spent with a diabetes inpatient specialist nurse (DISN) and insulin self-administration [132].

Satisfaction questionnaires were an integral part of NaDIA, which has run over several years [4]. The 2019 audit showed a wide variation in satisfaction scores between institutions, but a consistent finding was that the patient experience had worsened since

2011 in terms of meal choice, meal timing, and the individuals' perception of the knowledge of diabetes among the staff caring for them [4].

The role of the diabetes specialist team

The person with diabetes remains at the heart of the specialist team. Diabetes specialist inpatient teams are multidisciplinary and should include a consultant in diabetes with a specialist interest in inpatient care, who often is seen as the lead, working closely with DISNs or CDEs, diabetes dieticians, pharmacists, and specialist podiatrists. Extended foot team members should include orthopaedic and vascular surgeons, microbiologists, tissue viability nurses, and interventional radiologists. When necessary, rehabilitation teams should also be available. The specialist team should work together by individually contributing their specialist skills to provide a holistic approach to patient care. The success of such teamwork requires a culture that invests in excellent communication between the person with diabetes, diabetes specialists, and non-specialist teams to activate timely intervention to prevent glycaemic deterioration during the hospital stay.

Involvement of the specialist diabetes team, and in particular DISNs and CDEs, significantly reduces length of stay and insulin errors and improves the patient experience, while reducing readmissions [6, 107, 135–136].

A CDE is a health professional in North America who possesses comprehensive knowledge of and experience in diabetes management. Unlike the DISN in the UK, the role is not exclusive to nursing, but CDEs must have a relevant health-related degree and undergo extensive training. Both CDEs and DISNs educate and support people affected by diabetes to understand and manage the condition and promote self-management to achieve individualized behavioural and treatment goals that optimize health outcomes. Working in close partnership with people in the community, such as social workers, case managers, and home care coordinators, they are able to facilitate a smooth care pathway from hospital to home at discharge. The DSNs, who work exclusively in diabetes care, and the CDEs are also integral to providing ongoing staff training and may also be prescribers [107]. Aside from clinical care, they are frequently involved in medical and nursing education. Despite these numerous attributes, the 2019 NaDIA showed that almost one-fifth of UK hospitals do not have a DISN, while the number of hospitals offering inpatient dietetic or podiatry support is even worse [4].

Staff education

One of the key roles for the diabetes inpatient team is to educate ward-based non-specialist healthcare professionals and others, including paramedical, nursing, and medical students. Ward staff may have little or no protected time for education and training other than mandatory training defined by the employing organization. Despite the large numbers of people with diabetes in hospital, often the only mandatory training in diabetes is in blood glucose monitoring. People with diabetes, who may have a high level of knowledge about their condition, are therefore frequently managed by nursing and medical staff who only have a rudimentary knowledge and training in diabetes care [72–74, 137]. Hence it is the senior physicians who have the responsibility for educating junior medical staff, while the CDE and DISN teams are often best placed to offer education to ward-based staff because they can use the opportunity when reviewing patients to provide education to other non-specialist staff. Utilizing multiple professional groups, including medical, nursing, and pharmacy staff, to provide consistent safety messages to all professions will help to maximize the impact of education in a hospital setting.

Because so many people in hospital have diabetes, it is almost impossible for specialist team members to see every person on a regular basis. In the UK, specialist teams therefore have drawn up a priority list of those who should be referred for assessment (Figure 39.1); this can be adapted based on local need. Ward-based and specialist nursing staff in the UK have to undergo a revalidation process that includes ascertaining the views of the person with diabetes and demonstrating competency [137, 138].

Management of in-hospital hyperglycaemia

The ADA has stated that it is incumbent on organizations to ensure that diabetes is appropriately managed in hospital [81]. This sentiment is similar to one echoed by the now decommissioned NHS Institute for Innovation and Improvement in the UK, which said that it is as unacceptable for hospitals not to have a glycaemic management policy as it is for them not to have an infection control policy.

People with diabetes occupy a significant proportion of hospital beds, with one in six in the UK and about one in four in the USA [4, 7]. This does not include those who develop raised

glucose concentrations due to stress hyperglycaemia [10, 139]. The majority of people with diabetes are not admitted to hospital to address and treat complications associated with the diabetes. Management of blood glucose often becomes secondary to the care of the primary diagnosis requiring admission. In people without diabetes who develop dysglycaemia during an acute illness, high or low glucose levels are often ignored or treated inappropriately. Poor glycaemic management is common for many reasons [103]. Over the last decade or more, the issue of inpatient diabetes has become a higher priority, with the UK JBDS Inpatient Care Group producing different guidelines addressing various issues surrounding inpatient glycaemic management [48]. In the USA, the Partnership to Improve Diabetes Education (PRIDE) group was set up to address inpatient glycaemic management [140].

Medication to manage in-hospital hyperglycaemia

Because of the risks of ineffectiveness, the potential for drug-related side effects and toxicity, and the risk of hypoglycaemia, until recently oral agents had not been recommended for the management of hyperglycaemia in hospital [3, 11, 141]. Commonly, oral medication was stopped and intravenous insulin substituted because it provided the greatest flexibility in the hospital setting to achieve optimal blood glucose levels. However, it is increasingly recognized that the use of insulin and insulin secretagogues is associated with the development of severe hypoglycaemia [76, 142]. In addition, over the last 10 years studies have shown that some of the newer agents are safe within the hospital setting, leading to a change in recommendations. For those admitted to general medical and surgical wards or older people, appropriate oral medication, particularly dipeptidyl peptidase 4 (DPP-4) inhibitors [143–147], can work well, with or without basal insulin [148–150]. The risk of hypoglycaemia is low while managing mild to moderately raised glucose concentrations. The use of sitagliptin was also beneficial in a retrospective cohort study looking at people admitted with SARS-CoV-2 infection, where the addition of this drug at the time of admission was associated with a lower mortality compared to standard of care [151]. SGLT-2 inhibitor use in the outpatient setting has been associated with cardiovascular benefit, in particular with respect to heart failure and the progression of diabetes-related renal disease [118–123]. Use in the acute hospitalization setting remains controversial, because of the potential risk of dehydration, worsening renal function, and DKA. A small study looking at the use of empagliflozin in acute heart failure showed no change in dyspnoea, diuretic response, or NT-proBNP concentration [124]. However, it did show a reduction in urine output, leading to less heart failure and lower 60-day mortality rates [124]. A recent study looking at the use of dapagliflozin in people with and without diabetes admitted with Covid-19 infection and at least one cardiovascular risk factor showed no differences in outcomes compared to those given placebo [152]. These authors showed that the use of dapagliflozin was not associated with significant side effects, with only 2 people out of the 312 in the group given the drug who had diabetes developing ‘mild’ DKA, which resolved on withdrawal of the drug [152]. Because of the lack of robust evidence of benefit, routine use of SGLT-2 inhibitors in hospital is not recommended outside of a clinical trial setting [125].

With respect to insulin, Umpierrez et al. used more flexible insulin regimens, either with or without non-sulfonylurea oral agents, with some success in medical and surgical patients [153, 154]. Subcutaneous insulin given as a basal bolus regimen with correction bolus doses has also been used [154]. However, these regimens

require a degree of awareness and training among nursing and medical staff. Insulin administration errors are common and have been classified as a *never event* [155]. When incidents occur, they should be reviewed as part of a route cause analysis, regularly audited, and staff training put into place as necessary.

Technology

The use of technology to manage diabetes in hospital has evolved rapidly over the last few years, but remains some way from routine clinical use [156–159]. Trials of continuous glucose monitoring [160, 161] and the use of closed-loop systems have been conducted. Continuous subcutaneous insulin infusion use is not advocated in those who are unwell or unable to use the equipment [162]. Continuous subcutaneous insulin infusions complemented by implantable real-time glucose sensors have been used successfully in small studies [163–166]. They reduce the time spent in hypoglycaemia and also increase the time in range. The use of this technology is likely to become more frequent as the algorithms become more sophisticated, the risks of dysglycaemia lessen, and the cost of the technology falls sufficiently to make it cost-effective to use regularly [156].

Subcutaneous and intravenous insulin protocols

The ideal intravenous or subcutaneous insulin protocol should be safe, understandable, easily ordered, and readily implemented. It should be effective in correcting hyperglycaemia quickly and in maintaining glucose levels within a defined target range. If insulin is given intravenously, the provision of an easy-to-follow algorithm for making incremental changes to the infusion rate, which can be executed by nursing staff, is likely to improve the efficacy of the protocol.

The terms *variable-rate intravenous insulin infusion* (VRIII) and *fixed-rate intravenous insulin infusion* (FRIII) are preferred owing to the potential ambiguity associated with the term *sliding scale*. VRIII should only be used in situations where the person with diabetes is very sick, during labour and delivery, or when the person is unable to eat or drink normally. Whether the individual has previously recognized diabetes or not, insulin provides the greatest flexibility to meet rapidly changing requirements in different hospital settings to achieve optimal blood glucose levels. The indications for an intravenous insulin infusion are shown in Box 39.1 [167].

Box 39.1 Indications for an Intravenous Insulin Infusion

Hyperglycaemia in:

- Those with known diabetes or with hospital-related hyperglycaemia unable to take oral fluid/food and for whom adjustment of their own insulin regime is not possible.
- Vomiting (exclude diabetic ketoacidosis).
- Nil by mouth and will miss more than one meal.
- Severe illness with need to achieve optimal glycaemic levels, e.g. sepsis.

Special circumstances:

- Acute coronary syndrome (follow local guidelines).
- Total parenteral nutrition/enteral feeding.
- Steroid use.
- Pregnancy.

Glucose (mmol/l)	Insulin rates (ml/h) ^a (start on standard rate unless otherwise indicated) ^b		
	Reduced rate (for use in insulin-sensitive individuals, e.g. ≤24 units/day)	Standard rate (first choice in most individuals)	Increased rate (for insulin-resistant individuals, e.g. ≥100 units/day)
<4.0	0	0	0
4.1–8.0	0.5	1	2
8.1–12.0	1	2	4
12.1–16.0	2	4	6
16.1–20.0	3	5	7
20.1–24.0	4	6	8
>24.1	6	8	10

^a Using 50 units of human soluble insulin in 49.5 ml of 0.9% sodium chloride solution gives a concentration of 1 unit/ml.

^b If the individual normally takes basal subcutaneous insulin, continue this alongside the variable-rate intravenous insulin infusion.

The scales may be customized as necessary.

Source: Modified from George et al. 2015 [167].

FRIII should only be used when treating hyperglycaemic crises, DKA, or hyperosmolar hyperglycaemic syndrome (HHS) [24, 48]. The use of insulin regimens where the dose administered is dependent on the capillary glucose concentration with the insulin given intravenously or subcutaneously as the only means of managing a raised glucose concentration has been soundly discredited, but disappointingly continues [167–170]. Basal bolus regimens of subcutaneous insulin have been used successfully to manage glucose levels on medical and surgical wards [11, 154, 172].

How insulin is given is also a subject of contention. There is evidence for the use of a *basal plus* regimen, where a single daily dose of basal insulin is given along with six-hourly corrective doses of rapid-acting insulin if the person is not eating or drinking, or if glucose concentrations are high before meals [173, 174]. Twice-daily mixed subcutaneous insulin regimens have previously been advocated [3, 175], but their use is associated with high rates of iatrogenic hypoglycaemia, especially in the context of variable oral intake [176].

To use insulin safely requires a certain level of understanding, which is lacking among many junior medical staff, students, and nurses [72–74]. This may be why there is reluctance among junior medical staff to prescribe subcutaneous insulin earlier, even when glucose concentrations remain high.

Hypoglycaemia is a potential complication of intensified insulin therapy and is associated with poor outcomes. Thus intravenous insulin infusions should be supported by caloric input when glucose concentrations drop. In most people, this is in the form of a simultaneous infusion of glucose-containing fluid, but calories can be provided by other routes (e.g. enteral, parenteral, or in dialysis fluid). If the patient was taking a long-acting basal insulin (human or analogue) prior to admission, then this should be continued, because continuation of the background insulin prevents rebound hyperglycaemia or development of ketosis when the intravenous insulin is stopped [177].

Preparation and delivery of an intravenous insulin infusion

An intravenous insulin infusion is prepared by adding 50 units of soluble insulin to 49.5 ml of 0.9% sodium chloride solution, providing 1 unit of insulin in 1 ml, which is delivered via an infusion

pump. This insulin infusion can be piggy-backed into the glucose infusion using a three-way connector and a non-return valve. This is most often given as a variable-rate intravenous insulin infusion; it can be given as an FRIII, but this is limited to treatment of DKA or HHS (Table 39.1).

Transition from intravenous to subcutaneous insulin

Conversion to subcutaneous insulin should only be undertaken when the individual is able to eat and drink normally without nausea or vomiting. The most appropriate time to switch from intravenous to subcutaneous insulin is at the usual time of the person's subcutaneous insulin administration before a meal; however, when possible, this should not be done before the evening meal. People with type 1 diabetes will become insulin deficient within minutes of an intravenous infusion being stopped because of the short half-life of intravenous insulin. It is therefore good practice to continue the infusion of insulin for approximately 60 minutes after the subcutaneous insulin has been administered to allow time for the insulin to be absorbed [167].

If the person with diabetes has been on an established insulin regimen that has worked well, then this regimen should be restarted, but doses may have to be adjusted depending on the clinical condition. If the individual is new to insulin therapy, or if the previous regimen provided inadequate glycaemic levels (e.g. as evidenced by a raised HbA_{1c}), then a rough estimation of the total daily dose (TDD) of insulin required can be made from a simple calculation using the hourly rates delivered in the intravenous insulin infusion. Estimation of insulin doses can also be made according to body weight, which is useful in calculating TDD requirement in individuals who are new to insulin but have not required an insulin infusion (Table 39.2 and Box 39.2).

Avoiding and treating in-hospital hypoglycaemia

Hypoglycaemia, the commonest side effect of insulin and sulphonylurea treatment, represents a major barrier to satisfactory long-term glycaemic management. The other drug classes – that is, biguanides,

Box 39.2 Converting from Intravenous to Subcutaneous Insulin

Step 1

Calculate the total daily dose (TDD) using either of two methods: weight based, or using the dose delivered for the last sixhours using a variable-rate intravenous insulin infusion (VRIII).

In frail, older individuals, those with renal failure (chronic kidney disease stage 4 or 5) or severe hepatic failure, or those with newly diagnosed type 1 diabetes:

$$\text{TDD} = 0.3 \times \text{body weight in kg}$$

All other adults:

$$\text{TDD} = 0.5 \times \text{body weight in kg}$$

Ideally, 24hours of data should be utilized to make the calculation, but if this is not available then all available data on hourly

insulin requirements should be used. For example, if six hours of data are available, then the calculation is as follows:

Total dose of insulin administered in the last 6 hours of the VRIII / 6 = average hourly dose Average hourly dose × 20 (not 24, to reduce risk of hypoglycaemia) = estimated TDD

Step 2

Use the TDD to convert the individual to either a premixed twice-daily insulin regimen or a multiple basal bolus dose regimen.

For a basal bolus regimen, 50% of the TDD is usually given as basal insulin, and the remainder as rapid-acting insulin, divided equally between breakfast, lunch, and evening meal.

For a twice-daily, premixed insulin regimen, individuals usually need 60% of the TDD at breakfast and the remaining 40% with the evening meal.

Source: Modified from George et al. 2015 [167].

thiazolidinediones, DPP-4 inhibitors, SGLT-2 inhibitors, and glucagon-like peptide 1 (GLP-1) receptor agonists – are unlikely to result in hypoglycaemia owing to their modes of action, unless co-prescribed with insulin or sulfonylureas. Hypoglycaemia should be excluded in any person with diabetes who is acutely unwell, drowsy, unconscious, unable to cooperate, or presenting with aggressive behaviour or seizures. In-hospital hypoglycaemia is defined as a blood glucose level ≤ 3.9 mmol/l (70 mg/dl) [81]. Hypoglycaemia in hospital is widespread and coupled with insufficient knowledge of how to detect and manage it [82, 142].

Frequency of hypoglycaemia in hospital

Hypoglycaemia is given as the primary cause of hospital admission in about 5% of all people admitted with type 1 diabetes, and 1.5% of those with type 2 diabetes [178]. The 2019 UK NaDIA showed that 16.5% of people with diabetes in hospital experienced one or more hypoglycaemic episodes with a blood glucose less than 3.0–4.0 mmol/l (54–72 mg/dl), with 6.8% experiencing one or more hypoglycaemic episodes below than 3.0 mmol/l (54 mg/dl), and 1.4% requiring rescue treatment with intravenous glucose or intramuscular glucagon [4].

Farrokhi et al. reported a prevalence of severe hypoglycaemia ranging from 5% to 32% in those treated with insulin [179]. The highest proportion of episodes took place overnight (34.3%), between 9 p.m. and 9 a.m., when snack availability was likely to have been lowest; these observations have been confirmed elsewhere [180]. People treated with sulfonylureas were more likely to experience hypoglycaemia than those using insulin (75.3% vs 59.3%) [103, 180, 181].

The tight glycaemic levels achieved in ICUs led to much higher reported rates of hypoglycaemia, with the incidence of blood glucose ≤ 2.2 mmol/l (40 mg/dl) ranging from 5% to 18.7% [83, 87, 89, 182].

Causes of in-hospital hypoglycaemia

Common causes of hypoglycaemia are listed in Table 39.3. One of the most serious and common causes of hypoglycaemia is insulin prescription errors, including misreading poorly written prescriptions, such as when U is used for units (e.g. 4 U becoming 40 units), or confusing the insulin name with the dose (e.g. Humalog Mix25 becoming Humalog 25 units). The advent of electronic prescribing may be responsible for the small reductions in prescribing errors

reported by NaDIA [103]. Risk factors for hypoglycaemia include older age (>70 years), cognitive impairment, nephropathy, insulin or sulfonylurea treatment, being of Black, Asian or minority ethnic groups, raised C-reactive protein, being admitted as an emergency, and having low sodium or albumin concentrations [181, 184, 185].

Mortality and length of stay associated with in-hospital hypoglycaemia

Lake et al. published a systematic review and meta-analysis on the effects of hypoglycaemia during a hospital admission [112]. They found that experiencing a blood glucose of <4.0 mmol/l (72 mg/dl) led to an increased length of stay of 4.1 days (95% confidence interval [CI] 2.36 to 5.79) compared to those who did not. In addition, the relative risk (RR) of mortality was double (RR 2.09; 95% CI 1.64 to 2.67) [112]. Those experiencing an episode of hypoglycaemia had a 66% increased risk of death within one year, compared to those with no hypoglycaemia [186].

Management of in-hospital hypoglycaemia

People experiencing hypoglycaemia require prompt treatment with quick-acting carbohydrate to return their blood glucose levels to the normal range. The quick-acting carbohydrate should be followed by giving long-acting carbohydrate, either as a snack or as part of a planned meal. When it is safe to do so, a blood glucose measurement should be taken to confirm hypoglycaemia (especially if there is any suspicion that the person may be currently under the influence of alcohol or non-prescription drugs). If measurement is difficult (e.g. during a seizure), then treatment should not be delayed.

Adults who have suboptimal glycaemic levels may start to experience symptoms of hypoglycaemia at blood glucose levels >4.0 mmol/l (72 mg/dl), but the thresholds for cognitive dysfunction are unaffected; therefore, the only reason for treatment is symptomatic relief. Hence adults who are experiencing hypoglycaemia symptoms but have a blood glucose level >4.0 mmol/l (72 mg/dl) should be treated with a small carbohydrate snack only, such as a medium banana, a slice of bread, or a normal meal if due. All adults with a blood glucose level <4.0 mmol/l (72 mg/dl) with or without symptoms of hypoglycaemia should be treated as shown in Figure 39.2.

When rescue treatment is required, intramuscular glucagon should only be given once. It should not be given to those with a

history of known liver disease, or those with depleted glycogen reserves (e.g. alcohol excess), because it will likely be considerably less effective. A new formulation of intranasal glucagon has recently become available that has a similar efficacy to the intramuscular formulation [187]. When intravenous glucose is required 10% glucose is preferred, because retreatment rates were the same as those for 50% glucose, with lower risk of extravasation injury and lower likelihood of resultant high blood glucose concentrations [183, 188].

Evidence for treatment options

There is limited evidence regarding the quantity of quick-acting carbohydrate required to treat an episode of hypoglycaemia successfully. The initial quantities chosen were the result of expert consensus subsequently backed up by glucose clamp studies [189, 190]. Subsequent work has shown that ~20 g of rapid-acting carbohydrate is often sufficient, with less than 10 g likely to be inadequate [191, 192]. Chocolate- and sucrose-containing foods should be avoided, because the high fat content in chocolate slows gastric emptying, thus delaying absorption, and sucrose needs to be cleaved by intestinal disaccharidases prior to absorption [193, 194]. Fresh fruit juice or glucose-containing tablets or gel remain the most frequently used treatment for hypoglycaemia and are an essential component of Hypoboxes, which are commercially available [183, 190, 195]. The suggested contents of a Hypobox can be found in Box 39.3.

All hypoglycaemic events should be documented in the clinical records. The underlying cause of hypoglycaemia should be investigated and risk of recurrence reduced where possible. Regular capillary blood glucose monitoring should be continued for 24–48 hours. The person with diabetes should be told to continue this at home if they are to be discharged. Hypoglycaemia education should be given or a referral made to the DISN/CDE.

Box 39.3 Suggested Contents of a Hypobox

- A copy of the locally agreed hypoglycaemia algorithm (laminated and attached to the inside of the lid)
- 2 × 200 ml cartons of fruit juice
- 2 packets of glucose tablets
- 1 mini-pack of biscuits (source of long-acting carbohydrate)
- 3 tubes (one box) of glucose gel
- 20% glucose intravenous solution (100 ml vial)
- 1 × 18G intravenous cannula
- 1 × 16G intravenous cannula
- 1 × 10 ml sterile syringe
- 3 × 10 ml 0.9% sodium chloride solution ampoules for flush
- 1 × 21G sterile needle
- Chlorhexidine spray/alcohol wipes
- 1 dressing cover for the intravenous cannula
- 10% glucose for intravenous infusion (500 ml bag)
- Audit form
- Instructions on where to send the audit form and replenish supplies
- 1 glucagon pack: to be kept in the nearest drug refrigerator or labelled with a reduced expiry date of 18 months if it is stored at room temperature

Surgery in people with diabetes

Perioperative and postoperative hyperglycaemia is associated with short- and long-term harm, which has been reported in many settings, including general surgery [53, 54], cardiac surgery [196], vascular surgery [197, 198], neurosurgery [199], orthopaedic surgery [200, 201], colorectal surgery [202], trauma [203], breast surgery [204], liver transplantation [205], hepatobiliary and pancreatic surgery [206], cholecystectomy [207], burns [58], and foot and ankle surgery [208]. These harms include surgical site infection [59], length of time in hospital, acute kidney injury, myocardial infarction, time spent in an ICU or on a ventilator, and death. The perioperative mortality rate is up to 50% higher than in people without diabetes [54]. In addition, people with diabetes are less likely to be offered day-case surgery, are more likely to have emergency surgery, have longer lengths of stay following admission, and have a higher rate of 28-day readmission following surgery [209]. Thus, there is an imperative to optimize glycaemic levels prior to surgery and around the time of the operation. However, for elective surgery this optimization would require a great deal of coordination between all the teams and individuals involved in the care of the person with diabetes. In the UK, the National Confidential Enquiry into Patient Outcome and Death conducted a study into perioperative care and showed that there were several parts of the patient journey that could be improved [61]. Its recommendations are listed in Table 39.4.

Currently, there is a lack of good communication between primary care and surgeons when referring for elective surgery [60, 61]. This is important, because individuals who have been identified as having diabetes prior to surgery have a significantly lower risk of poor outcomes, regardless of their glycaemic levels [53]. This may be because of the improved communication between staff. Furthermore, if an individual is treated with an intravenous insulin infusion, it is likely that they will have more frequent contact with nursing staff, if only to have a capillary glucose measurement taken. Indeed, pooled data from a large number of Veterans Affairs (VA) hospitals in the USA suggested that people known to have diabetes were more likely to have their glucose checked postoperatively (with higher preoperative HbA_{1c} being associated with a higher number of tests) [75]. In addition, those with higher postoperative glucose concentrations were more likely to go onto insulin [75]. Hence if complications do occur, they may be picked up at an earlier stage.

In the UK, the JBDS guideline for the perioperative management of adults with diabetes recommends that the glucose targets for patients undergoing surgery are to keep levels between 6.0 and 10.0 mmol/l (108 and 180 mg/dl), with an acceptable range of 4.0–12.0 mmol/l (72–216 mg/dl) in the awake surgical patient [55]. In those who are asleep, or unable to communicate, the risk of developing hypoglycaemia increases at the lower limit, hence the range is recommended to be 6.0–12.0 mmol/l (108–216 mg/dl) [86, 210]. The USA and other countries do not yet have similar guidelines, although given the recent evidence that a perioperative HbA_{1c} level of >8.0% (64 mmol/mol) is associated with greater harm, organizations may begin to address this in the future [140, 211].

Due to the greatly increased risk of postoperative complications associated with hyperglycaemia, it may be necessary for units to adopt a policy to measure a capillary glucose level in at-risk individuals at the preoperative assessment clinic or at the time of acute admission, to ensure that those with undiagnosed hyperglycaemia,

Table 39.4 List of recommendations around peri-operative diabetes care made by the UK National Confidential Enquiry into Patient Outcome and Death in its report on perioperative diabetes care.

1. Write and implement a national joint standard and policy for the multidisciplinary management of patients with diabetes who require surgery.
2. Appoint a clinical lead for perioperative diabetes care in hospitals where surgical services are provided.
3. Use a standardized referral process for elective surgery to ensure appropriate assessment and optimization of diabetes.
4. Ensure that patients with diabetes undergoing surgery are closely monitored and their glucose levels managed accordingly.
5. Ensure a safe handover of patients with diabetes from theatre recovery to ward, which should be documented in the case notes.
6. Develop a preoperative assessment clinic policy and standards for the management of patients with diabetes. These should be developed by the lead anaesthetist and the clinical lead for perioperative diabetes management.
7. Ensure that patients with diabetes attending a preoperative assessment clinic prior to elective surgery have (i) access to the diabetes multidisciplinary team; and (ii) written instructions regarding their diabetes management plan prior to surgery.
8. A clinical lead for day surgery should be in place in all hospitals providing day surgery services.
9. Cancellation of elective surgery in patients with diabetes should be avoided, particularly for known clinical reasons.
10. Develop and implement referral criteria for surgical inpatients with diabetes to members of the diabetes multidisciplinary team members as required.
11. Record and monitor the time at which a patient begins fasting (for surgery or clinical reasons).
12. Prioritize patients with diabetes on the operating list to avoid prolonged starvation.
13. Provide patients with diabetes with education and information about their diabetes management at discharge from hospital as part of the discharge planning process.

either diabetes or stress hyperglycaemia, can be identified early and appropriately treated promptly.

Potential mechanisms of beneficial effects of glucose lowering in surgical settings

Although the data to show that lowering blood glucose is beneficial in surgical patients are only emerging now, it is well recognized that insulin has several beneficial effects on the inflammatory cascade that are independent of its metabolism-regulating effect. These effects include reducing the degree of oxidative stress by its action on free radical production and clearance [213], and also beneficial effects on reducing pro-inflammatory cytokine levels in addition to improving white cell and endothelial function [213–215]. These effects may be in part responsible for the reduction in surgical site infections and reduced mortality seen when optimal glucose concentrations are maintained [78, 216]. What constitutes *optimal glycaemic management*, however, varies between studies [216].

The role of primary care in supporting diabetes care before elective surgery

The patient journey for elective surgery usually starts with a primary care assessment and referral to the surgeons [55]. A study of 1919 referrals made to all surgical specialties across 11 hospitals across one week in the East of England showed that communication between primary and secondary care at the time of referral for a

surgical opinion is poor [60]. There were 8.8% of referrals for people with diabetes (compared to the 6.5% prevalence of diabetes in the general population). Of those taking a glucose-lowering agent, 22% had diabetes mentioned as a comorbidity in the letter. Only 7.7% of those with diabetes had a recent HbA_{1c} documented, and 11.8% had the medication listed [60]. While a meta-analysis suggested that there was no relationship between HbA_{1c} and outcomes in surgical patients [217], studies have shown that improving glycaemic management reduces the risk of developing surgical site infections [78].

In the absence of randomized controlled trials, the current guidelines are pragmatic because it is well recognized that high-risk surgical patients are often older and have multiple coexisting medical conditions. Attempts to lower glycaemic levels aggressively may be associated with harm in the form of hypoglycaemia. However, HbA_{1c} levels >64 mmol/mol (8%) are associated with poor outcomes [211] and the UK National Guidelines suggest that HbA_{1c} should be <69 mmol/mol (8.5%) [55]. Hence it is incumbent on the primary care provider to optimise glycaemic levels prior to referral, if possible, or after referral is made, to reduce the risk of the procedure being cancelled or postponed owing to hyperglycaemia and the risk of harm postoperatively. The information provided by the primary care team should help the surgeon when individuals are seen in the surgical outpatient clinic.

Preoperative assessment

If the decision is made to operate, then the surgeon should communicate the presence of diabetes to the preoperative assessment team, the anaesthetists, and the operating list planners, so that the patient may be placed early on a theatre list to minimize starvation time and subsequent metabolic disturbance. This would also increase the likelihood that they could be same-day admissions. In addition, the provision should be made for postoperative admission to critical care, if this is indicated, especially with people who are at high risk and with suboptimal glycaemic levels.

The opportunity to optimize preoperative glycaemic levels should be taken, either by referring back to the primary healthcare team responsible for their diabetes or using a DSN or CDE as necessary [209]. The management of other comorbidities should also be optimized. There should be good lines of communication between the pre-assessment team and the surgical team, such that the patient is aware when they are due to come in, where they are due to go, and what time their surgery is. They should also have explicit written instructions on how to manage their diabetes medication. These are shown in Tables 39.5 and 39.6.

Many people with diabetes in the UK have been inappropriately denied day-case surgery [6]. This means that these individuals are unnecessarily admitted to hospital for an overnight hospital stay, adding to the cost burden, in the belief that being in hospital will lead to glycaemic optimization. However, the reality is likely to be that the person is admitted to a ward the evening prior to surgery, when there are fewer nursing staff available, treated with a VR III, and looked after by one of the most junior members of the medical team, who may have inadequate levels of knowledge of diabetes management [72–74]. More recently, initiatives have been put into place in many institutions to improve perioperative care [218, 219].

Hospital admission

During the hospital admission, it is important that the individualized care plan is communicated to all staff involved in the care of the person with diabetes and that all efforts are made to minimize the metabolic consequences of starvation and surgical stress. Work

Table 39.5 Guidelines for perioperative adjustment of insulin.

	Insulins	Day prior to admission	Morning surgery	Afternoon surgery
Long-acting insulin	Once-daily long-acting (morning) (e.g. Hypurin®, Bovine Lente, Lantus®, Levemir®, Tresiba®, Insulatard®, Humulin I®, Insuman Basal®, Abasaglar®, Toujeo®, Semglee®, Xultophy®)	Doses should remain unchanged	Dose will need to be reduced by 20% and blood glucose should be checked on admission	Dose will need to be reduced by 20% and blood glucose should be checked on admission
	Once-daily long-acting (lunchtime) (e.g. Hypurin®, Bovine Lente, Lantus®, Levemir®, Tresiba®, Insulatard®, Humulin I®, Insuman Basal®, Abasaglar®, Toujeo®, Semglee®, Xultophy®)	Dose will need to be reduced by 20%	Restart insulin at normal dose when eating and drinking	Restart insulin at normal dose when eating and drinking
	Once-daily long-acting (evening) (e.g. Hypurin®, Bovine Lente, Lantus®, Levemir®, Tresiba®, Insulatard®, Humulin I®, Insuman Basal®, Abasaglar®, Toujeo®, Semglee®, Xultophy®)	Dose will need to be reduced by 20%	No dose adjustment necessary	No dose adjustment necessary
	Twice-daily long-acting (e.g. Hypurin®, Bovine Lente, Lantus®, Levemir®, Tresiba®, Insulatard®, Humulin I®, Insuman Basal®, Abasaglar®, Toujeo®, Semglee®, Xultophy®)	Morning dose will need to stay the same Evening dose will need to be reduced by 20%	Morning dose will need to be reduced by 20% and blood glucose should be checked on admission Evening dose will remain unchanged	Morning dose will need to be reduced by 20% and blood glucose should be checked on admission Evening dose will remain unchanged
Premixed insulin	Twice-daily premixed (e.g. Novomix 30®, Humulin M3®, Humalog Mix 25®, Humalog Mix 50®, Insuman Comb 15®, Insuman Comb 25®, Insuman Comb 50®, Hypurin Porcine 30/70 Mix®)	Morning and evening doses should remain unchanged	Halve usual morning dose. Blood glucose should be checked on admission Resume normal insulin with evening meal	Halve usual morning dose. Blood glucose should be checked on admission Resume normal insulin with evening meal
	Three times per day premixed (e.g. Novomix 30®, Humulin M3®, Humalog Mix 25®, Humalog Mix 50®, Insuman Comb 15®, Insuman Comb 25®, Insuman Comb 50®, Hypurin Porcine 30/70 Mix®)	Doses should remain unchanged	Halve usual morning dose. Blood glucose will be checked on admission Omit lunchtime dose Resume normal insulin with evening meal	Halve usual morning dose. Blood glucose should be checked on admission Omit lunchtime dose Resume normal insulin with evening meal
Mixture of short- and intermediate-acting insulin	Twice-daily (two different types of insulin) combined by the patient into one injection	Morning and evening doses should remain unchanged	Calculate the total dose of both morning insulins and give half of this total dose as intermediate-acting insulin only, in the morning	Calculate the total dose of both morning insulins and give half of this total dose as intermediate-acting insulin only, in the morning
	Short-acting (e.g. Insuman Rapid®, Humalog®, Actrapid®, Hypurin® Bovine Neutral, Hypurin® Porcine Neutral, NovoRapid®, Humulin S®, Apidra®, Fiasp®, Lyumjev®)		Blood glucose should be checked on admission	Blood glucose should be checked on admission
	AND intermediate-acting (e.g. Hypurin® Bovine Isophane, Hypurin® Porcine Isophane, Insulatard®, Humulin I®, Insuman Basal®)		Resume normal insulin with evening meal	Resume normal insulin with evening meal
Short-acting insulin	Short-acting insulin with meals (2–4 doses a day) (e.g. Insuman Rapid®, Humalog®, Actrapid®, Hypurin® Bovine Neutral, Hypurin® Porcine Neutral, NovoRapid®, Humulin S®, Apidra®, Fiasp®, Lyumjev®)	Doses should remain unchanged	Omit morning dose if no breakfast is eaten Blood glucose should be checked on admission Omit lunchtime dose if not eating and drinking normally Resume normal insulin with evening meal	Take usual morning insulin dose with breakfast Omit lunchtime dose if not eating Blood glucose should be checked on admission Resume normal insulin with evening meal

Resume taking normal insulin the morning after surgery (procedure). However, blood glucose may be higher than usual for a day or so.

If a variable-rate intravenous insulin infusion is used, then the dose of long-acting insulin should be reduced by 20%. Short-acting, intermediate, and pre-mixed insulins should be discontinued. Normal insulin doses should be recommenced when that person is eating and drinking normally.

At the preoperative assessment clinic, all individuals should have emergency treatment for hypoglycaemia written on their drug chart, i.e. 40% glucose gel, and 20% glucose rapid-acting insulin should also be prescribed.

If the patient requires an ongoing variable-rate intravenous insulin infusion, then the long-acting background insulin should be continued but at 80% of the usual dose. Normal insulin doses should be recommenced when the person is eating and drinking normally.

Table 39.6 Guidelines for perioperative adjustment of non-insulin medication.

Diabetes medication	Day prior to admission	Timing of surgery		
		Morning surgery	Afternoon surgery	If a VRIII is being used
Acarbose	Take as normal	Omit morning dose if not eating	Give morning dose if eating	Stop if VRIII running, do not restart until eating and drinking normally
Meglitinide (repaglinide or nateglinide)	Take as normal	Omit morning dose if not eating	Give morning dose if eating	VRIII running, do not restart until eating and drinking normally
Metformin (eGFR >60 ml/min/1.73 m ² and procedure not requiring use of contrast media, or major liver surgery ^a)	Take as normal	If taken once or twice a day – take as normal If taken three times per day, omit lunchtime dose	If taken once or twice a day – take as normal If taken three times per day, do not take lunchtime dose	VRIII running, do not restart until eating and drinking normally
Sulfonylurea (e.g. glibenclamide, gliclazide, glipizide, glimepiride)	Take as normal	Omit on morning of surgery If taken twice daily, take evening dose	Do not take on day of surgery	VRIII running, do not restart until eating and drinking normally
Pioglitazone	Take as normal	Take as normal	Take as normal	VRIII running, do not restart until eating and drinking normally
DPP-4 inhibitor (e.g. sitagliptin, vildagliptin, saxagliptin, alogliptin, linagliptin)	Take as normal	Take as normal	Take as normal	VRIII running, do not restart until eating and drinking normally
GLP-1 receptor agonist (e.g. exenatide, liraglutide, lixisenatide, dulaglutide, semaglutide)	Take as normal	Take as normal	Take as normal	Take as normal
SGLT-2 inhibitor ^b (e.g. dapagliflozin, canagliflozin, empagliflozin, ertugliflozin)	Take as normal	Do not take on day of surgery	Do not take on day of surgery	Omit until eating and drinking normally
Sotagliflozin (an SGLT-1/2 inhibitor)				

The person with diabetes should resume taking their normal tablets the morning after surgery if they are eating and drinking normally.
Warn the person with diabetes that their blood glucose control may be erratic for a few days after the procedure.
In the case of major liver surgery (i.e. removal of three or more liver segments), then metformin should be stopped 48 h prior to surgery.

DPP-4, dipeptidyl peptidase 4; eGFR, estimated glomerular filtration rate; GLP-1, glucagon-like peptide 1; NBM, nil by mouth; SGLT-2, sodium–glucose co transporter 2; VRIII, variable-rate intravenous insulin infusion.

^a If contrast medium is to be used and eGFR <60 ml/min/1.73 m², metformin should be omitted on the day of the procedure and for the following 48 h.

^b If there is likely to be a period of reduction in oral intake prior to a procedure – e.g. colonoscopy – then the drug should be omitted starting on the day of the reduced intake. This may mean omitting the drug the day prior to the procedure, as well as the day of the procedure. US and other guidelines recommend stopping SGLT2 inhibitors 72 hours prior to a planned procedure.

Source: Modified from Dhatariya et al. 2015 [55].

has shown that adequate staff education can be difficult to achieve [220–222]. At the same time, optimal glycaemic levels should be achieved using the standard of care for that institution, such as a basal bolus insulin regimen [154, 173]. The principles of the enhanced recovery after surgery programme should be put into place. However, the role of preoperative carbohydrate loading in people with diabetes remains controversial [223]. When the starvation time is short – that is, less than one missed meal – there is no need for a VRIII; however, if the starvation period is likely to be longer, then one should be *in situ* and the use of long-acting insulin should be continued to prevent rebound hyperglycaemia when the intravenous insulin regimen is stopped [177]. During the entire admission, pressure areas, including heels and feet, should be regularly inspected.

In the operating theatre and recovery

While the person with diabetes is in theatre and in recovery, glucose and electrolyte concentrations should be monitored and normoglycaemia should be maintained [225]. The use of

multimodal analgesia with an appropriate antiemetic to permit an early return to a normal diet and the usual diabetes regimen is paramount, although the use of dexamethasone in this situation remains a matter for debate [225].

Postoperative period

Several factors influence glycaemic levels in the postoperative period, including a variation in nutritional intake, the discontinuation of the usual blood glucose-lowering medication, the decrease in physical activity, the increase in stress hormones, and the presence of infection or pain. It is therefore important that glycaemic levels are maintained in addition to fluid and electrolyte balance and that pain and postoperative nausea and vomiting are controlled.

Hospital discharge

In the preoperative stage and prior to hospital discharge, it is important to identify factors that may delay discharge from hospital and to make the necessary arrangements to allow the person to go back to their usual place of care once medically fit. The person

should be made aware that the metabolic and endocrine effects of surgery may last for several days because of ongoing changes in the amount that they eat, their activity levels, and the levels of stress hormones. The person should be advised that their blood glucose management may need to change for some time postoperatively and that more frequent monitoring may be required. The diabetes specialist team or usual provider of diabetes care should be involved in this discussion.

Emergency surgery

For those requiring emergency surgery where preoperative glycaemic optimization is not possible, the use of a VR III is likely to be necessary, trying to maintain a blood glucose level between 6.0 and 10.0 mmol/l (108 and 180 mg/dl). This should be continued until the person is eating and drinking normally. Some individuals who are not known to have diabetes may develop transient hyperglycaemia (so-called stress hyperglycaemia) [9, 10]. These individuals should be treated just as aggressively as people known to have diabetes, because their risk of postoperative complications is far higher than in those who were previously known to have diabetes [53, 54, 226].

Continuous subcutaneous insulin infusions (pumps)

The use of an insulin pump depends on the length of surgery and the length of starvation. If the length of starvation is short – that is, less than one missed meal – the pump therapy can usually be continued and the person should remain on their basal rate until they are eating and drinking normally [227]. Regular blood glucose testing is necessary. If, however, the starvation period is likely to be prolonged, then the pump should be discontinued and a VR III started. If there is a period of post- or perioperative hypotension, or significant use of inotropes, then peripheral skin perfusion may be compromised, thus reducing the absorption of insulin given subcutaneously and possibly necessitating treatment with a VR III, especially if the person is unable to self-manage. If the insulin pump has been discontinued and replaced with a VR III, the insulin pump should be restarted once the person is eating and drinking normally and the VR III should be discontinued 30 minutes after the first mealtime bolus.

There remains some uncertainty about the use of continuous subcutaneous insulin infusion (CSII) during an operation. The use of a diathermy in close proximity to the pump may interfere with its function, so the pump should be placed as far away as possible. Pump manufacturers suggest avoiding pumps when a diathermy is being used, but strategies have been developed to try to use them safely [228, 229].

Glucocorticoid use

Prior to the Covid-19 pandemic and the evidence that glucocorticoid use reduces morbidity and mortality in the infected population [38–42], the prevalence of steroid use in hospitals was estimated to be approximately 13% [36]. The use of steroid treatment in people with pre-existing diabetes is likely to result in worsening glucose levels, which is termed steroid-induced hyperglycaemia. This rise warrants temporary additional, and more active, glycaemic management. A rise in glucose level may occur in

people without a known diagnosis of diabetes, and this is termed steroid-induced diabetes. It may or may not resolve when the steroids are withdrawn. Short courses of steroids resulting in minimal periods of hyperglycaemia may not warrant intervention, although higher-dose steroids, for longer periods, may result in significant symptomatic hyperglycaemia with the potential for acute complications [230]. Hence addressing the hyperglycaemia may reduce these risks.

Steroid therapy: impact on blood glucose

Steroids may be administered by various regimens and at variable doses. A single daily dose of steroid (e.g. prednisolone/prednisone) in the morning is the commonest mode of administration. In susceptible individuals, this will often result in a rise in blood glucose by late morning that continues through to the evening. Overnight, the blood glucose generally falls back to baseline levels by the next morning. Therefore, treatment should be tailored to treating the hyperglycaemia, while avoiding nocturnal and early-morning hypoglycaemia.

Multiple daily doses of steroid, be it intravenous hydrocortisone or oral dexamethasone, can cause a hyperglycaemic effect throughout the 24-hour period. A twice-daily premixed or basal bolus regimen may be needed if oral medication or once-daily insulin proves insufficient to treat the hyperglycaemia. Close attention should be paid to blood glucose monitoring and early intervention may be necessary.

Glucose levels in most individuals can be predicted to rise ~4–8 hours following the administration of oral steroids, and sooner following the administration of intravenous steroids. Again, capillary blood glucose monitoring is paramount to guide appropriate therapeutic interventions. Conversely, glucose levels may improve to pre-steroid levels 24 hours after intravenous steroids have been discontinued. If oral steroids are weaned over several weeks, the glucose levels may decline in a dose-dependent fashion, but this may not occur, particularly in those with previously undiagnosed diabetes.

Monitoring

At the commencement of steroid therapy, or for those already on a supraphysiological dose of corticosteroid, capillary blood glucose testing should be initiated twice daily, prior to breakfast and perhaps most appropriately prior to the evening meal, when the hyperglycaemic effect of a morning dose of steroid is likely to be greatest.

Medication options for people taking steroid therapy

Non-insulin therapies

Given their mode of action, a short-acting sulfonylurea taken once daily may best manage the glucose excursion associated with a once-daily oral steroid. The dose of sulfonylurea may be maximally titrated in the morning to reduce the risk of hypoglycaemia. Intuitively, pioglitazone may seem an appropriate choice to manage steroid-induced hyperglycaemia; however, the evidence base for its use is weak [231]. There are currently no data to support the use of GLP-1 receptor agonists or DPP-4 inhibitors; however, their mode of action may suggest that they would be beneficial in this circumstance. A study examining the effect of dapagliflozin in steroid-induced hyperglycaemia showed no benefit [232].

Insulin therapies

Morning administration of intermediate-acting basal human insulin may closely fit the glucose excursion induced by a single morning dose of oral steroid. Basal insulin analogues may be appropriate if hyperglycaemia is present for more prolonged periods. However, care should be taken to identify and protect against hypoglycaemia overnight and in the early morning if long-acting insulin analogues are used in this context. In those taking multiple steroid doses per day, a basal bolus regimen may be considered to be the best option.

Hospital discharge

When an individual is discharged from hospital on steroid therapy, a clear strategy for the management of hyperglycaemia or potential hyperglycaemia, and the titration of therapy to address the hyperglycaemia, should be communicated to the community diabetes team (if available) and primary care team. Individuals commenced on steroids in hospital and discharged after a short stay with the intention of continuing high-dose steroids should receive standard education regarding diabetes, encompassing the risks associated with hyper- and hypoglycaemia, such as dysglycaemia-related symptoms on which to seek advice.

If steroids are discontinued prior to discharge, and hyperglycaemia persists, then capillary blood glucose (CBG) testing should be continued on discharge until normoglycaemia returns or until a definitive test for diabetes is undertaken (HbA_{1c} , fasting glucose, or oral glucose tolerance test). If steroid treatment is ceased in hospital and CBG tests are in the normal range, then post-discharge testing is not recommended. A definitive test for diabetes should still be undertaken at least six weeks after steroid cessation.

Steroid treatment in end-of-life care

People with diabetes at the end stages of life have a unique set of clinical needs (Chapter 73). Steroid therapy is frequently used in palliative care for symptom control, usually as dexamethasone or prednisolone/prednisone. The hyperglycaemia associated with once-daily steroid therapy can often be managed by morning administration of a long-acting sulfonylurea, or morning intermediate-acting basal human insulin. However, if steroids are taken twice daily, it is probable that an alternative approach will be needed. Twice-daily short-acting sulfonylurea or isophane insulin can be effective, but there is a risk of early-morning hypoglycaemia. If hypoglycaemia is a concern, a once-daily long-acting insulin analogue given in the morning may be a safer, less complex regimen, especially for those new to insulin.

Short-term courses (<3 days) of steroids may only require closer CBG testing, but longer courses will require a review of glucose-lowering therapy and may result in a switch from oral agents to insulin. In the latter situation, an intermediate-acting basal human insulin given once daily could be considered. In those without a diagnosis of diabetes prior to the commencement of steroids, CBG testing and patient and carer education should be undertaken.

Hospital readmission

Readmission for those with diabetes is common, with hypoglycaemia and hyperglycaemia during acute hospital admission being risk factors [51]. Work has been done to identify what interventions are

available to minimize the risk of readmission, which include the provision of specialist diabetes teams, whole-system embracement of recognition of the need to improve diabetes during hospitalization with a hospital-wide approach, continuous quality improvement programmes, and good communications between secondary and primary care on discharge [233].

Foot care

In the UK, the diabetic foot remains the commonest cause for a diabetes-specific acute hospital admission [103], and it was estimated that in 2014–2015 ~£1 in every £110 spent by the NHS in England was on diabetes-related foot disease [234], much of this on in-hospital care (Chapter 53). A multidisciplinary foot team, including a specialist podiatrist, diabetologist, vascular and orthopaedic surgeon, interventional radiologist, tissue viability nurse, microbiologist, DSN/CDE, and orthoptist, leads to better outcomes [235–237]. Specialist diabetes podiatrists provide the best value when considering admission avoidance, reducing length of hospital stay, and lowering amputation rates [238, 239].

The general principles for foot care in people with diabetes should apply to all admissions, not just those with active foot disease. These measures include taking a specific foot history and an inspection of the feet, looking for evidence of neuropathy, ischaemia, ulceration, inflammation, and/or infection, deformity, or Charcot neuroarthropathy. It is important to take the shoes, socks, and any dressings off the feet to inspect any underlying wounds, ensuring that pressure areas are healthy. The feet should be inspected daily during the hospital stay and any new problems should be managed in conjunction with the specialist diabetes foot multidisciplinary team.

Conclusions

People with diabetes are twice as likely to be admitted to hospital and stay twice as long as those without diabetes. They have worse outcomes and a poorer experience than those without diabetes. Given the large numbers of people with diabetes in hospital, and the considerable excess costs associated with their care, diabetes inpatient care is now being taken more seriously. However, although there is a wealth of evidence that specialist inpatient diabetes teams reduce length of stay, reduce errors in prescribing, and improve the patient experience and clinical outcomes, many institutions still lack teams specializing in inpatient diabetes.

There are numerous national and international guidelines that should make the inpatient care of people with diabetes easier to achieve. Much work remains to be done to provide more evidence to substantiate the consensus opinions within the guidelines, but as more evidence accrues showing which interventions work, the excess morbidity and mortality seen in this cohort of patients should reduce to equal those of individuals without diabetes. Until more evidence is available, it remains incumbent on those delivering the care to ensure that an attitude of nihilism is avoided – *the absence of evidence does not mean the absence of effect*. All attempts should be made to achieve suitable glycaemic levels, while avoiding symptomatic hyperglycaemia or debilitating hypoglycaemia.

Key points

- Iatrogenic hypoglycaemia is a key limiting factor in the glycaemic management of diabetes. It occurs during treatment with a sulfonylurea, a glinide, or insulin.
- The key physiological defences against falling plasma glucose concentrations are decrements in insulin and increments in glucagon and epinephrine. The behavioural defence is carbohydrate ingestion prompted by symptoms that are the result of both sympathetic neural activation and neuroglycopenia.
- Hypoglycaemia in diabetes is the result of therapeutic hyperinsulinaemia. As glucose levels fall, increments in glucagon are lost because of β -cell failure in type 1 diabetes and advanced type 2 diabetes. In that setting, attenuated increments in epinephrine cause the syndrome of defective glucose counter-regulation.
- Attenuated increments in sympathetic neural activity largely bring about the syndrome of impaired awareness of hypoglycaemia. The failure to recognize impending hypoglycaemia is largely because the glucose threshold for sympathoadrenal activation falls below that for cognitive impairment.
- The main causes of defective glucose counter-regulation and impaired awareness of hypoglycaemia in diabetes include duration of diabetes, residual β -cell reserve, repeated episodes of hypoglycaemia, antecedent exercise, or sleep.
- Impaired awareness of hypoglycaemia and reduced sympathoadrenal activation are in part reversible in many individuals with diabetes. This may result from as little as 2–3 weeks' scrupulous avoidance of hypoglycaemia. Running high glucose levels does not provide additional benefit and is unnecessary.
- The risk factors for hypoglycaemia are related to this pathophysiology and include both relative and absolute therapeutic insulin excess, complete endogenous insulin deficiency, a history of severe hypoglycaemia, impaired awareness of hypoglycaemia, antecedent exercise, sleep, alcohol, and medication.
- This pathophysiology explains why the incidence of iatrogenic hypoglycaemia increases over time in type 2 diabetes, approaching that in type 1 diabetes. Most episodes of hypoglycaemia occur in people with type 2 diabetes, reflecting the larger numbers affected by type 2 diabetes globally.
- Minimizing the risk of iatrogenic hypoglycaemia requires acknowledging the problem, educating and empowering people with diabetes to effectively self-manage while applying the principles of flexible intensive insulin therapy, and addressing the risk factors. This includes agreeing individualized glucose targets, taking into account age, life expectancy, comorbidities, and the wishes of the person with their diabetes.
- Advances in diabetes technology including insulin analogues, continuous glucose monitoring, insulin pumps, and hybrid closed-loop systems have considerable potential to reduce hypoglycaemic risk. They appear more effective when combined with education that teaches effective self-management.
- Some individuals continue to experience recurrent severe hypoglycaemia despite structured education and the use of technology. Specifically designed psycho-educational approaches may offer a useful additional option.
- Maintenance of individualized glycaemic targets that can be accomplished safely in a given individual at a given stage of their diabetes journey is in the person's best interest. Concerns about hypoglycaemia should not be an excuse for suboptimal glycaemic management.

Overview of the clinical problem

Iatrogenic hypoglycaemia is one of the main limiting factors in the glycaemic management of diabetes [1]. It causes negative biological, psychological, and social consequences in most people with type 1 diabetes and in many with advanced type 2 diabetes. Indeed, as well as provoking substantial morbidity, hypoglycaemia is sometimes fatal. Episodes of hypoglycaemia compromise physiological and behavioural defences against subsequent falling plasma glucose

concentrations and thus induce a vicious cycle of recurrent hypoglycaemia. By preventing attainment of relative euglycaemia, hypoglycaemia deprives people with diabetes of the proven benefits of keeping close to target glucose levels.

Hypoglycaemia in diabetes is fundamentally iatrogenic, and essentially a side effect of pharmacokinetically imperfect treatments with an insulin secretagogue (e.g. a sulfonylurea or a glinide) or with exogenous insulin causing hyperinsulinaemia. This is often combined with a mismatch in the amount of carbohydrates consumed or in special situations, for example during physical exercise,

following excessive alcohol, or in groups that are particularly vulnerable, such as during pregnancy, at the extremes of age, in people with impaired awareness of hypoglycaemia, and those with comorbidities such as hepatic or renal impairment. Thus, hypoglycaemia is typically the net result of relative or absolute therapeutic insulin excess and compromised physiological and behavioural defences against falling plasma glucose [1].

In this chapter, we first explore physiological homeostatic mechanisms that prevent hypoglycaemia through glucose counter-regulation, before discussing specific acquired defects of glucose counter-regulation in diabetes, which provides an insight into risk factors for hypoglycaemia. We then discuss the size of the clinical problem followed by the biological impact of hypoglycaemia, with a specific focus on both neurological and cardiovascular consequences. Finally, we discuss hypoglycaemia in children and adolescents, including how hypoglycaemia can be approached in clinical practice, prior to providing an overall perspective on where additional research is required to address current and future needs of people with diabetes.

Hypoglycaemia and the brain

The brain relies on glucose as an obligate oxidative fuel under physiological conditions and, despite the average brain only constituting ~2% of total body weight, cerebral function accounts for 20% of whole-body glucose utilization [1–4]. The brain is almost entirely dependent on a continuous supply of glucose from the circulation for normal function. This is because it cannot synthesize glucose, utilize physiological concentrations of circulating non-glucose fuels such as amino acids, ketones, and lactate effectively, or store more than a few minutes' supply as glycogen [1,5]. This requires the plasma glucose concentration to be maintained within a tight homeostatic range to allow facilitated diffusion of sufficient glucose via glucose transporters (GLUT) across the blood–brain barrier (GLUT1) and into neurones (GLUT3) to maintain critical cerebral function. Hypoglycaemia of sufficient depth causes functional brain failure through disruption in adenosine triphosphate (ATP) and creatine phosphate metabolism, two key substrates for brain function [3,6]. Perturbations in cerebral function are initially reversible; however, with severe prolonged hypoglycaemia there is complete depletion of ATP and creatine phosphate, which can cause permanent cerebral damage and even death [3,6]. This explains both the vulnerability of individuals to hypoglycaemia and the array of defences that have evolved as a stress response to maintain near-normal plasma glucose concentrations.

Responses to hypoglycaemia

Falling plasma glucose concentrations cause a sequence of responses in individuals without diabetes termed *counter-regulatory responses* (opposing the regulatory effects of insulin) (Figure 40.1) [1,7–11]. The first physiological response, which occurs as plasma glucose concentrations decline, is a decrease in insulin secretion followed by release of glucagon and epinephrine, which increase endogenous glucose concentrations by stimulating gluconeogenesis and glycogenolysis (Figure 40.2). Lower plasma glucose levels cause a more intense sympathoadrenal (sympathetic neural and adrenomedullary) response that reduces peripheral glucose utilization and inhibits insulin secretion, in addition to triggering symptoms that prompt a behavioural response and ingestion of food. Raised cortisol and growth hormone concentrations stimulate gluconeogenesis and reduce peripheral glucose utilization, but since subsequent increases in blood glucose lag in time, these responses are less

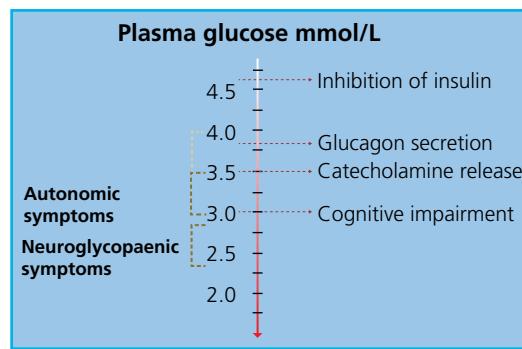

Figure 40.1 Hierarchical counter-regulatory responses to hypoglycaemia.

Source: Created by A. Iqbal in Biorender.com.

relevant in acute counter-regulation of hypoglycaemia [13]. Even lower plasma glucose concentrations cause functional brain failure, which is on a clinical continuum ranging from deficits in executive function to coma and even death [3].

Clinical manifestations of hypoglycaemia

The symptoms and signs of hypoglycaemia are not specific [10,14]. Thus, in clinical practice it can be helpful to evaluate hypoglycaemia using Whipple's triad:

- Symptoms, signs, or both, consistent with hypoglycaemia.
- A low, reliably measured plasma glucose concentration.
- Resolution of those symptoms and signs after the plasma glucose is raised.

Symptoms of hypoglycaemia can be broadly categorized into neuroglycopenic and neurogenic symptoms. Neuroglycopenic symptoms occur as a result of impaired cerebral function and include cognitive impairment, loss of concentration, confusion, behavioural changes, and psychomotor abnormalities and, at lower plasma glucose concentrations, seizures and coma [1,3,10,14]. Neurogenic symptoms occur in response to activation of both the sympathetic (palpitations, tremulousness, and arousal/anxiety) and parasympathetic (sweating, hunger, and paraesthesia) components of the autonomic nervous system in response to hypoglycaemia [10,14]. Central mechanisms may also be involved in some of the latter symptoms, such as hunger that prompts a behavioural response to consume food [15]. Awareness of hypoglycaemia is at least in part the result of the perception of neurogenic symptoms [10], which are more prominent at the diagnosis of diabetes, but with time neuroglycopenic symptoms become more prominent.

Signs of hypoglycaemia include pallor and diaphoresis, the result of adrenergic cutaneous vasoconstriction and cholinergic activation of sweat glands, respectively [1]. Neuroglycopenic manifestations are often observable and those affected may complain of confusion or loss of concentration.

Counter-regulation during hypoglycaemia

Given the near-total dependence of the brain on a normal and stable systemic glucose concentration and the serious consequences of hypoglycaemia on cerebral function, a tight systemic glucose balance is maintained under physiological conditions. Bidirectional fluxes in plasma glucose that could result in hypoglycaemia or hyperglycaemia are prevented. This is achieved through homeostatic regulation of endogenous glucose production, principally in the liver but also in the kidneys, and this is balanced with peripheral glucose utilization by skeletal muscle [1,6]. Insulin plays a key role in regulating endogenous glucose production and peripheral

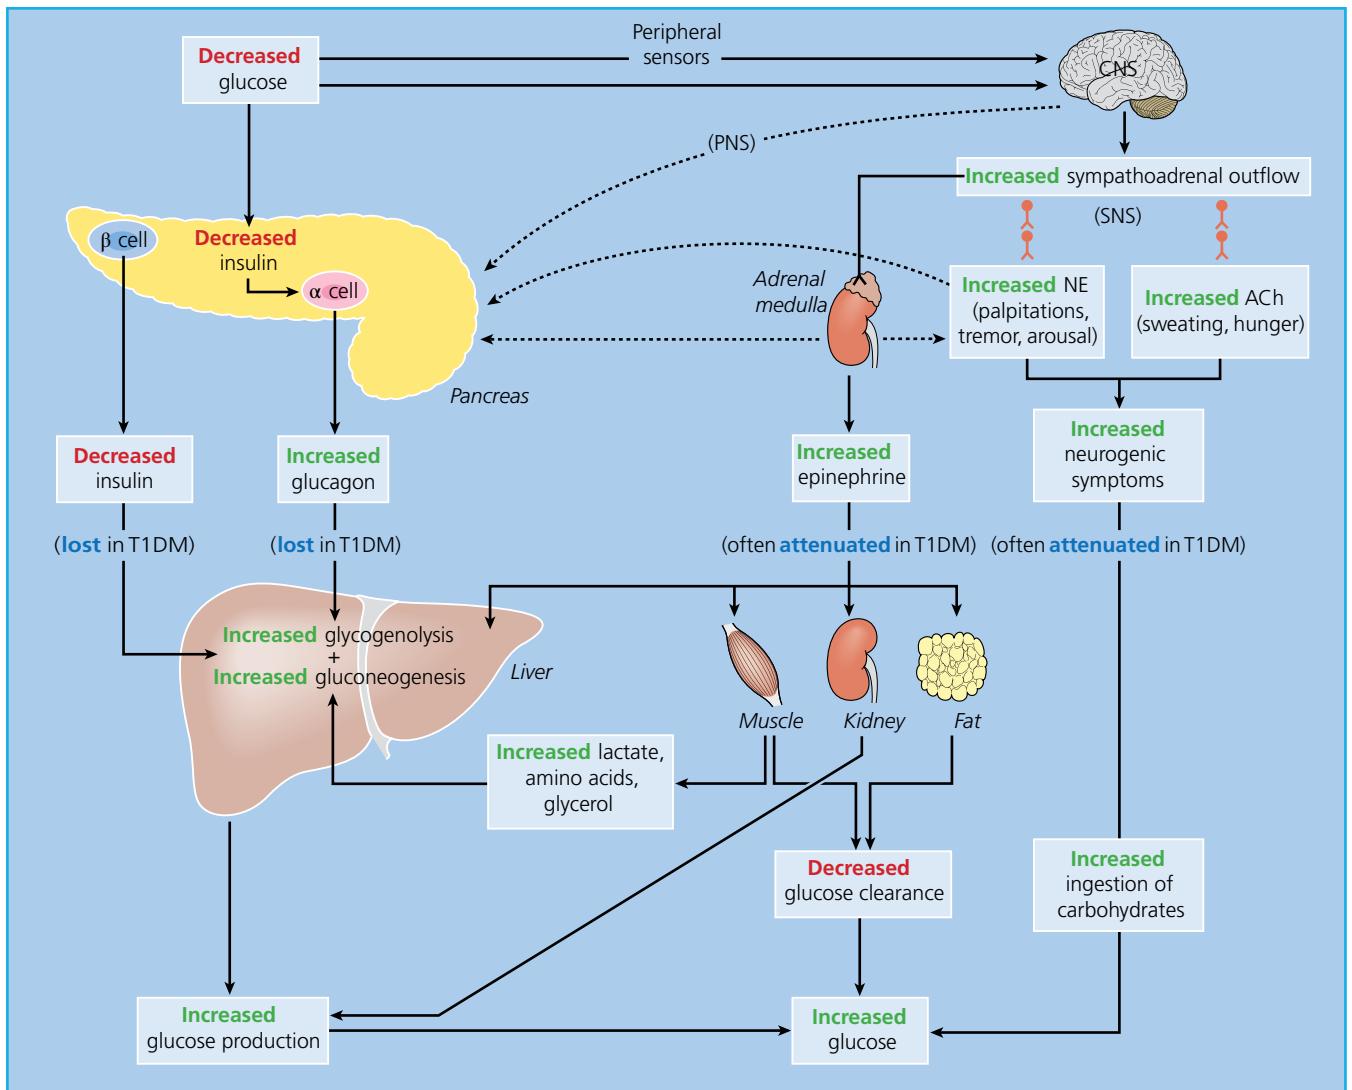

Figure 40.2 Physiological and behavioural defences against hypoglycaemia in humans. glucose utilization in non-neuronal tissues, although other neurotransmitters, metabolic substrates, and hormones are involved (Figures 40.1 and 40.2) [6, 16].

The processes of counter-regulation that correct hypoglycaemia involve an array of hormones. Seminal contributions from experimental medicine studies from the mid-1970s to the early 1990s have established an order of relative importance within counter-regulatory hormonal responses that can be conceptualized as lines of defence against hypoglycaemia [17–20]. The first physiological defence against hypoglycaemia is a decrease in pancreatic islet β -cell insulin secretion. This occurs as plasma glucose concentrations decline below 4.7 mmol/l (85 mg/dl) (Figure 40.1) and favours increased hepatic and renal glucose production, with virtual cessation of glucose utilization by insulin-sensitive tissues such as muscle (Figure 40.2). The second physiological defence is an increase in pancreatic islet α -cell glucagon secretion. This occurs as plasma glucose concentrations fall just below 3.9 mmol/l (70 mg/dl) (Figure 40.1) and stimulates glucose release through glycogenesis and glycogenolysis (Figure 40.2). Under physiological conditions, pancreatic α cells are under tonic

inhibition of intra-islet insulin [17]. During hypoglycaemic conditions, a decrease in intra-islet insulin among other β -cell secretory products, including the neurotransmitter γ -aminobutyric acid and zinc [1, 21–23], signals increased glucagon secretion. Further, a secondary putative mechanism that results in increased glucagon production is through activation of both the sympathetic and parasympathetic branches of the autonomic nervous system [1, 24]. As blood glucose concentrations fall further and just below the physiological range, the third physiological defence of epinephrine secretion from the adrenal medulla comes into play. This stimulates glucose release through gluconeogenesis and glycogenolysis, largely via β_2 -adrenergic stimulation, as well as reducing peripheral glucose utilization by inhibiting insulin secretion via α_2 -adrenergic receptors (Figure 40.2) [1, 6, 25]. Adrenomedullary epinephrine secretion becomes critical when glucagon is deficient. There is also a norepinephrine response to hypoglycaemia, which is largely secreted from the adrenal medulla but compared to epinephrine appears to play a less prominent role in glucose counter-regulation [14]. Additional hormones released when blood glucose levels fall between

3.6–3.9 mmol/l (65–70 mg/dl) are growth hormone and cortisol [8,9]. Collectively, these hormones induce gluconeogenesis, lipolysis, and ketogenesis over several hours and are thus less relevant to acute counter-regulation [26]. They may have an important role in initiating longer-term adaptive responses to hypoglycaemia [27].

These complex homeostatic mechanisms are chiefly controlled by the central nervous system (CNS) [6]. The evidence supporting this is primarily derived from animal studies, where direct glucose infusion into the brain to maintain euglycaemia was studied with parallel induction of peripheral hypoglycaemia [28]. In these experiments in rats, peripheral hypoglycaemia did not result in activation of glucagon and catecholamine counter-regulation. This and other studies led to the hypothesis that the ventromedial hypothalamic nucleus in the brain is a key glucose sensor for hypoglycaemia counter-regulation [28]; however, the ventromedial hypothalamic nucleus is likely to be one part of a larger glucose-sensing network in the brain [6]. Glucose-sensing neurones are highly specialized cells that employ changes in ambient glucose levels to alter their action potential, thus transducing a metabolic signal into neuronal activity [29]. Glucokinase and ATP-sensitive K⁺ channels appear to be primarily involved in glucose sensing and subsequent counter-regulation [29,30]. There may also be important species differences between rodents and humans.

If these physiological defences fail to abort an episode of developing hypoglycaemia, lower plasma glucose concentrations cause a more intense sympathoadrenal response that causes neurogenic symptoms and is primarily driven by sympathetic neural activation as opposed to adrenomedullary discharge (Figure 40.2) [14]. These symptoms cause awareness of hypoglycaemia that prompts the behavioural defence of carbohydrate ingestion. Physiological responses act in concert to prevent hypoglycaemia in healthy people without diabetes, but are typically compromised in people with type 1 diabetes and those with advanced (i.e. absolutely endogenous insulin-deficient) type 2 diabetes (Figure 40.2) [1].

Pathophysiology of glucose counter-regulation in diabetes

Insulin excess

Absolute or relative therapeutic hyperinsulinaemia is a key factor in producing iatrogenic hypoglycaemia [1]. Whether any given episode of therapeutic hyperinsulinaemia results in clinically significant hypoglycaemia in people with diabetes, however, is also determined by the integrity of hormonal and behavioural mechanisms that ordinarily constitute the counter-regulatory defence. Counter-regulatory deficiencies in diabetes are not a binary ‘present or absent’ phenomenon, but exist on a continuum that is influenced by several factors. Since some of these impairments appear to be functional, this implies they may be reversible (Figure 40.2; Table 40.1) [27,32,33].

Defective glucose counter-regulation

Insulin

Individuals with fully developed (minimal residual β-cell function) type 1 diabetes and advanced insulin-treated type 2 diabetes are unable to self-regulate endogenous insulin secretion in response to falling plasma glucose concentrations (Table 40.1) [34]. This compromises the first counter-regulatory defence against hypoglycaemia,

Table 40.1 Responses to falling plasma glucose concentrations in humans.

Plasma glucose	Individuals	Plasma		
		Insulin	Glucagon	Epinephrine
↓	No-diabetes	↓	↑	↑
↓	Type 1 diabetes ^a	No ↓	No ↑	Attenuated ↑
↓	Early type 2 diabetes	↓	↑	↑
↓	Late type 2 diabetes ^a	No ↓	No ↑	Attenuated ↑

^a These alterations account for the appearance of defective glucose counter-regulation and impaired awareness of hypoglycaemia in people with type 1 diabetes and late type 2 diabetes.

as therapeutic delivery of insulin or sulfonylureas and related medication results in unregulated hyperinsulinaemia [21]. Hyperinsulinaemia promotes glucose lowering through peripheral glucose uptake in the liver, skeletal muscle, and adipose tissue in addition to suppressing gluconeogenesis and inhibiting lipolysis, which generates alternate fuels [27]. In addition, insulin inhibits pancreatic α-cell glucagon release, partly through direct local action in the pancreas [35] but also through central modulation in the ventromedial hypothalamic nucleus [36].

Glucagon

In the absence of the ability to *switch off* endogenous insulin in response to falling glucose concentrations, people with diabetes have to rely on glucagon secretion, which is the second line of physiological defence against hypoglycaemia. Glucagon plays a primary role in opposing the glucose-lowering effects of insulin during hypoglycaemia, accounting for ~40% of glucose recovery [37]. However, impaired glucagon responses to hypoglycaemia are apparent as early as within the first year of diagnosis in type 1 diabetes [38] and are significantly diminished in most people within five years after diagnosis (Table 40.1) [39]. Glucagon and other counter-regulatory responses to hypoglycaemia are less extensively studied in type 2 diabetes, but limited evidence suggests that in type 2 diabetes glucagon responses are initially either elevated or modestly reduced (Table 40.1) [40–43], but become gradually impaired [33,44–46].

An interesting phenomenon observed in clinical practice is that some individuals with type 2 diabetes, especially those with suboptimal metabolic management and thus relatively high ambient plasma glucose concentrations, report symptoms suggestive of counter-regulation occurring at normal glucose values. Furthermore, experimental data suggest that the threshold for activation of counter-regulatory responses to hypoglycaemia may be reset to normal glucose values in some individuals with type 2 diabetes [41]. Loss of a glucagon response results in significantly reduced glycogenolysis and gluconeogenesis and increases the risk of severe hypoglycaemic episodes [27,47]. Mechanisms that lead to loss of α-cell glucagon release in diabetes are not fully understood. Several mechanistic studies have been performed in animals, which may not directly apply to the human condition due to species differences in pancreatic physiology. It appears, however, that the α-cell defect, at least in those with type 1 diabetes, is specific to hypoglycaemia, as α-cell stimulation with amino acids such as arginine results in an intact glucagon response [17]. The α-cell glucagon

release appears to be impaired on account of a functional as opposed to a structural defect, raising the theoretical possibility of interventions that may re-enable glucagon secretion in response to a hypoglycaemic stimulus.

One plausible explanation for the loss of glucagon response to hypoglycaemia in type 1 diabetes and advanced type 2 diabetes is β -cell failure, as described in the *intra-islet* hypothesis [21, 33]. As intra-islet insulin, among other β -cell secretory products, regulates α -cell glucagon secretion in response to hypoglycaemia [17], with progressive β -cell failure either through T-cell-mediated autoimmune destruction in type 1 diabetes or gradual β -cell loss with advancing type 2 diabetes, the absence of intra-islet insulin signalling results in a loss of the glucagon response to hypoglycaemia [48]. Heller et al. were the first to explore the *intra-islet* hypothesis in humans and contrasted this with animal data [49]. They studied glucagon responses in healthy volunteers who underwent two hypoglycaemic clamps, one with intravenous tolbutamide infusion to stimulate high portal insulin concentrations, and compared this with a standard intravenous insulin infusion clamp with an equivalent hypoglycaemic nadir. They showed a reduced glucagon response to tolbutamide-induced hypoglycaemia where portal insulin concentrations were high, suggesting that intra-islet insulin signalling contributes to regulation of glucagon release during hypoglycaemia in humans [49].

Other early experimental data that support the *intra-islet* hypothesis were a demonstration of impaired glucagon secretion during hypoglycaemia, closely mirroring a decline in C-peptide levels (a marker of endogenous β -cell function) in people with insulin-treated diabetes [50]. In a more recent study, when people with insulin-treated type 2 diabetes were compared with those on

oral hypoglycaemic agents only, there was no difference in the peak glucagon response during a hypoglycaemic clamp [51]. However, this was almost certainly because even insulin-treated participants had relatively preserved β -cell function (mean C-peptide 1000 pmol/l). A similarly designed study examined glucagon responses to experimental hypoglycaemia in people with type 2 diabetes treated with oral hypoglycaemic agents and compared people treated with insulin and lower mean basal C-peptide values (mean C-peptide insulin-treated group 364 pmol/l vs mean C-peptide oral hypoglycaemic group 1026 pmol/l) [33]. Here, mean glucagon responses following 60 minutes of experimental hypoglycaemia were significantly higher in the oral hypoglycaemic group compared to the insulin-treated group. Further, recent observational studies in both type 1 diabetes and insulin-treated type 2 diabetes suggest that the incidence of continuous glucose monitoring (CGM)-recorded hypoglycaemia is significantly lower in those with preserved C-peptide levels, inferring an intact glucagon response and lending credence to the *intra-islet* hypothesis [52, 53].

Catecholamines

With both the first and second physiological defences against hypoglycaemia being lost, people with diabetes have to rely on the catecholamine (principally epinephrine) response to hypoglycaemia – the third line of defence. Notably, when the glucagon response is poor, hepatic glucose production during hypoglycaemia and exercise is significantly modulated by catecholamines, highlighting the critical nature of this *fail safe* [27, 54, 55]. However, in those with type 1 diabetes and advanced type 2 diabetes, the epinephrine response to hypoglycaemia is progressively attenuated (Figure 40.3; Table 40.1) [1, 32, 33, 39]. An attenuated adrenomedullary epinephrine response

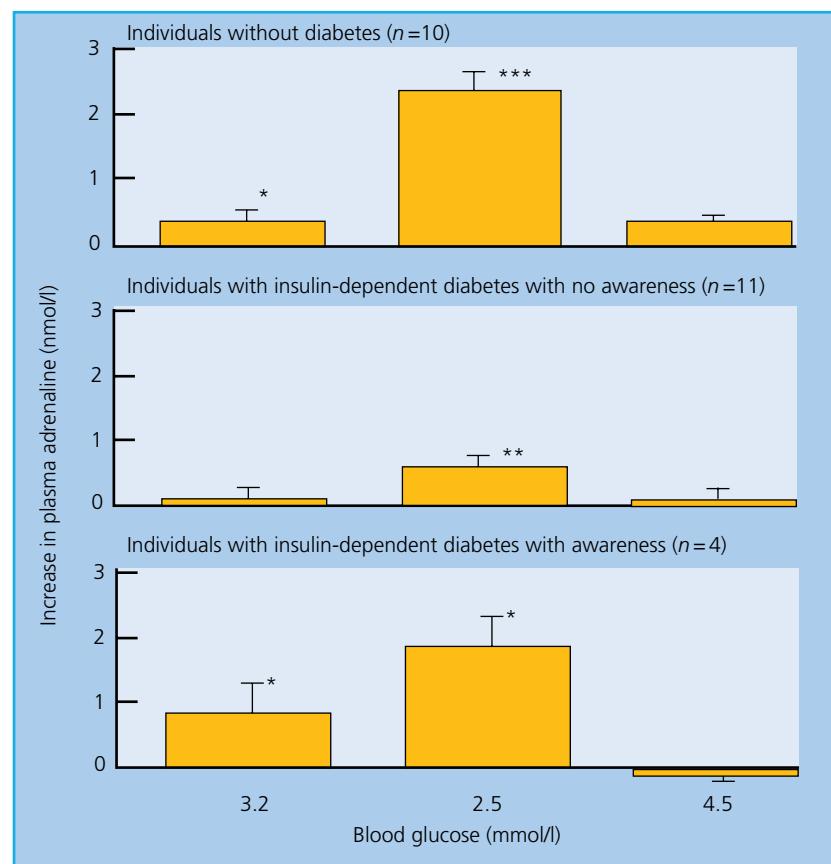

Figure 40.3 Mean (\pm standard error [SE]) plasma epinephrine concentrations during stepped hyperinsulinaemic hypoglycaemic glucose clamps in 10 individuals without diabetes and 15 individuals with insulin-dependent diabetes ($n = 4$ with intact awareness of hypoglycaemia and $n = 11$ with reduced awareness of hypoglycaemia symptoms). Source: Heller et al. 1987 [56]. Reproduced with permission from The Lancet.

together with an absent glucagon response is associated with a 25-fold [47] or greater [57] increase in the risk of severe hypoglycaemia in type 1 diabetes. In addition, a diminished adrenal epinephrine response is a marker for an attenuated autonomic response to hypoglycaemia, including a sympathetic neural response (Table 40.1), which is primarily responsible for reduced neurogenic symptoms [14] and the clinical syndrome of impaired awareness of hypoglycaemia. The adrenal glands are regulated by the autonomic nervous system [27]. The impaired catecholamine response to hypoglycaemia in individuals with type 1 diabetes and advanced type 2 diabetes arises mainly through an altered sympathetic drive, with a gradual shifting of the glycaemic threshold for activation to lower glucose values [58]. There is no structural defect in the secretory apparatus within the adrenal medulla, however, given that a catecholamine response to alternate stimuli such as exercise remains intact [55, 58].

Overall, the pathophysiology of glucose counter-regulation is similar in type 1 diabetes and advanced (i.e. absolutely endogenous insulin deficiency) type 2 diabetes, albeit with different time courses (Table 40.1) [1, 32, 33]. The pathogenesis of an episode of iatrogenic hypoglycaemia involves therapeutic hyperinsulinaemia, resulting in falling plasma glucose concentrations and loss of the appropriate reduction in insulin and compensatory secretion of glucagon. Each episode of hypoglycaemia, in turn, reduces the sympathoadrenal responses to subsequent hypoglycaemia. Because β -cell failure, which causes loss of both insulin and glucagon responses [1, 32, 33], occurs rapidly in type 1 diabetes but more insidiously in type 2 diabetes, the syndromes of defective glucose counter-regulation and impaired awareness of hypoglycaemia develop early in type 1 diabetes but later in type 2 diabetes. This temporal pattern of compromised glycaemic defences explains why iatrogenic hypoglycaemia becomes progressively more frequent as individuals approach the insulin-deficient end of the spectrum of type 2 diabetes.

Impaired awareness of hypoglycaemia

Important work by Heller and Cryer in the early 1990s showed that in healthy volunteers, a single episode of hypoglycaemia is sufficient to attenuate sympathoadrenal (and glucagon) responses to subsequent hypoglycaemia [20]. This phenomenon, subsequently replicated in those with type 1 diabetes (Figures 40.4 and 40.5) [32, 59] and type 2 diabetes [60], reduces an individual's ability to perceive the onset of hypoglycaemia symptoms [60]. Hypoglycaemia of greater depth [61], longer duration [62], and higher frequency [63, 64] results in a greater attenuation of counter-regulatory responses to subsequent hypoglycaemia [27]. It is unclear, however, if the progressive impairment in sympathoadrenal responses that occurs in diabetes of increasing duration is entirely due to repeated hypoglycaemia [34]. Clinical experience indicates that many individuals with longstanding insulin-treated diabetes have a diminished ability to perceive the symptoms of acute hypoglycaemia. No holistic definition for the clinical syndrome of impaired hypoglycaemia awareness exists, but it is recognized that absolute unawareness is rare and thus the term *hypoglycaemia unawareness* has been replaced with *impaired awareness of hypoglycaemia* [34].

Scales developed by Gold [65] and Clarke [66] are two tools used in routine clinical practice to identify impaired awareness of hypoglycaemia in type 1 diabetes, but they have limitations. Recent studies have used a Gold score of ≥ 4 to define impaired awareness of hypoglycaemia [67, 68]; however, there is significant variation in how impaired awareness of hypoglycaemia is defined in older studies, making it challenging to draw meaningful comparisons between

populations, especially where duration of treatment with insulin differs. Where there is broad consistency in definitions of impaired awareness of hypoglycaemia, the reported prevalence is ~25% in type 1 diabetes, rising to ~50% after 25 years or more of treatment [69–71]. In type 2 diabetes, the prevalence of impaired awareness of hypoglycaemia is ~8–10% [72, 73], with the prevalence being higher in insulin-treated type 2 diabetes [72]. This is intuitive, as the duration of insulin treatment is a key predictor of rates of severe hypoglycaemia, with higher rates reported in both type 1 diabetes and type 2 diabetes with longer treatment duration [74]. Interestingly, when individuals with type 1 diabetes and type 2 diabetes were matched for duration of treatment with insulin in one study [75], hypoglycaemia rates were comparable. This has important implications for healthcare resources around the world, since the global prevalence of type 2 diabetes is far higher, comprising 90% of all cases of diabetes [76]. Improved access to insulin together with longer life expectancies will mean that hypoglycaemia will continue to remain a significant clinical challenge [77].

Although impaired awareness of hypoglycaemia is largely the result of reduced release of the neurotransmitters norepinephrine and acetylcholine [1, 14], there is decreased β -adrenergic sensitivity, specifically reduced cardiac chronotropic sensitivity to isoproterenol, in affected individuals [78, 79]. However, vascular sensitivity to β_2 -adrenergic agonism was not found to be reduced in people with impaired awareness [80]; reduced sensitivity to β -adrenergic signalling of neurogenic symptoms remains to be demonstrated in those with impaired awareness of hypoglycaemia, and it would be necessary to postulate decreased cholinergic sensitivity to explain reduced cholinergic symptoms such as sweating.

Mechanisms of counter-regulatory failure and impaired awareness

Epidemiological and mechanistic studies have shown that duration of type 1 diabetes and insulin treatment in type 2 diabetes are key contributors to deficient counter-regulation and impaired awareness of hypoglycaemia. Repeated episodes of hypoglycaemia are also fundamental to these pathological syndromes that make insulin-treated individuals so susceptible to the limitations of therapeutic insulin and other therapies.

Following the seminal studies conducted in the early 1990s, further studies showed that an episode of antecedent hypoglycaemia can attenuate counter-regulatory responses to further hypoglycaemia up to one week later [81]. Brief twice-weekly episodes of mild hypoglycaemia have a similar effect [82]. Furthermore, prior exercise [83–85] and sleep [86–88] cause diminished counter-regulation to subsequent hypoglycaemia. Prolonged effects of antecedent hypoglycaemia on diminished counter-regulation to subsequent hypoglycaemia appear to explain why tight glycaemic management with intensive insulin therapy can lead to a resetting of the glycaemic threshold at which counter-regulatory mechanisms are activated [34, 59, 89]. Thus, stimuli such as prior hypoglycaemia, sleep, and exercise can plausibly contribute to transient impaired awareness of hypoglycaemia by attenuating the sympathoadrenal and resultant neurogenic symptom responses to subsequent hypoglycaemia.

It remains unclear how these factors lead to chronic impaired awareness. Nonetheless, recurrent episodes of hypoglycaemia of sufficient depth and duration progressively blunt and impair normal counter-regulatory responses to hypoglycaemia, predisposing people with diabetes to a vicious cycle of ever more frequent hypoglycaemia episodes with a falling glycaemic threshold to activate counter-regulation (Figure 40.6) [34, 90]. Cryer has termed

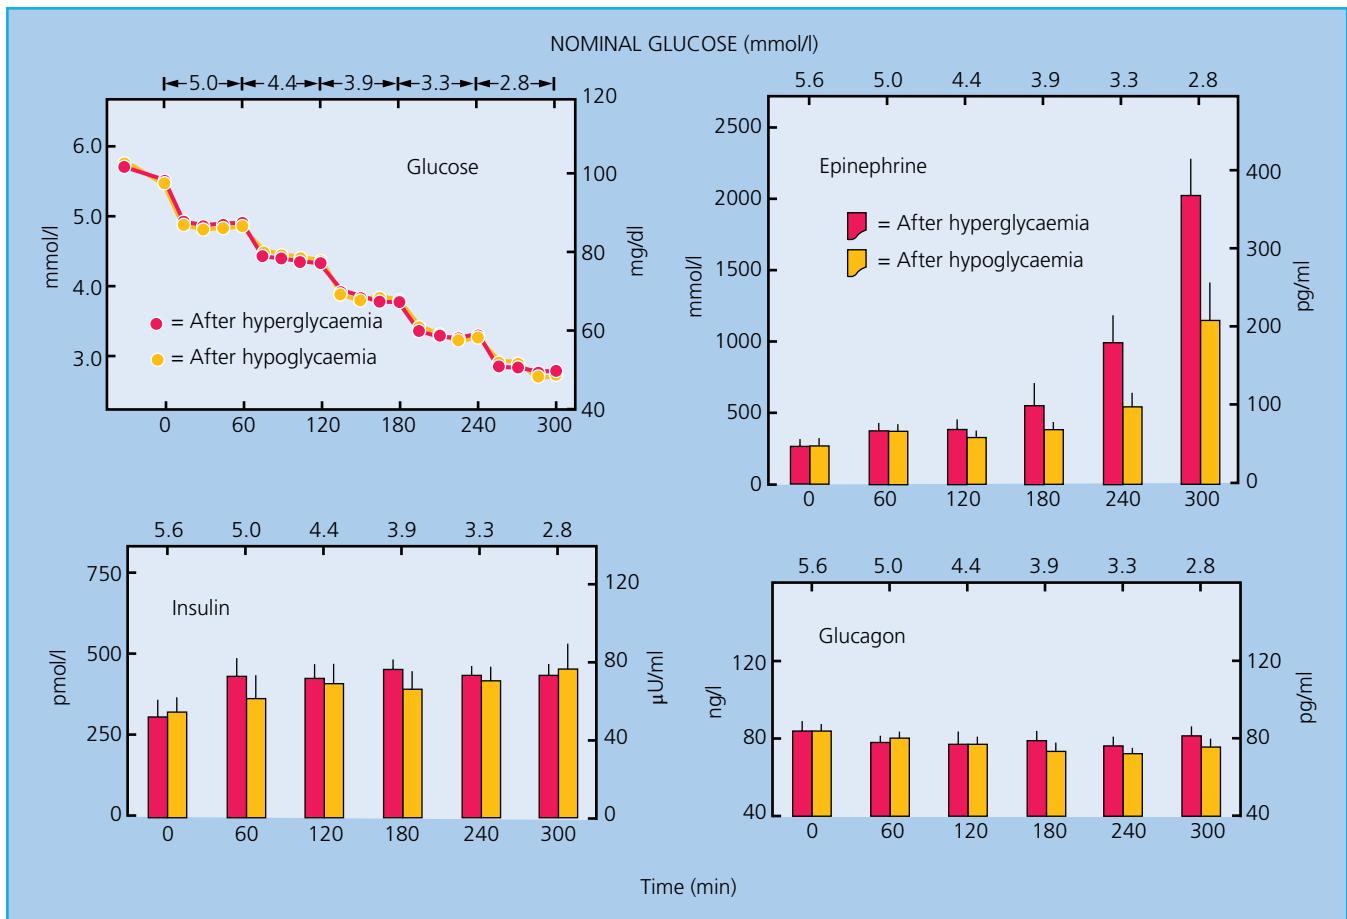

Figure 40.4 Mean (\pm standard error [SE]) plasma glucose, insulin, epinephrine, and glucagon concentrations during hyperinsulinaemic stepped hypoglycaemic glucose clamps in people with type 1 diabetes without classic diabetic autonomic neuropathy on mornings following afternoon hyperglycaemia (red circles and columns) and on mornings following afternoon hypoglycaemia (yellow circles and columns). this phenomenon *hypoglycaemia-associated autonomic failure* in diabetes [91]. This is a dynamic functional disorder that is distinct from classic diabetic autonomic neuropathy [1,34], a common neuropathic complication of diabetes. While there is no failure of the autonomic system in hypoglycaemia-associated autonomic failure, an attenuated sympathoadrenal response to a given level of hypoglycaemia, a key feature of hypoglycaemia-associated autonomic failure, is common to diabetic autonomic neuropathy [92,93]. However, since structural autonomic neuropathy is generally only observed in individuals with a long duration of diabetes, it is difficult to assess the additional contribution of autonomic neuropathy to counter-regulatory failure. A more accurate term would be hypoglycaemia-associated counter-regulatory impairment, to distinguish it from impairment secondary to other factors such as treatment duration, exercise, and sleep; nevertheless, the term hypoglycaemia-associated autonomic failure is now used widely.

The clinical impact of hypoglycaemia-associated counter-regulatory impairment is well established in type 1 diabetes [32,82,94–98]. Recent antecedent hypoglycaemia, even asymptomatic nocturnal hypoglycaemia, reduces epinephrine, symptomatic, and cognitive responses to a given level of subsequent hypoglycaemia [98], reduces detection of hypoglycaemia in the clinical setting [82], and reduces defence against hyperinsulinaemia [32] in type 1 diabetes. Perhaps the most compelling evidence to support the concept of hypoglycaemia as a cause of counter-regulatory impairment is the finding, initially by three independent research teams [94–98], that as little as 2–3 weeks of scrupulous avoidance of hypoglycaemia reverses impaired awareness of hypoglycaemia (Figure 40.7) and improves the attenuated epinephrine component of defective glucose counter-regulation in most affected individuals.

People with advanced type 2 diabetes are also at risk for acquired counter-regulatory impairment [33]. Glucagon responses to hypoglycaemia are lost [33], as they are in type 1 diabetes. Furthermore, the glycaemic thresholds for sympathoadrenal and symptomatic (among other) responses to hypoglycaemia are shifted to lower plasma glucose concentrations by recent antecedent hypoglycaemia [33], as they are in type 1 diabetes.

There are three recognized causes of counter-regulatory failure, each of which leads to attenuated sympathoadrenal and symptomatic (among other) responses to a given level of hypoglycaemia [1]. Antecedent hypoglycaemia related counter-regulatory failure [20, 32, 33] led the concept. Exercise-related counter-regulatory failure [84–86] is exemplified by late post-exercise hypoglycaemia, which typically occurs 6–15 hours after strenuous exercise and is often nocturnal [99, 100]. Sleep-related counter-regulatory failure [87–89] is the result of further attenuation of the sympathoadrenal response to hypoglycaemia during sleep. Sleeping individuals are therefore much less likely to be awakened by hypoglycaemia than individuals without diabetes [87, 89]. There may well be additional, as yet unrecognized, functional, and therefore potentially reversible, causes of hypoglycaemia-associated counter-regulatory impairment [1]. In addition, there may be a structural component [1].

The mechanisms of counter-regulatory impaired awareness are summarized in Figure 40.8 [1]. Loss of the insulin and glucagon responses to falling plasma glucose concentrations caused by therapeutic hyperinsulinaemia is the result of β -cell failure in type 1 diabetes and advanced type 2 diabetes.

In the setting of absent insulin and glucagon responses to falling plasma glucose concentrations, attenuated sympathoadrenal responses cause both defective glucose counter-regulation and impaired awareness of hypoglycaemia. The underlying mechanism responsible for the attenuated sympathoadrenal response is poorly understood, but it is plausible that it is at the level of the brain (or the afferent or efferent components of the sympathoadrenal system) (Figure 40.8). The proposed mechanisms include the systemic

mediator, brain fuel transport, and brain metabolism hypotheses, all of which have been previously reviewed [21, 101, 102].

Much of the research into the pathogenesis of counter-regulatory failure has focused on the hypothalamus, the central integrator of the sympathoadrenal responses to hypoglycaemia [102]. While the primary alteration could reside in the hypothalamus, the changes in hypothalamic function could be secondary to those in other brain regions. For example, measurements of regional cerebral blood flow with $[^{15}\text{O}]$ water and positron emission tomography (PET) [103] indicate that hypoglycaemia activates widespread but interconnected brain regions, including the medial prefrontal cortex, the lateral orbitofrontal cortex, the thalamus, the globus pallidus, and the periaqueductal grey region. These studies also show that recent antecedent hypoglycaemia both reduces the sympathoadrenal and symptomatic responses and causes a greater increase in synaptic activity in the dorsal midline thalamus during subsequent hypoglycaemia [11]. Hence there may be a cerebral network that results in thalamic inhibition of hypothalamic activity in hypoglycaemia-associated counter-regulatory impairment (Figure 40.8) [11]. That suggestion is generically consistent with the findings of various patterns of ^{18}F -deoxyglucose uptake in people with type 1 diabetes with and without impaired awareness of hypoglycaemia [104].

More recently, Choudhary et al. have investigated brain responses to hypoglycaemia in type 1 diabetes with and without impaired awareness of hypoglycaemia [105]. Using three-dimensional pseudo-continuous arterial spin labelling (3DpCASL) magnetic resonance imaging (MRI), they demonstrated changes in cerebral blood flow in response to hypoglycaemia in brain regions involved in arousal, decision making, and reward in those with impaired awareness of hypoglycaemia. They hypothesized that changes in these neural pathways may disrupt these individuals' ability to recognize and effectively manage hypoglycaemia [105]. They extended this work by restoring awareness of hypoglycaemia in those with type 1 diabetes through enrolment on a structured education programme (Dose Adjustment for Normal Eating), specialist support, and sensor-augmented pump therapy [106]. Cerebral blood flow responses during hypoglycaemia

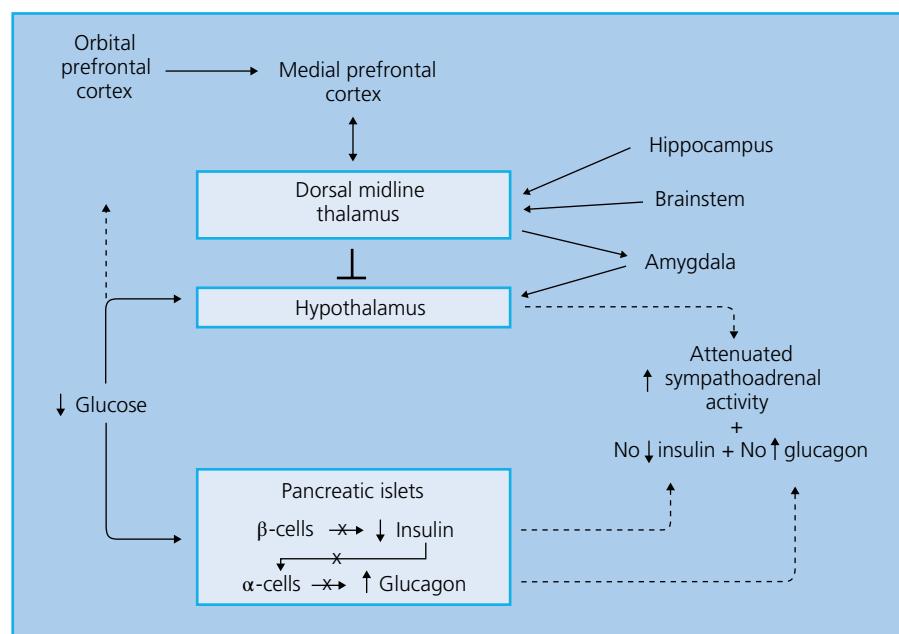

Figure 40.8 Pancreatic islet, hypothalamic, and cerebral network mechanisms of hypoglycaemia-associated autonomic failure (HAAF) in diabetes. Source: Cryer 2008 [1]. Reproduced with permission from the American Diabetes Association.

were studied pre- and post-intervention using 3DpCASL MRI. Interestingly, following restoration of hypoglycaemia awareness, increased blood flow was seen in neural pathways involved in self-awareness and decision making (anterior cingulate cortex), suggesting reversibility in brain responses lost in impaired awareness of hypoglycaemia [106]. However, brain regions involved in arousal and emotional processing (fronto-thalamic networks) were less responsive to restoration of hypoglycaemia awareness [106]. This may partly explain why some individuals with impaired awareness of hypoglycaemia never fully achieve restoration of awareness with use of structured education and diabetes technology [106].

Experimental limitations in studying the mechanisms contributing to hypoglycaemia in diabetes

It remains unclear how duration of diabetes and antecedent hypoglycaemia, the two key contributors to impaired awareness and counter-regulatory failure, interact mechanistically in causing the syndromes that underly the vulnerability of those with insulin-treated diabetes to hypoglycaemia. Most experimental work has focused on antecedent hypoglycaemia, as it is more easily reproduced in the laboratory whether in clinical experimental models or in animal studies. Since impaired awareness is increasingly observed as the duration of diabetes increases, it may reflect structural changes within the brain that prevent the reversal of sympathoadrenal failure to hypoglycaemia by avoiding further episodes. Reversal studies have shown restoration of awareness, at least in part without any improvement in rises in counter-regulatory hormones, particularly epinephrine, suggesting that sympathoadrenal responses to hypoglycaemia are still impaired [94–98].

Conversely, there are those with a long duration of diabetes who show full awareness of hypoglycaemia and still develop sweating and tremor. Have they largely avoided hypoglycaemia throughout their lives by running higher glucose levels or do they possess or have they acquired other protective mechanisms that protect against hypoglycaemia? For example, those who retain some endogenous insulin secretion in type 1 diabetes continue to exhibit a hypoglycaemic response to glucagon [107].

Another limitation in studying mechanisms of counter-regulatory failure and impaired awareness is an inability to clearly define the clinical phenotype. Some cases of impaired awareness may be almost entirely due to repeated episodes of hypoglycaemia and largely reversible (this is often seen in children), whereas others may be due to a gradual decline in hypoglycaemic warnings as their diabetes progresses due to different mechanisms that are irreversible.

These limitations may help to understand why, over 30 years after the clinical studies that described repeated hypoglycaemia as an important cause of counter-regulatory failure, we still rely on avoidance of hypoglycaemia as a treatment for impaired awareness and have not yet developed any effective pharmacological therapies that can treat or prevent it.

Risk factors for hypoglycaemia in diabetes

The risk factors for hypoglycaemia in diabetes follow directly from the pathophysiology of glucose counter-regulation. They are based on the principle that iatrogenic hypoglycaemia is typically the result

of an interplay between relative or absolute therapeutic insulin excess and compromised physiological and behavioural defences against falling plasma glucose concentrations in type 1 diabetes and advanced type 2 diabetes [1, 108].

Absolute or relative insulin excess

The conventional risk factors for hypoglycaemia in diabetes are based on the premise that absolute or relative therapeutic insulin excess is the sole determinant of risk (Table 40.2) [1, 108]. Absolute therapeutic insulin excess occurs when insulin secretagogue or insulin doses are excessive, ill-timed, or of the wrong type, or when insulin clearance or metabolism is reduced, as in renal or hepatic failure. Relative therapeutic insulin excess occurs under a variety of conditions. It occurs when exogenous glucose delivery is decreased (for example, following missed or low-carbohydrate meals and during the overnight fast), when glucose utilization is increased (for example, during and shortly after exercise), when endogenous glucose production is decreased (for example, following alcohol ingestion), and when sensitivity to insulin is increased (for example, after weight loss or improved glycaemic levels and during the night). People with diabetes, their caregivers, and physicians have to work together in identifying and addressing these risk factors when the problem of iatrogenic hypoglycaemia is recognized. Overall, however, these factors likely explain only a minority of episodes of hypoglycaemia [109].

Compromised defences against hypoglycaemia

The risk factors indicative of impaired counter-regulatory responses and impaired awareness (Table 40.2) [50, 108, 110–115] include absolute endogenous insulin deficiency [50, 108, 110, 111, 113, 114]; a history of severe iatrogenic hypoglycaemia, impaired awareness of hypoglycaemia, or both; recent antecedent hypoglycaemia, prior exercise, or sleep [108, 110, 111, 115]; and intensive glycaemic therapy (i.e. lower glycated haemoglobin [HbA_{1c}], lower glycaemic targets, or both) [108, 110–115]. The degree of endogenous insulin deficiency (i.e. β -cell failure) determines the extent to which insulin levels will not decrease and glucagon levels will not increase as plasma glucose concentrations fall in response to therapeutic hyperinsulinaemia. A history of severe hypoglycaemia indicates, and that of impaired awareness of hypoglycaemia implies, a long duration of diabetes, recent antecedent hypoglycaemia, or both. The latter causes attenuated sympathoadrenal and symptomatic responses to

Table 40.2 Risk factors for hypoglycaemia in diabetes.

Relative or absolute insulin excess

1. Insulin or insulin secretagogue doses are excessive, ill-timed, or of the wrong type
2. Exogenous glucose delivery is decreased (e.g. following missed meals and during the overnight fast)
3. Glucose utilization is increased (e.g. during and shortly after exercise)
4. Endogenous glucose production is decreased (e.g. following alcohol ingestion)
5. Sensitivity to insulin is increased (e.g. in the middle of the night and following weight loss or improved glycaemic levels)
6. Insulin clearance or metabolism is decreased (e.g. with renal or liver failure)

Hypoglycaemia-associated counter-regulatory impairment

1. Absolute endogenous insulin deficiency
2. A history of severe hypoglycaemia, impaired awareness of hypoglycaemia, or both, and also recent antecedent hypoglycaemia, prior exercise, and sleep
3. Intensive glycaemic therapy (lower glycated haemoglobin [HbA_{1c}], lower glycaemic goals)

subsequent hypoglycaemia. Studies of intensive glycaemic therapy with a control group treated to a higher HbA_{1c} level consistently report higher rates of hypoglycaemia in the group treated to lower HbA_{1c} levels in type 1 diabetes [116–118] and type 2 diabetes [113, 119, 120]. The challenge in clinical practice is to allow people with diabetes to derive the benefits of intensive glycaemic management while minimizing the risk and consequences of hypoglycaemia.

Magnitude of the clinical problem of hypoglycaemia in diabetes

Diabetes is an increasingly common disease and iatrogenic hypoglycaemia affects most of those with type 1 diabetes and people with type 2 diabetes treated with insulin or secretagogues [1, 5]. Indeed, because maintenance of euglycaemia is needed over a lifetime of diabetes, the barrier of hypoglycaemia ultimately affects most people with diabetes [1, 5].

Frequency of hypoglycaemia

Hypoglycaemia is a fact of life for people with type 1 diabetes (Table 40.3) [1, 5, 110, 112, 132]. The average person has untold numbers of episodes of asymptomatic hypoglycaemia and experiences

on average, around two episodes of symptomatic hypoglycaemia per week – thousands of such episodes over a lifetime of diabetes – and one or more episodes of severe, temporarily disabling hypoglycaemia, often with seizure or coma, per year. There is little evidence that this problem has abated since it was highlighted by the Diabetes Control and Complications Trial (DCCT) in 1993 [116]. For example, in 2007 the UK Hypoglycaemia Study Group [74] reported an incidence of severe hypoglycaemia that was twice that in the DCCT in people with type 1 diabetes for <5 years, and an incidence fivefold higher than that in the DCCT in those with type 1 diabetes for >15 years (Table 40.3). An incidence comparable to the latter was also found in a large observational study [112].

Overall, hypoglycaemia is less frequent in type 2 diabetes (Table 40.3) [1, 5, 73–75, 112, 115, 118, 121, 122, 124–130, 133–136], but for the pathophysiological reasons discussed, hypoglycaemia becomes progressively more frequent as people approach the insulin-deficient end of the spectrum of type 2 diabetes [1, 5, 74, 75]. Indeed, its frequency has been reported to be similar in those with type 2 diabetes and type 1 diabetes matched for duration of insulin therapy [75]. When the UK Hypoglycaemia Study Group [74] contrasted people with type 2 diabetes treated with insulin for <2 years with those treated with insulin for >5 years, they found severe hypoglycaemia prevalence rates of 7% and 25% and incidence rates

Table 40.3 Event rates for severe hypoglycaemia (that requiring the assistance of another person), expressed as episodes per 100 person-years, in insulin-treated diabetes.

of 10 and 70 episodes per 100 person-years, respectively. The pattern for self-treated hypoglycaemia was similar [74]. Thus, although the incidence of iatrogenic hypoglycaemia is relatively low (with current less than euglycemic goals) in the first few years of insulin treatment of type 2 diabetes, the risk increases substantially in advanced type 2 diabetes, approaching that in type 1 diabetes.

Because asymptomatic episodes will almost invariably be missed, and symptomatic episodes may not be recognized as the result of hypoglycaemia [66] and, even if they are, they are not long remembered [71, 137], estimates of the frequency of iatrogenic hypoglycaemia are underestimates. Although they represent only a small fraction of the total hypoglycaemic experience, because they are dramatic events that are more likely to be reported (by the person with diabetes or family or carers) [71, 137], estimates of the frequency of severe hypoglycaemia, requiring the assistance of another person, are more reliable, particularly if they are determined in population-based prospective studies focused on hypoglycaemia [1, 5].

The prospective population-based data of Donnelly et al. [122] indicate that the overall incidence of hypoglycaemia in insulin-treated type 2 diabetes is approximately one-third of that in type 1 diabetes (Table 40.3). The incidence of any and of severe hypoglycaemia was ~4300 and 115 episodes per 100 patient-years, respectively, in type 1 diabetes and ~1600 and 35 episodes per 100 patient-years, respectively, in insulin-treated type 2 diabetes. In addition, in population-based studies, the incidence of severe hypoglycaemia requiring emergency treatment in insulin-treated type 2 diabetes was ~40% [135] and ~100% [136] of that in type 1 diabetes. In the global Hypoglycaemia Awareness Tool study [123], using a six-month retrospective and four-week prospective self-adjustment questionnaire and diaries of 27 585 individuals with type 1 diabetes or insulin-treated type 2 diabetes worldwide, hypoglycaemia rates were three times higher than reported in population-based studies (Table 40.3). Because the prevalence of type 2 diabetes is ~20-fold greater than that of type 1 diabetes, and most people with type 2 diabetes ultimately require treatment with insulin, most episodes of iatrogenic hypoglycaemia, including severe hypoglycaemia, occur in people with type 2 diabetes.

Impact of hypoglycaemia

Iatrogenic hypoglycaemia causes recurrent physical and psychological morbidity, increases mortality, impairs defences against subsequent hypoglycaemia, and precludes maintenance of euglycaemia over a lifetime of diabetes [1, 5]. In the short term, it causes brain fuel deprivation that, if unchecked, results in functional brain failure that is typically corrected after the plasma glucose concentration is raised [3]. Rarely, it causes sudden, presumably cardiac arrhythmic [138, 139] death or, if it is profound and prolonged, brain death [3]. Three early reports indicated that 2–4% of people with diabetes die from hypoglycaemia [140–142]. More recent reports indicated that 6% [143], 7% [144], and 10% [145] of deaths of people with type 1 diabetes were the result of hypoglycaemia. In type 2 diabetes, mortality rates of up to 10% during episodes of severe sulfonylurea-induced hypoglycaemia have been reported [146]. In one trial of type 2 diabetes, between 1% and 9% of evaluable deaths were attributed to hypoglycaemia [147].

Excess mortality during intensive glycaemic therapy with increased rates of hypoglycaemia was found in randomized controlled trials (RCTs) in individuals in the intensive care unit [148] and in people with type 2 diabetes [119]. Overall, increased mortality has been consistently associated with severe hypoglycaemia in six

RCTs, two in individuals in the intensive care unit [148, 149] and four in people with type 2 diabetes [119, 120, 150, 151].

The physical morbidity of an episode of hypoglycaemia ranges from unpleasant symptoms to seizure and coma [1, 3, 5]. It can impair judgement, behaviour, and performance of physical tasks. Permanent neurological damage is rare, although there is concern that recurrent hypoglycaemia might cause chronic cognitive impairment. The developing brain is susceptible to effects of severe hypoglycaemia [152, 153], while from young adulthood to middle age the brain may be more resistant [154]. Cumulative exposure to severe hypoglycaemia in early-onset type 1 diabetes may be associated with poorer cognitive performance in adulthood. In the 32-year follow-up of the DCCT trial, both higher HbA_{1c} and a larger number of severe hypoglycaemic episodes were associated with greater cognitive decline [155]. There was notably a dose-response relationship, with a higher number of severe hypoglycaemic episodes linked to greater decrements in psychomotor function and mental efficiency that was most evident in later life [155, 156]. The psychological morbidity of fear of hypoglycaemia [157] should not be underestimated and can pose a barrier to optimal glycaemic levels.

Hypoglycaemia and cardiovascular disease

Hypoglycaemia can lead to cardiovascular consequences [158]. The role of tight glycaemic management in reducing microvascular complications in newly diagnosed type 2 diabetes was established in the UK Prospective Diabetes Study (UKPDS) in 1998 [134]. While there was a non-significant reduction in the relative risk of myocardial infarction ($p = 0.052$) in the original trial, a 10-year follow-up of the UKPDS cohort showed significant reductions in myocardial infarction and cardiovascular mortality in the intensively treated group [159]. Three, multicentre RCTs subsequently tested the hypothesis that intensive glycaemic management reduces cardiovascular events in type 2 diabetes by recruiting 23 182 participants globally with known cardiovascular disease or established risk factors [117, 118, 150]. In all trials, no significant reduction in major cardiovascular events was observed. Indeed, mortality in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial actually increased [119]. Possible explanations for this include weight gain, specific medications, or simply the play of chance, but it is telling that compared to the Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) trial, where there was no increase in mortality, rates of severe hypoglycaemia in ACCORD were in the order of four to five times higher [158]. An association between hypoglycaemia and cardiovascular mortality has also been reported in type 1 diabetes, albeit less consistently [123, 160, 161]. It is uncertain, however, if the association between hypoglycaemia and cardiovascular mortality in diabetes is causal or due to confounding. Hypoglycaemia could be a marker for susceptibility by virtue of being more prevalent in those with comorbidities, including frailty, liver and kidney disease; these conditions are likely to lead to hypoglycaemia, but also independently increase the risk of cardiovascular mortality [162].

Concerns around confounding have led to additional *post hoc* analyses of global cohort studies (epidemiological and clinical trials) with tens and thousands of participants with type 1 diabetes and type 2 diabetes. Collectively, these studies demonstrate a 1.5–6-fold increased risk of cardiovascular events and mortality in those who experience hypoglycaemia compared with those who do not [158]. The association between hypoglycaemia and stroke,

however, is less convincing [163]. A large systematic review and meta-analysis of nearly a million people employed specific statistical adjustments to conclude that comorbidities alone cannot explain the relationship between hypoglycaemia and cardiovascular disease in type 2 diabetes [164]. Nonetheless, whether hypoglycaemia is a risk factor for cardiovascular disease or simply a risk marker is still debated [158]. A recent *post hoc* analysis of the DEVOTE trial population supports the hypothesis that hypoglycaemia is a risk factor for cardiovascular events in type 2 diabetes [165]. Further, Heller et al. recently conducted a *post hoc* analysis of the Liraglutide Effect and Action in Diabetes (LEADER) trial, first to test a potential association between non-severe and severe hypoglycaemia episodes; and second to test a potential association between hypoglycaemia severity and risk of subsequent cardiovascular events in those with type 2 diabetes [166]. Although non-severe hypoglycaemia episodes (>2 per year) were associated with an increased risk of severe hypoglycaemia, no association was found between lower rates (2–11 episodes per year) of non-severe hypoglycaemia and cardiovascular events; however, higher rates (≥ 12 episodes per year) of non-severe hypoglycaemia were associated with a higher risk of cardiovascular events and mortality, suggesting a dose-response relationship [166]. Overall, the true picture is likely to be multifactorial, with confounding and causality likely to be contributing and the magnitude of risk also influenced by the severity and frequency of hypoglycaemia, underlying cardiovascular risk, type and duration of diabetes, and potentially other as yet undetermined biological variables.

It is challenging to establish cause and effect between hypoglycaemia and cardiovascular events in diabetes through *post hoc* analyses. To definitively answer this question, a clinical trial would involve exposure of one group to severe hypoglycaemia while the other was not exposed, with cardiovascular events and mortality as key trial outcomes [158]. Such a study is impractical and clearly unethical, especially as intensive glycaemic management appears to confer a greater cardiovascular risk in those with a high pre-existing cardiovascular burden [167]. However, recent experimental studies have elucidated novel mechanisms through which hypoglycaemia could cause adverse cardiovascular events in those with diabetes [168–173]. These mechanisms are illustrated in Figure 40.9.

Clinical definition and classification of hypoglycaemia

The American Diabetes Association (ADA) and ADA/Endocrine Society Workgroups on Hypoglycaemia [174, 175] defined hypoglycaemia in diabetes as ‘all episodes of abnormally low plasma glucose concentration that expose the individual to potential harm’. However, it is not possible to state a specific plasma glucose concentration that defines clinical hypoglycaemia; although symptoms typically develop at plasma glucose concentrations of 2.8–3.1 mmol/l (~50–55 mg/dl) (Figure 40.1) [176] in individuals without diabetes, the glycaemic threshold for symptoms (and also those for glucose counter-regulatory and cognitive dysfunction responses) shifts to lower plasma glucose concentrations in people with tightly managed diabetes and recurrent hypoglycaemia [59, 175], and to higher plasma glucose concentrations in those with suboptimally managed diabetes [59, 175, 177].

The ADA workgroups on hypoglycaemia with drug-treated diabetes (implicitly those treated with an insulin secretagogue or insulin) became concerned about the possibility of developing hypoglycaemia at a plasma glucose concentration of 3.9 mmol/l (≤ 70 mg/dl) [174, 175]. Within the error of self-monitoring of blood glucose (or continuous glucose sensing), that conservative alert value approximates the lower limit of the post-absorptive plasma glucose concentration range in people without diabetes [176] and the normal glycaemic thresholds for activation of physiological glucose counter-regulatory systems [176], and is low enough to reduce glycaemic defences against subsequent hypoglycaemia [61] in individuals without diabetes. Indeed, impairment of a complex function, driving, has been demonstrated at plasma glucose levels in this general range in type 1 diabetes [178]. It also generally provides some margin for the relative inaccuracy of glucose monitors at low plasma glucose concentrations.

The International Hypoglycaemia Study Group (IHSG) sought to standardize the definition of hypoglycaemia in clinical trials and proposed three levels of hypoglycaemia: level 1 (< 3.9 mmol/l); level 2 (< 3.0 mmol/l); and level 3, which corresponds to severe hypoglycaemia requiring external assistance (Table 40.4) [179]. The group recommended that glucose < 3.0 mmol/l should be regarded as

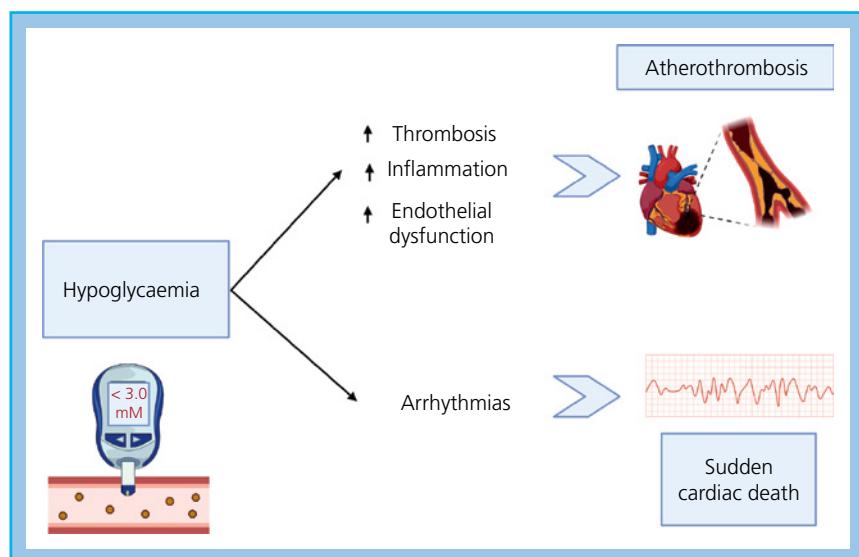

Figure 40.9 Mechanisms through which hypoglycaemia may cause adverse cardiovascular events. Source: Created by A. Iqbal in Biorender.com.

Table 40.4 International Hypoglycaemia Study Group definition of levels of hypoglycaemia that should be reported in clinical trials.

Level	Classification	Definition
1	Hypoglycaemia alert	Glucose <3.9 mmol/l (70 mg/dl)
2	Clinically important	Glucose <3.0 mmol/l (54 mg/dl) is sufficiently low to indicate serious, clinically important hypoglycaemia Should be reported in clinical trials
3	Severe	Severe hypoglycaemia with as defined by American Diabetes Association [175] denotes severe cognitive impairment requiring external assistance for recovery

Source: Modified by permission from International Hypoglycaemia Study Group 2017 [179].

clinically significant and should be reported in clinical trials. The basis for the proposed new classification is as follows:

- The level of 3 mmol/l (54 mg/dl) represented a glucose level below which clinically relevant consequences can develop; these include cognitive impairment, cardiac arrhythmias, and evidence that repeated episodes of glucose levels below this concentration can lead to impaired awareness and counter-regulatory impairment.
- Agreeing a third level (level 2) that was not severe but was clinically important would increase the statistical power of studies comparing different interventions to prevent and treat hypoglycaemia.
- Agreeing a revised classification would permit researchers to combine trial data in systematic reviews and permit meta-analysis.
- Adding the phrase ‘cognitive impairment requiring the assistance of a third party’ would allow paediatricians to adopt the same classification as used in adult practice. Paediatric classifications previously had defined severe hypoglycaemia as coma or needing parenteral therapy, as all young children ‘need the help of another person’ when treating any episode of hypoglycaemia.

The classification was adopted by both the ADA and the European Association for the Study of Diabetes (EASD) and subsequently by other organizations, including the Juvenile Diabetes Research Foundation (JDRF), International Society for Paediatric and Adolescent Diabetes (ISPAD), Advanced Technologies and Treatments for Diabetes (ATT), and at least one regulator (European Medicines Agency, EMA).

Prevention and treatment of hypoglycaemia in diabetes: hypoglycaemia risk factor reduction

Iatrogenic hypoglycaemia is a barrier to glycaemic management in people with diabetes [1,5], but the barrier can be lowered in individuals with diabetes by the practice of hypoglycaemia risk factor reduction (Table 40.5) [1,5,108]. That involves four steps:

1. Acknowledge the problem.
2. Apply the principles of aggressive glycaemic therapy [1,5,108,180–184].
3. Consider the conventional risk factors for hypoglycaemia (Table 40.2).
4. Consider the risk factors for hypoglycaemia-associated counter-regulatory impairment in diabetes (Table 40.2).

Table 40.5 Hypoglycaemic risk factor reduction.

- 1 Acknowledge the problem
- 2 Apply the principles of aggressive glycaemic therapy
 - Diabetes self-management (patient education and empowerment)
 - Frequent self-monitoring of blood glucose and increasingly continuous glucose monitoring
 - Flexible and appropriate insulin (and other drug) regimens
 - Individualized glycaemic goals
 - Ongoing professional guidance and support
- 3 Consider the conventional risk factors for hypoglycaemia (Table 40.2)
- 4 Consider the risk factors indicative of hypoglycaemia-associated counter-regulatory impairment (Table 40.2)

The issue of hypoglycaemia should be addressed in every contact with people with diabetes, at least those treated with a sulfonylurea, a glinide, or insulin [1,5,108]. Acknowledging the problem allows the caregiver either to move on if hypoglycaemia is not an issue, or to address it, and keep it in perspective, if hypoglycaemia is an issue. Patient concerns about the reality, or even the possibility, of hypoglycaemia can be a barrier to glycaemic management [185,186]. It is often helpful also to question close associates of the person with diabetes, because they may have observed clues to episodes of hypoglycaemia not recognized by the individual with diabetes. Even if no concerns are expressed, examination of the self-monitoring of blood glucose or CGM records will often disclose that hypoglycaemia is a problem.

If hypoglycaemia is an issue, the principles of intensive glycaemic therapy in diabetes [1,5,108,180–184] should be reviewed and applied. These include diabetes self-management based on diabetes education and empowerment, frequent self-monitoring of blood glucose (and increasingly use of CGM), flexible and appropriate insulin (and other drug) regimens, individualized glycaemic goals, and ongoing professional guidance and support (Table 40.5).

Diabetes self-management education and empowerment are fundamentally important. As the therapeutic regimen becomes progressively more complex, both early in type 1 diabetes and later in type 2 diabetes, the success of glycaemic management becomes progressively more dependent on the many management decisions and skills of the well-informed person with diabetes. In addition to basic training about diabetes, people with insulin secretagogue or insulin-treated diabetes need to learn about hypoglycaemia [187]. They need to know the common symptoms of hypoglycaemia, and their individual most meaningful symptoms, and how to treat (and not overtreat) an episode. Close associates also need to be taught the symptoms and signs of hypoglycaemia, and when and how to administer glucagon. The individual needs to understand the relevant conventional risk factors for hypoglycaemia (Table 40.2), including the effects of the dose and timing of their individual secretagogue or insulin preparation(s) and also the effects of missed meals and the overnight fast, exercise, and alcohol ingestion. They also need to know that episodes of hypoglycaemia signal an increased likelihood of future, often more severe, hypoglycaemia [110,111,113,115,187–190]. Finally, individuals using an online glucose monitoring system need to apply those data critically to their attempts to minimize both hypoglycaemia and hyperglycaemia.

The core approach to virtually all individuals in whom iatrogenic hypoglycaemia becomes a problem is structured education (or often re-education), which reduces the rates of severe hypoglycaemia

[67, 191–193]. This is often coupled with short-term scrupulous avoidance of hypoglycaemia, which reverses impaired awareness of hypoglycaemia in most affected individuals [94–97]. The therapeutic objective is to minimize the number and the magnitude of episodes of hypoglycaemia, not to promote hyperglycaemia. Indeed, it is often possible to lower HbA_{1c}.

In people treated with an insulin secretagogue, and particularly those treated with insulin, frequent self-monitoring of blood glucose becomes progressively more key to diabetes self-management as the therapeutic regimen grows more complex, both early in type 1 diabetes and later in type 2 diabetes. Ideally, individuals should estimate their glucose levels whenever they suspect hypoglycaemia. That would not only confirm or exclude an episode of hypoglycaemia, it would also help the individual learn the key symptoms of their hypoglycaemic episodes and might lead to regimen adjustments. It is particularly important for people with impaired awareness of hypoglycaemia to monitor their glucose level before performing a critical task such as driving. Self-monitoring of blood glucose provides a glucose estimate only at one point in time; it does not indicate whether glucose levels are falling, stable, or rising. That limitation is addressed by evolving technologies for real-time CGM [194–196]. Subcutaneous glucose concentrations lag changes in plasma glucose by 10–15 minutes and their measurement suffers from some inaccuracy. Nonetheless, CGM is associated with an average HbA_{1c} reduction of 0.4–0.6% (4–6 mmol/mol) in adults with type 1 diabetes who used the device when prescribed without an increase in detected hypoglycaemia [194]. However, in one study, the sensitivity and specificity for the detection of low glucose levels were only 65% and 80%, respectively, and both false-negative and false-positive results were common [196].

Flexible and appropriate drug regimens are key components of hypoglycaemia risk factor reduction [1, 5, 108]. Hypoglycaemia is typically the result of relative or absolute therapeutic (endogenous or exogenous) insulin excess and compromised defences against falling plasma glucose concentrations. The relevant treatments include insulin or an insulin secretagogue such as a sulfonylurea (e.g. glibenclamide [glyburide], glipizide, glimepiride, and gliclazide) or a glinide (e.g. repaglinide and nateglinide). Early in the course of type 2 diabetes, people may respond to drugs that do not raise insulin levels at low or normal plasma glucose concentrations and therefore should not, and probably do not, cause hypoglycaemia [1, 5]. These include the biguanide metformin, which nonetheless has been reported to cause self-reported hypoglycaemia [115], thiazolidinediones, α -glucosidase inhibitors, glucagon-like peptide 1 (GLP-1) receptor agonists, dipeptidyl peptidase 4 (DPP-4) inhibitors, and sodium–glucose co-transporter 2 (SGLT-2) inhibitors. All these drugs require endogenous insulin secretion to lower plasma glucose concentrations, and insulin secretion declines appropriately as glucose levels fall into the normal range. That is true even for the GLP-1 receptor agonists and the DPP-4 inhibitors, which enhance glucose-stimulated insulin secretion (among other actions). They do not stimulate insulin secretion at normal or low plasma glucose concentrations (i.e. they increase insulin secretion in a glucose-dependent fashion). However, all five categories of drugs can increase the risk of hypoglycaemia if used with an insulin secretagogue or insulin.

Among the commonly used sulfonylureas, the longer-acting glibenclamide (glyburide) is more often associated with hypoglycaemia than the shorter-acting glimepiride [146, 197]. The use of long-acting insulin analogues (e.g. glargin or detemir), rather than neutral protamine Hagedorn (NPH) insulin, as the basal insulin in

a multiple daily injection insulin regimen reduces at least the incidence of nocturnal hypoglycaemia, and perhaps also that of total, symptomatic, and nocturnal hypoglycaemia, in type 1 diabetes and type 2 diabetes [197–199]. The use of a rapid-acting analogue (e.g. lispro, aspart, or glulisine) as the prandial insulin in a multiple daily injection regimen reduces the incidence of nocturnal hypoglycaemia, at least in type 1 diabetes [198–201]. Second-generation basal analogues (insulin degludec, insulin glargine 300 U/ml) have more consistent pharmacokinetic profiles. Compared with first-generation insulin glargine 100 U/ml, both are associated with a lower risk of hypoglycaemia, particularly nocturnal hypoglycaemia, while achieving similar HbA_{1c} [202–204]. In a randomized crossover trial, insulin degludec was associated with lower rates of symptomatic hypoglycaemic episodes in people with type 1 diabetes (2201 vs 2463 episodes per 100 person-years' exposure) compared with insulin glargine 100 U/ml [205].

Significant advances have been made in CGM systems, which detect interstitial glucose using enzymatic sensors, integrated with a mobile reader to deliver real-time glucose levels (real-time or rtCGM) or on scanning (intermittently scanned or isCGM). Such systems can warn the user or care partner of hypoglycaemia or impending hypoglycaemia. In RCTs, rtCGM reduced hypoglycaemia compared with self-monitoring of blood glucose in type 1 diabetes [204], including those with impaired awareness [207]. In type 2 diabetes, use of isCGM reduced hypoglycaemia in open-label trial settings [208]. Significant reductions in severe hypoglycaemic events with isCGM were also reported in real-world settings [209], although the accuracy of CGM sensors in the hypoglycaemia range remains a limiting factor.

Because the basal insulin infusion rate can be varied across the day, continuous subcutaneous insulin infusion using insulin pumps should be superior to multiple daily injections. It may reduce HbA_{1c}, the frequency of hypoglycaemia, or both, in selected capable and motivated individuals [210]. However, in the HypoCOMPASS trial [68], neither pump therapy alone (compared with multiple daily injections) nor CGM (compared with self-monitoring of blood glucose) reduced severe hypoglycaemia or improved awareness of hypoglycaemia to a greater extent. Sensor-augmented pumps, which combine rtCGM with an insulin pump, achieve an ~0.5% (5 mmol/mol) greater decrease in HbA_{1c} than multiple daily injections alone without an increase in hypoglycaemia [211, 212]. A sensor-augmented pump that temporarily suspends insulin infusion for up to two hours when the CGM value falls below a pre-selected level (a low glucose suspend [LGS] feature) reduces the frequency of severe hypoglycaemia [213, 214].

Significant advances have been made in closed-loop insulin delivery, which combines CGM and insulin pump with an automated controller. Current commercially available systems are hybrid closed-loop systems that provide algorithm-driven automated insulin delivery, but still require manual or *announced* mealtime boluses. Compared with sensor-augmented pumps, hybrid closed-loop systems have been associated with significant reductions in HbA_{1c} and time in hypoglycaemia by CGM in adults and adolescents with type 1 diabetes [215–216]. Bihormonal pumps, with automated delivery of both insulin and glucagon, are actively under clinical development and may confer additional protection from hypoglycaemia [219–221]. Islet transplantation can restore α - and β -cell function in longstanding type 1 diabetes in individuals with impaired awareness of hypoglycaemia or recurrent severe hypoglycaemia with undetectable C-peptide. Long-term follow-up of transplant recipients has shown that they remained completely

free of severe hypoglycaemic episodes at 10 years with reduced insulin requirements [222]. Although closed-loop and islet transplantation may be effective in reducing hypoglycaemia, the cost and complexity of these technologies currently preclude them from being used widely. Patient motivation and education remain paramount in achieving the best outcomes with new technologies. Indeed, several psycho-educational interventions, including blood glucose awareness training [223], have demonstrated reduced numbers of severe hypoglycaemia in recent trials.

Given the evidence that optimal glycaemic management partially prevents or delays microvascular complications of diabetes, and may partially prevent or delay macrovascular complications, it follows that a lower HbA_{1c} is in the best interests of people with diabetes if it can be achieved and maintained safely [138]. Thus, a reasonable individualized glycaemic goal is the lowest HbA_{1c} that does not cause severe hypoglycaemia, preferably with little or no symptomatic or even asymptomatic hypoglycaemia, at a given stage in the evolution of the individual's diabetes [138]. That links the selection of a glycaemic goal to the risk of hypoglycaemia, as well as the use of drugs that can cause hypoglycaemia and the type and duration of diabetes, a surrogate for endogenous insulin deficiency. If the therapeutic regimen produces severe hypoglycaemia or impaired awareness of hypoglycaemia, or an unacceptable number of symptomatic or asymptomatic episodes, hypoglycaemia has become a problem that needs to be addressed.

Because the glycaemic management of diabetes is empirical, caregivers should work with each individual over time to find the most effective and safest method of glycaemic management at a given point in the course of that person's diabetes. Care is best accomplished by a team that includes, in addition to a physician, professionals trained in, and dedicated to, translating the standards of care into the care of the individual and making full use of modern communication and computing technologies.

Another step is to consider the conventional risk factors for hypoglycaemia, especially those that result in both relative and absolute therapeutic insulin excess. In addition to insulin secretagogue or insulin doses, timing, and type, these include conditions in which exogenous glucose delivery or endogenous glucose production is decreased, glucose utilization or sensitivity to insulin is increased, or insulin clearance is reduced (Table 40.2).

Finally, the risk factors for counter-regulatory impairment need to be considered. These include the degree of endogenous insulin deficiency, a history of severe hypoglycaemia, impaired hypoglycaemia awareness, or both, and also any relationship between hypoglycaemic episodes and recent antecedent hypoglycaemia, prior exercise or sleep, and lower HbA_{1c} levels (Table 40.2). Unless the cause is easily remediable, a history of severe hypoglycaemia should prompt consideration of a fundamental regimen adjustment. Without that, the risk of a subsequent episode of severe hypoglycaemia is high [110, 111, 113, 115, 187–190]. Given a history of impaired awareness of hypoglycaemia, a 2–3-week period of scrupulous avoidance of hypoglycaemia, without running glucose levels high, is advisable since it may improve awareness [94–98]. Interestingly, few of the reversal studies have led to significant restoration of impaired counter-regulatory hormone responses [95–98]. A history of late post-exercise hypoglycaemia, nocturnal hypoglycaemia, or both should prompt appropriately timed regimen adjustments (generally, less insulin action, more carbohydrate ingestion, or both).

When prevention fails, treatment of hypoglycaemia becomes necessary. Most episodes of asymptomatic hypoglycaemia (detected by self-monitoring of blood glucose or CGM) and of mild–moderate

symptomatic hypoglycaemia are effectively self-treated by ingestion of glucose tablets or carbohydrate-containing juice, soft drinks, other snacks, or a meal [224, 225]. A reasonable dose is 20 g of glucose [225]. Clinical improvement should occur in 15–20 minutes; however, in the setting of ongoing hyperinsulinaemia, the glycaemic response to oral glucose is transient, typically less than two hours [225]. Thus, ingestion of a more substantial snack or meal shortly after the plasma glucose concentration is raised is generally advisable.

Parenteral treatment is required when a hypoglycaemic patient is unwilling (because of neuroglycopenia) or unable to take carbohydrate orally. Glucagon, injected subcutaneously or intramuscularly (in a usual dose of 1.0 mg in adults) by an associate of the patient, may be used. That can be life-saving, but it often causes substantial, albeit transient, hyperglycaemia and it can cause nausea or even vomiting. Smaller doses of glucagon (e.g. 150 µg), repeated if necessary, are effective without side effects [226]. Because it acts by stimulating hepatic glycogenolysis, glucagon is ineffective in glycogen-depleted individuals (e.g. following a binge of alcohol ingestion). New formulations of nasal glucagon are now available that are easier to administer. In a real-world prospective study, hypoglycaemic episodes resolved within 30 minutes of nasal glucagon administration, and in 95% of individuals and severe hypoglycaemic episodes resolved without additional external help within 15 minutes of receiving glucagon [227]. New glucagon analogues are also entering clinical practice as pre-filled pens with a long shelf-life.

Although glucagon can be administered intravenously by medical personnel, intravenous glucose is the standard parenteral therapy [224]. The glycaemic response to intravenous glucose is, of course, transient in the setting of ongoing hyperinsulinaemia.

The duration of an episode of iatrogenic hypoglycaemia is a function of its cause. An episode caused by a rapid-acting insulin secretagogue or insulin analogue will be relatively brief, while that caused by a long-acting sulfonylurea or insulin analogue will be substantially longer. The latter can result in prolonged hypoglycaemia requiring hospitalization for monitoring and parenteral glucose infusion if required.

Hypoglycaemia in children and adolescents

The majority of individuals with type 1 diabetes are adults, but nearly three-quarters of new type 1 diabetes diagnoses occur in childhood and adolescence [228]. Despite recent advances in knowledge, education, and diabetes technologies and treatments, most children and adolescents with type 1 diabetes do not achieve recommended glycaemic targets [229, 230]. Specifically, only a quarter of young people achieve the internationally established recommended HbA_{1c} target of <53 mmol/mmol (<7%), known to be associated with reduced diabetes complications in adulthood [231]. Hypoglycaemia and the fear of hypoglycaemia remain significant barriers to achieving these targets.

Hypoglycaemia is a common complication in the management of type 1 diabetes in children and adolescents. It interferes with daily living and poses a constant perceived threat to the individual and their families. It has long been recognized as a limiting factor in achieving optimal glycaemic levels [232] with an impact on quality of life [233]. As with adults, minimizing hypoglycaemia and its impact is a key objective of paediatric diabetes care.

Although hypoglycaemia in the young person with type 1 diabetes has much in common with hypoglycaemia in adults, there are important differences, which will be highlighted in this section. For example, there are differences in the physiology of the symptomatic and hormonal counter-regulatory responses to hypoglycaemia, its epidemiology, and risk factors. Furthermore, the impact of hypoglycaemia may differ because the child's organs, in particular the brain, are developing. In addition, the effects of changing behaviour as the young person matures modify the impact and response to hypoglycaemia. Finally, more so than for adults, the role and responses of caregivers are crucial.

Definition of hypoglycaemia in children and young people

The definition and classification of hypoglycaemia in children have been aligned with those in adults (Table 40.4) [234]. An important consideration in young children is that they require assistance to correct even mild hypoglycaemia. As a result, to define a severe event accurately requires an assessment by the caregiver and clinician as to the presence (or not) of hypoglycaemia-induced cognitive dysfunction. A subgroup of severe hypoglycaemia is hypoglycaemic coma: this is a hypoglycaemic event resulting in coma or convulsion. These events should be recorded independently, as they are unequivocal and significant in outcome.

The increasing adoption of CGM into routine clinical care, particularly in children [235], has added a new dimension to assessing hypoglycaemia. Using CGM, hypoglycaemia can be reported as a proportion of time spent with a sensor glucose value below a certain value. A recent international consensus recommended targets for sensor glucose: for time with sensor glucose <3.9 mmol/l (70 mg/dl) the target is <4% (1 h/d) and for time with sensor glucose <3.0 mmol/l (<54 mg/dl) the target is <1% (15 min) [236].

Prevalence and incidence of hypoglycaemia in children and young people

Mild hypoglycaemia is common and its exact incidence is difficult to determine. Unless CGM is used, asymptomatic hypoglycaemia and hypoglycaemia during sleep are unreported. Symptomatic hypoglycaemia occurs on an average twice per week. In contrast, the accurate recall of severe hypoglycaemia is more likely to be robust, although variations in definitions, sample sizes, and retrospective surveys have made comparisons between studies difficult.

The DCCT was one of the first studies to prospectively document hypoglycaemia incidence. In that trial there was a threefold increased risk of severe hypoglycaemia events in individuals randomized to the intensive management arm of the study and rates were higher in adolescents both in the intensive and conventional treatment arms [110]. The incidence of severe hypoglycaemia requiring treatment assistance was 61 per 100 person-years in those intensively treated. Similar high rates were reported in contemporary observational cohorts from Colorado and Western Australia [237, 238].

More recently, rates have substantially reduced. Population-based studies from Western Australia, Denmark, and Germany/Austria (Diabetes-Patienten-Verlaufsdocumentation, DPV registry) demonstrated a reduction of severe hypoglycaemia rates (convulsions and coma) in children and young people by >50% over the last two decades [238–241]. Historically, severe hypoglycaemia was associated with lower HbA_{1c} [242, 243], although this relationship has weakened in recent years, as observed in a large longitudinal cohort study from Europe and Australia, with a reduction in the rates

of severe hypoglycaemia [244]. In that analysis, the severe hypoglycaemic coma rate decreased by an annual average of 2% and 6% in the European DPV and the Western Australian cohort, respectively. Likewise, younger age, historically a risk factor for severe events, did not increase the risk of severe hypoglycaemia, in spite of improved glycaemic levels [244, 245]. Similarly, a combined analysis from the US type 1 diabetes (T1D) Exchange and the DPV registry did not find increased rates of severe hypoglycaemic coma in those <6 years of age with HbA_{1c} <7.5% (58 mmol/mol) compared to those with higher HbA_{1c} [245]. The causes of these changes can only be subject to speculation, but improved knowledge and education along with increased use of insulin analogues and insulin pump therapy are likely contributors [240, 246–248]. Even though rates have reduced, hypoglycaemia continues to be a significant problem for young people living with diabetes and their families.

Signs and symptoms

As in adults, hypoglycaemia is often accompanied by signs and symptoms of autonomic (adrenergic) activation and/or neurological dysfunction from glucose deprivation in the brain (neuroglycopenia). As the blood glucose falls, the initial symptoms result from activation of the autonomic nervous system and include shakiness, sweating, pallor, and palpitation. In healthy individuals with no diabetes, these symptoms occur at a higher blood glucose level in children than in adults (3.2–3.4 mmol/l [58–61 mg/dl] vs 2.8–3.1 mmol/l [50–56 mg/dl], children vs adults) [249]. The threshold for symptoms in individuals with diabetes will depend on their glycaemic levels [178, 249, 250], with an adaptive shift of the glycaemic threshold for symptom onset to a higher glucose level with chronic hyperglycaemia and a lower glucose level with chronic hypoglycaemia.

Signs of hypoglycaemia in children include behavioural changes: irritability, agitation, quietness, stubbornness, and tantrums may be the prominent symptom particularly for preschool children, and may result from a combination of neuroglycopenic and autonomic responses [251]. In this younger age group, observed signs, such as pallor, are more important. The dominant symptoms of hypoglycaemia tend to differ depending on age, with neuroglycopenia more common than autonomic symptoms in the young [252].

Physiological responses in children and adolescents

Although many of the physiological responses to hypoglycaemia are similar throughout the lifespan, developmental and age-related differences have been described in children and adolescents. As described for symptoms, counter-regulatory hormone responses differ in adolescents, who release catecholamines, cortisol, and growth hormone at a higher blood glucose than adults [249]. Adolescents also have deficient glucagon responses to hypoglycaemia within three months from diagnosis of type 1 diabetes [253].

To date, nearly all studies have been conducted in adolescents and young adults, primarily due to the difficulty of studying a younger age group. As a result, little is known about whether responses in pre-adolescents demonstrate a similar or different effect.

Impact and consequences of hypoglycaemia in children and young people

Hypoglycaemia is a constant concern for children, adolescents, and their families. Symptoms may be distressing or embarrassing, potentially compromising academic, social, and physical activities. Transient cognitive dysfunction associated with neuroglycopenia can affect education and present a risk for the young person.

Furthermore, the daily requirement to adjust therapy to prevent hypoglycaemia is a significant ongoing burden for caregivers.

Psychological impact of hypoglycaemia

Severe hypoglycaemic episodes tend to have negative psychosocial consequences for the individual [254]. Fear of hypoglycaemia can induce anxiety and, although in some cases this anxiety can lead to appropriate vigilance in glucose management, high levels of anxiety can lead to disruptions in daily activities and suboptimal diabetes management [255]. Fear of hypoglycaemia can have impacts not only on the child but also the parents, and result in increased anxiety, poor sleep, and reduced quality of life [256]. This fear could lead families and/or physicians to accept high glucose levels, with behaviours directed towards avoiding hypoglycaemia leading to suboptimal glycaemic levels.

Neurological sequelae of hypoglycaemia

Although severe and prolonged hypoglycaemia has the potential to result in neurological impairment [257], multiple studies have only found subtle impacts of hypoglycaemia on the brain in children. Children with early-onset type 1 diabetes (<6 years of age) have cognitive defects on neuropsychological testing and changes on brain imaging [258]. This was assumed to be the result of hypoglycaemia, but detailed studies have not confirmed this and more recent evidence suggests that chronic hyperglycaemia [259,260] and even diabetic ketoacidosis [261] are more injurious to the brain in the young.

Impaired awareness of hypoglycaemia

Impaired awareness of hypoglycaemia may develop in children as well as adults, with a prevalence of between 19% and 37% [262,263]. As in adults, impaired awareness is associated with a significantly increased risk of a severe hypoglycaemia event [262]. Determining the level of hypoglycaemia awareness is an important component of routine clinical care.

Mortality

Mortality from hypoglycaemia in children and young people is rare, but has been reported [144,145]. Although rare, it is a common source of parental anxiety and fear of hypoglycaemia.

Risk factors for hypoglycaemia in children and young people

Undoubtedly, the most important risk factor for hypoglycaemia lies within insulin therapy itself and the mismatch between administered insulin and consumed food. An absolute excess of insulin could result from increased doses due to poor understanding of insulin type and action or accidental delivery. Similarly, a relative insulin excess is seen with reduced food intake or missed meals, and in situations where glucose utilization is increased (during exercise) or endogenous glucose production is decreased (after alcohol intake).

Managing type 1 diabetes and balancing the risk factors for hypoglycaemia in young children and young people present unique challenges owing to the child's developmental level, unpredictability of an infant or toddler's dietary intake, and the child's irregular activity level, emotional maturity, and behaviour.

Risk factors for recurrent hypoglycaemia

Most children with type 1 diabetes who experience severe hypoglycaemia have isolated events; however, a few experience recurrent episodes. After a severe episode, the risk of recurrent severe events

is increased, in one report for up to four years [264]. When hypoglycaemia is recurrent, it is important to exclude impaired awareness of hypoglycaemia and rule out coexisting autoimmune disorders, such as subclinical hypothyroidism, coeliac disease, and Addison's disease [265–267]. Unexplained hypoglycaemia particularly in adolescence may be factitious due to self-administration, often a sign of psychological distress [268].

Exercise

Glucose response to exercise is affected by many factors, including the duration, intensity, and type of exercise; the time of day when exercise is performed; plasma glucose and insulin levels; and the availability of supplemental and stored carbohydrates [269,270]. The risk of hypoglycaemia is increased immediately after or during exercise, but may also be delayed up to 12 hours after exercise due to changes in insulin sensitivity and muscle glycogen restoration [271]. A range of strategies may be used to prevent exercise-induced hypoglycaemia, including close glucose monitoring, altering insulin doses, and carbohydrate ingestion [269].

Alcohol

Alcohol inhibits gluconeogenesis and may lead to hypoglycaemia [272]. Furthermore, the symptoms of hypoglycaemia may be obscured or masked by the cerebral effects of alcohol.

Nocturnal hypoglycaemia

Hypoglycaemia during sleep is a major concern for parents, and children have more frequent and prolonged periods of hypoglycaemia at night [273]. Younger age, lower HbA_{1c}, antecedent exercise, and hypoglycaemia are associated with a greater frequency of nocturnal hypoglycaemia [274]. Counter-regulatory catecholamine responses to hypoglycaemia are suppressed during sleep.

Hypoglycaemia treatment in children and young people

A goal of diabetes education is the prevention of hypoglycaemia through awareness of the problem, recognition of risk factors, regular glucose monitoring, and self-care behaviours such as appropriate insulin dosing and food intake. Despite this, hypoglycaemia may occur and a treatment plan is a required component of management.

When the glucose level falls below 3.9 mmol/l (70 mg/dl), remedial actions to prevent a further drop in glucose are recommended. The amount of glucose required may vary between individuals, circumstances, and insulin treatment. One study found that in children, 0.3 g/kg of rapidly acting carbohydrate-containing preparations effectively resolves hypoglycaemia in most children and raises median blood glucose by 1–1.3 mmol/l (90–113 mg/dl) in 10 minutes and 2.0–2.1 mmol/l (180–190 mg/dl) in 15 minutes without rebound hyperglycaemia at the next meal [275]. For children using insulin pump therapy, a lower amount of glucose may be required along with suspension of insulin delivery [276].

Urgent treatment is required in the event of severe hypoglycaemia, which can be safely reversed by glucagon administered intravenously, intranasally, intramuscularly, or subcutaneously [277,278]. In hospital, intravenous glucose or glucagon may be given. Intravenous glucose should be administered by trained personnel over several minutes to reverse hypoglycaemia. If glucose is given in excessive concentration (50% dextrose) or too rapidly, there is a risk of brain injury due to rapid osmolar change and cerebral oedema [279].

Diabetes technology and hypoglycaemia in children and young people

The introduction of diabetes technologies into routine diabetes care has offered new approaches to reducing the impact of hypoglycaemia on young people with type 1 diabetes. Insulin pump therapy has been associated with lower hypoglycaemia rates in trials and real-world data reports [280, 281]. With pump therapy it is possible to adjust insulin delivery to more closely mimic physiological insulin delivery. CGM provides 24-hour glucose monitoring and allows the individual, or healthcare providers, to assess trends in glucose levels and early intervention to prevent hypoglycaemia. Trials and real-world outcome studies have shown reduced rates of hypoglycaemia with the use of these systems [281–283]. CGM that has the capacity for remote monitoring has the potential to provide caregivers with an alarm if glucose levels in a child are falling; in one trial their use was associated with improved parental quality of life and better sleep [284].

Sensor-augmented pump therapy with insulin suspension

The incorporation of algorithms that automatically suspend insulin delivery based on sensor glucose readings reduces the incidence of severe hypoglycaemia and the time spent in a low glucose range [214, 285, 286]. Current systems suspend on predicted hypoglycaemia.

Automated insulin delivery systems (hybrid closed-loop)

Automated insulin delivery, with continuous glucose sensing and insulin delivery without user intervention, offers the potential to reduce the significant glycaemic excursions associated with conventional therapy. These systems utilize a control algorithm that autonomously and continually increases and decreases the subcutaneous delivery of insulin on the basis of real-time sensor glucose levels. These devices improve the time in target glucose range and reduce the time spent in hypoglycaemia in clinical trials and observational studies [215, 287–289].

Perspective on hypoglycaemia in diabetes

Glycaemic management, a focus of this chapter, is but one aspect of the management of diabetes. It is now possible to drive plasma low-density lipoprotein (LDL) cholesterol concentrations to subphysiological levels and to normalize blood pressure pharmacologically, usually without major side effects, in most people with diabetes. Weight loss and smoking cessation are more challenging. Although it is not possible to maintain euglycaemia over a lifetime of diabetes, because of the barrier of hypoglycaemia, maintenance of the lowest mean glycaemia that can be accomplished safely is in the best interests of people with diabetes.

Despite the difficulty, people with diabetes and their caregivers should keep the problem of iatrogenic hypoglycaemia in perspective. Early in the course of type 2 diabetes, by far the most common type of diabetes, hyperglycaemia may respond to lifestyle changes, specifically weight loss, or to anti-diabetes drugs that do not raise insulin levels and therefore do not cause hypoglycaemia. In theory, when such drugs are effective in the absence of side effects, there is no reason not to accelerate their dosing until euglycaemia is achieved. Over time, however, as people with type 2 diabetes become progressively more insulin deficient, those drugs, even in combination, fail to maintain

glycaemic levels. Insulin secretagogues are also effective early in the course of type 2 diabetes, but they cause hyperinsulinaemia and therefore introduce both the risk of weight gain and hypoglycaemia. Euglycaemia is not an appropriate goal during therapy with an insulin secretagogue or with insulin. Nonetheless, the frequency of hypoglycaemia is relatively low during treatment with an insulin secretagogue or even with insulin early in the course of type 2 diabetes when glycaemic defences against falling plasma glucose concentrations are still intact. Therefore, over much of the course of the most common type of diabetes, it is possible to maintain a meaningful glycaemic level with a relatively low risk of hypoglycaemia.

The challenge is greater in people with advanced type 2 diabetes and type 1 diabetes caused by compromised defences against falling plasma glucose concentrations and the resulting higher barrier of iatrogenic hypoglycaemia. It is striking that it is 30 years since the recognition of the importance of repeated episodes of antecedent hypoglycaemia in damaging counter-regulatory mechanisms leading to impaired awareness of hypoglycaemia. Yet despite a substantial research effort in both basic and clinical arenas, our only effective therapeutic approaches involve therapeutic interventions that reduce the time individuals spend in hypoglycaemia. Nonetheless, concerns about hypoglycaemia should not be used as an excuse for suboptimal glycaemic levels. It should be recalled that the DCCT [110, 290] documented that the relationship between microvascular complications and mean glycaemia is curvilinear: some degree of glycaemic management puts the person with diabetes at substantially lower risk than little or no glycaemic management.

Diabetes will eventually be cured and prevented. Pending that, elimination of hypoglycaemia from the lives of people with diabetes will probably be accomplished by new treatment methods that provide plasma glucose-regulated insulin replacement or secretion. In the meantime, innovative research is needed if we are to improve the lives of all people affected by diabetes by lowering the barrier of iatrogenic hypoglycaemia.

Acute Metabolic Complications of Diabetes: Diabetic Ketoacidosis and the Hyperosmolar Hyperglycaemic State in Adults

Philip Newland-Jones¹, Mayank Patel¹, and Ketan Dhatariya²

¹ University Hospital Southampton NHS Foundation Trust, Southampton, UK

² Norfolk and Norwich University Hospitals NHS Foundation Trust and University of East Anglia, Norwich, UK

Key points

Diabetic ketoacidosis:

- Diabetic ketoacidosis (DKA) is based on a triad of hyperglycaemia, ketonaemia, and metabolic acidosis with a high anion gap.
- The most common causes are infection or insulin omission or inadequate dosing.
- Nausea, vomiting, abdominal pain, and Kussmaul breathing are key features, along with osmotic diuresis due to hyperglycaemia and ketonaemia.
- Administration of intravenous fluid and insulin aims to correct dehydration, hyperglycaemia, and electrolyte imbalances.
- Identification of underlying causes and precipitants will reduce the risk of recurrence.

Hyperosmolar hyperglycaemic state:

- Hyperosmolar hyperglycaemic state (HHS) is characterized by hyperosmolarity due to extreme hypovolaemia, hyperglycaemia, and electrolyte disturbance.
- It typically affects older individuals with type 2 diabetes or reveals newly diagnosed type 2 diabetes in a much wider age range.
- The most common cause is infection, although other acute situations that release counter-regulatory stress hormones such as surgery, trauma, acute coronary syndromes, or acute stroke can also predispose to HHS.
- Fluid resuscitation and electrolyte management form the mainstay of treatment, with many individuals also requiring intravenous insulin.

Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are life-threatening emergencies in diabetes. Prompt clinical suspicion is vitally important to ensure early diagnosis, thus enabling protocol-based treatment to be commenced promptly, to reduce morbidity and mortality. Though discussed as clinically distinct phenomena, DKA and HHS should be considered as different points on the spectrum of hyperglycaemic emergencies. Both are characterized by hyperglycaemia with insulinopaenia, with only the degree of hyperglycaemia, level of associated dehydration, and severity of the associated metabolic acidosis distinguishing them [1–4]. Hospital-based treatment involves close monitoring, careful fluid replacement to restore circulation, and correction of electrolyte derangement and hyperglycaemia, with effort made to identify the precipitant so that future preventive measures can be taken. This chapter reviews the pathogenesis and pathophysiology, precipitating factors, clinical presentation, management, complications, and prevention of DKA and HHS.

Diabetic ketoacidosis

Definitions

Diabetic ketoacidosis (DKA) is based on a triad of hyperglycaemia (blood glucose >11 mmol/l (200 mg/dL) or known diabetes), ketonaemia (>3 mmol/l; 30 mg/dL), and a metabolic acidosis with a high anion gap (serum bicarbonate <15 mmol/l and/or venous pH <7.3) (Table 41.1) [4, 6]. DKA is the result of either absolute or relative insulin deficiency in the context of increased counter-regulatory hormones that increase insulin resistance and reduce insulin secretion [4, 7]. DKA occurs much more commonly in those with type 1 diabetes and was considered to be one of the key clinical features that differentiated type 1 diabetes; however, it can also occur in those with type 2 diabetes during intercurrent illness or surgical stress, and more rarely in newly diagnosed type 2 diabetes [8, 9]. This ketosis-prone type 2 diabetes seems to present more commonly in those of African or Hispanic origin,

Table 41.1 Diagnostic criteria for diabetic ketoacidosis.

Severity			
Mild	Moderate	Severe	
Arterial or venous pH	7.25–7.30	7.0–7.24	<7.0
Bicarbonate (mmol/l)	15–18	10–14.9	<10
Anion gap	10–12	>12	>12
Mental status	Alert	Alert/drowsy	Stupor/coma

Source: Adapted from Dhatriya et al. 2020 [5] (criteria) and Kitabchi et al. 2009 [3] (severity).

although it can occur in all populations. Despite presenting with DKA with insulin insufficiency, people with type 2 diabetes will often restore and recover β -cell function quickly after treatment, thus avoiding the need for ongoing insulin therapy [8]. With increasing use of sodium–glucose cotransporter 2 (SGLT-2) inhibitors in the treatment of type 2 diabetes, there is a growing number of individuals developing euglycaemic DKA (blood glucose 4–11 mmol/l; 70–200 mg/dL), a potential complication of this class of medication. It is more common

in those using concomitant insulin therapy and the risk is significantly increased if medication cessation *sick-day rule* advice is not followed during intercurrent illness or surgical stress (ensuring that the individual knows never to stop basal insulin in type 1 diabetes, keeps well hydrated, monitors glucose and ketone levels every 2–3 hours, taking additional insulin if indicated, and seeks advice promptly when unwell) [10–12]. Overall, mortality with DKA has been reported as less than 1%, but a recent review of mortality in the UK reported that between 2017 and 2019 the mortality rate was 3.8% [13]. This increases considerably with ageing, which is likely related to the underlying precipitant of the DKA (e.g. infection, trauma), with mortality rates for those over 65 years old reaching 10–20% [3, 14].

Pathogenesis and pathophysiology

Although the mechanisms for the development of DKA are multifactorial, there is always an undercurrent of absolute or relative insulin deficiency, often with a concomitant increase in counter-regulatory hormones (glucagon, catecholamines, cortisol, and growth hormone) [4, 7, 15]. This mismatch in insulin production and insulin requirement leads to hydrolysis of triglycerides, delivering free fatty acids to the liver, which leads to the production of ketones (β -hydroxybutyrate, acetoacetate, and acetone) [4, 7, 15]. Counter-regulatory hormones increase gluconeogenesis and glycogenolysis, resulting in hyperglycaemia worsening osmotic diuresis, leading to hypovolaemia and higher concentrations of ketone bodies and glucose, leading to a metabolic acidosis [4, 16, 17]. Figure 41.1 outlines the pathogenesis of DKA.

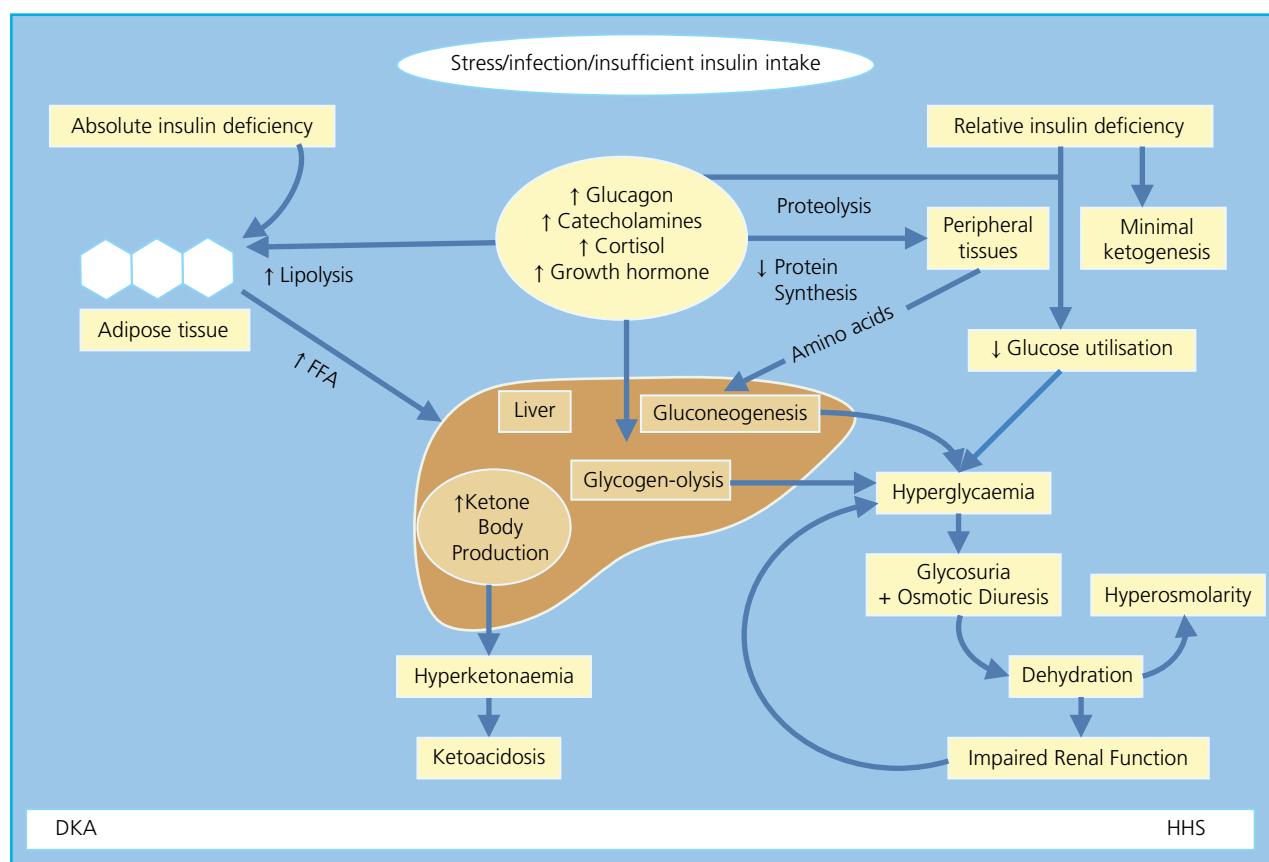

Figure 41.1 Pathogenesis of diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS). FFA, free fatty acids. Source: Reproduced from English and Williams 2004 [15] by permission of BMJ Publishing Group Ltd.

Hyperglycaemia

Hyperglycaemia in DKA is predominantly caused by the cumulative effect of absolute or relative insulin deficiency in the context of raised counter-regulatory hormones. This results in increased gluconeogenesis, glycogenolysis, and an impairment in peripheral glucose utilization, leading to hyperglycaemia [16, 18]. Both hypercortisolaemia and insulin deficiency lead to catabolism of protein from muscles, providing amino acid precursors for gluconeogenesis and ketogenesis [19–21]. The severity of hyperglycaemia is further exacerbated by osmotic diuresis driven by increased glucose levels. This osmotic diuresis leads to dehydration, hypovolaemia, and a reduction in glomerular filtration rate, which will further concentrate glucose and reduce glucose excretion [22].

Ketogenesis and ketoacidosis

Insulin deficiency and an increase in counter-regulatory hormones lead to the release of free fatty acids and glycerol from adipose tissue through increased tissue lipase activity, which in turn leads to unrestricted oxidation in the liver and ketone generation [23–25]. Acetone, acetoacetate, and β -hydroxybutyrate form the three ketone bodies generated by the liver. Acetone gives the classic *fruity* or *pear-drops* breath in those in DKA. The remaining acidic ketone bodies, acetoacetate and β -hydroxybutyrate, accumulate, leading to a decrease in serum bicarbonate concentration, the development of a high anion gap, and metabolic acidosis [26–29]. The severity of DKA is differentiated by the degree of acidosis and associated mental status, where acidosis, if severe and prolonged, can lead to irreversible damage, coma, and death.

Fluid and electrolyte disturbance

Both hyperglycaemia and ketonaemia precipitate an osmotic diuresis that leads to dehydration, hypovolaemia, and loss of electrolytes [22]. Hypovolaemia decreases glomerular filtration rate and increases counter-regulatory hormones further, which exacerbates existing hyperglycaemia and may also cause hypoperfusion, resulting in increased lactic acid levels [4, 7, 22]. The combination of osmotic diuresis, vomiting due to ketosis, and subsequent inability to maintain fluid intake can lead to severe dehydration, which makes avoidance of hospitalization difficult. A combination of acidosis, insulin deficiency, and hypertonicity cause a shift of potassium from the intracellular to the extracellular space, where it may be excreted in the urine or lost in vomit [15]. Hypovolaemia increases the concentration of aldosterone, which through promotion of sodium reabsorption in the kidneys leads to the excretion of potassium in the urine, further exacerbating potassium loss. This often results in an acute presentation of hyperkalaemia on a background of an overall total body deficit in potassium stores, which becomes evident on treatment initiation with fluid and insulin [22, 30]. Phosphate and magnesium are also often depleted on presentation of DKA, with the effects possibly exacerbating the arrhythmogenic effect of hyper- or hypokalaemia described [7].

Sodium-glucose cotransporter 2 inhibitor-induced ketoacidosis

The use of SGLT-2 inhibitors has increased significantly in recent years, leading to an increase in presentation of euglycaemic DKA [31]. It is usually precipitated by intercurrent illness or metabolic stress (surgery, infection, decreased oral intake, gastrointestinal losses), where appropriate medication cessation has not occurred as described in sick-day rule guidance [32]. SGLT-2 inhibitors create a pseudo-fasted state, the promotion of glycosuria, and

lower circulating glucose levels, to which the body responds by reducing insulin production and increasing glucagon release. During intercurrent illness and subsequent increased insulin resistance due to counter-regulatory hormones, a disconnect between insulin requirement and production develops. The relative insulinopaenia leads to increased lipolysis, ketosis, and eventually acidosis, but importantly, due to ongoing glycosuria and low plasma glucose, this occurs in the context of euglycaemia rather than hyperglycaemia [32–34].

Precipitating factors

Initial presentation with DKA at the point of diagnosis of type 1 diabetes is more common in children, but can occur in up to 20% of adults with diabetes [35, 36]. For those with known diabetes, the most common precipitants are infections, intercurrent illness, and insulin omission or inadequate dosing (Table 41.2). A large single-centre study of 786 consecutive admissions showed that the distribution of precipitants has changed over time, with intercurrent illness and suboptimal insulin dosing remaining the most common causes, but increasingly SGLT-2 inhibitor use, immune therapy-induced diabetes [38], and Covid-19 infection also being causes [39].

The importance of the relationship between psychological factors and insulin treatment should not be underplayed. Diabetes distress, depression, anxiety, and eating disorders are common among people with type 1 diabetes, which can increase the risk of developing DKA [35, 40–42]. During the initial stages of the Covid-19 pandemic, national data from across England showed that admissions for DKA in those known to have type 1 diabetes dropped significantly [43]. It was thought that this was due to being in lockdown: people were able to pay more attention to their diabetes, but were also following their sick-day rules. However, the same data showed that admissions with DKA in those with known type 2

diabetes rose significantly, as well as in those newly diagnosed with diabetes [43]. Again, it was thought that there was a behavioural aspect to this, with people not seeking help from primary or secondary care teams (or unable to do so), and thus when they did present they were sicker than they otherwise might have been had they had swifter access to healthcare professionals. To prevent DKA recurrence, it is important to clearly identify the underlying cause for DKA and formulate a plan via a shared decision-making process.

Clinical presentation and diagnosis

Though often preceded by a brief period of general malaise, DKA usually develops in less than 24 hours and can affect both young and old individuals, so age at presentation is less relevant. Common presenting symptoms with their associated underlying pathophysiological causes and signs are shown in Table 41.3. Nausea, vomiting, and abdominal pain are relatively common early features, most likely due to a combination of evolving ketonaemia, dehydration, and delayed gastric emptying [35, 44]. Physical examination often reveals signs of dehydration, such as reduced skin turgor, hypotension, and tachycardia. Impaired mental state, drowsiness, and coma can also result. In particular, clinicians must be aware that rapid, deep breathing (Kussmaul respiration) may not just reflect a primary respiratory problem, but actually represent an appropriate physiological response to the significant metabolic acidosis in DKA [35, 45]. Fever often suggests a concurrent infection.

The diagnosis of DKA is made based on the presence of all three of hyperglycaemia, ketonaemia, and metabolic acidosis (Table 41.1) [3, 46]. It can be classified as mild, moderate, or severe, based on the degree of acidosis and conscious level [3]. There are plans to publish update diagnostic criteria in late 2023, unifying the most commonly used definitions from the UK and the USA [3, 27]. Ketoacidosis has also been reported with normal to modestly elevated glucose levels, particularly in association with pregnancy, prolonged starvation, and use of SGLT-2 inhibitors [10, 47, 48]. Reduced hepatic glucose output, with an associated low blood glucose concentration, can also be associated with alcohol dependency and significant liver disease [4, 49, 50].

Table 41.3 Clinical features of diabetic ketoacidosis.

Symptoms	Signs
Unplanned weight loss (Adipose and muscle breakdown-usually new type 1 diabetes)	Ketonuria Glycosuria Fruity smell on breath (acetone)
Polyuria, polydipsia (Osmotic diuresis due to hyperglycaemia)	Tachypnoea Kussmaul breathing – deep and laboured
Blurred vision (Change in water content in eyeball and lens Nausea and vomiting) (Hyperketonaemia)	Dehydration ± postural drop in blood pressure Tachycardia
Abdominal pain (Acidosis-induced ileus)	
Lethargy (Cells lacking glucose as metabolic substrate)	
Shortness of breath (Increased work of breathing to correct acidotic state by expelling carbon dioxide)	

Source: Adapted from Dhatariya et al. 2020 [4] and Patel 2021 [37].

Measurement of blood β -hydroxybutyrate rather than urinary acetoacetate ketone is preferred, as this provides a real-time quantitative indicator of the key metabolic product in DKA, which can be monitored serially when treatment is commenced as one of the markers of metabolic recovery [27, 28, 51]. Blood gas analysis is also essential, to inform the degree and confirm the expected raised anion gap metabolic acidosis state ($[Na^+] + [K^+] - ([Cl^-] + [HCO_3^-])$), with consideration given to the other causes of a raised anion gap that could be clinically relevant (e.g. salicylate poisoning). Development of a transient hyperchloraemic non-anion gap metabolic acidosis during treatment is also commonly observed and, although it has no acute adverse effects, may slow down time to DKA resolution [7, 51, 52]. Baseline biochemical electrolyte and haematological profiles should be measured too, along with hepatic and renal function. Other investigations, such as blood cultures, myocardial biomarkers, and a chest X-ray, should be performed if clinically indicated, with an electrocardiogram also useful to identify any potassium-related cardiac rhythm disturbances [37].

Serum potassium is usually elevated at presentation in DKA [4, 7]. This is a result of insulin deficiency, acidaemia, and water deficiency, promoting an intracellular to extracellular shift of potassium [22, 30]. The serum sodium level is typically low as a result of the osmotic shift of water from the intracellular to the extracellular space when hyperglycaemia is present. Though leucocytosis is a common finding, it often does not suggest active infection [53]. The presence of nausea, vomiting, and abdominal pain should also prompt a measurement of serum amylase, to exclude acute pancreatitis, though hyperamylasaemia is not definitive for a diagnosis of pancreatitis in DKA [44].

Management

The management of DKA is based on four key goals [4]:

- To restore circulating volume.
- To correct hyperglycaemia through the parallel reduction of serum glucose and plasma osmolarity.
- To correct hyperketonaemia and electrolyte imbalance.
- To identify and address precipitating factors.

Close monitoring is essential, with strict fluid balance and careful use of insulin other key elements of management. Serial monitoring of glucose, electrolytes, venous pH, bicarbonate, and β -hydroxybutyrate can also help track metabolic progress towards DKA resolution. Those with severe DKA or with an underlying critical illness should be managed in the intensive care unit (ICU), while mild to moderate DKA cases can be managed in an appropriate acute (level 1 care) general ward [3, 54–57]. Management is usually protocol driven, with consideration given to the aforementioned key goals. An example is given in Figure 41.2.

Fluid therapy

Given that there is an estimated fluid deficit of 100 ml/kg body weight at diagnosis, aggressive fluid replacement is a key early priority, to expand intravascular volume and restore renal perfusion [7]. In addition, fluid replacement is useful for improving insulin sensitivity by reducing circulating counter-regulatory hormones and diluting plasma glucose levels. The aim is to replace half of the estimated fluid deficit over 24 hours [3, 27]. The UK guidelines state that 0.9% sodium chloride infused at 500–1000 ml/h for the first 1–2 h will usually restore blood pressure and renal perfusion. The rate and choice of subsequent fluids used will depend on the haemodynamic and hydration state, as well as serum electrolyte levels and urine output [3, 27]. For the majority of individuals,

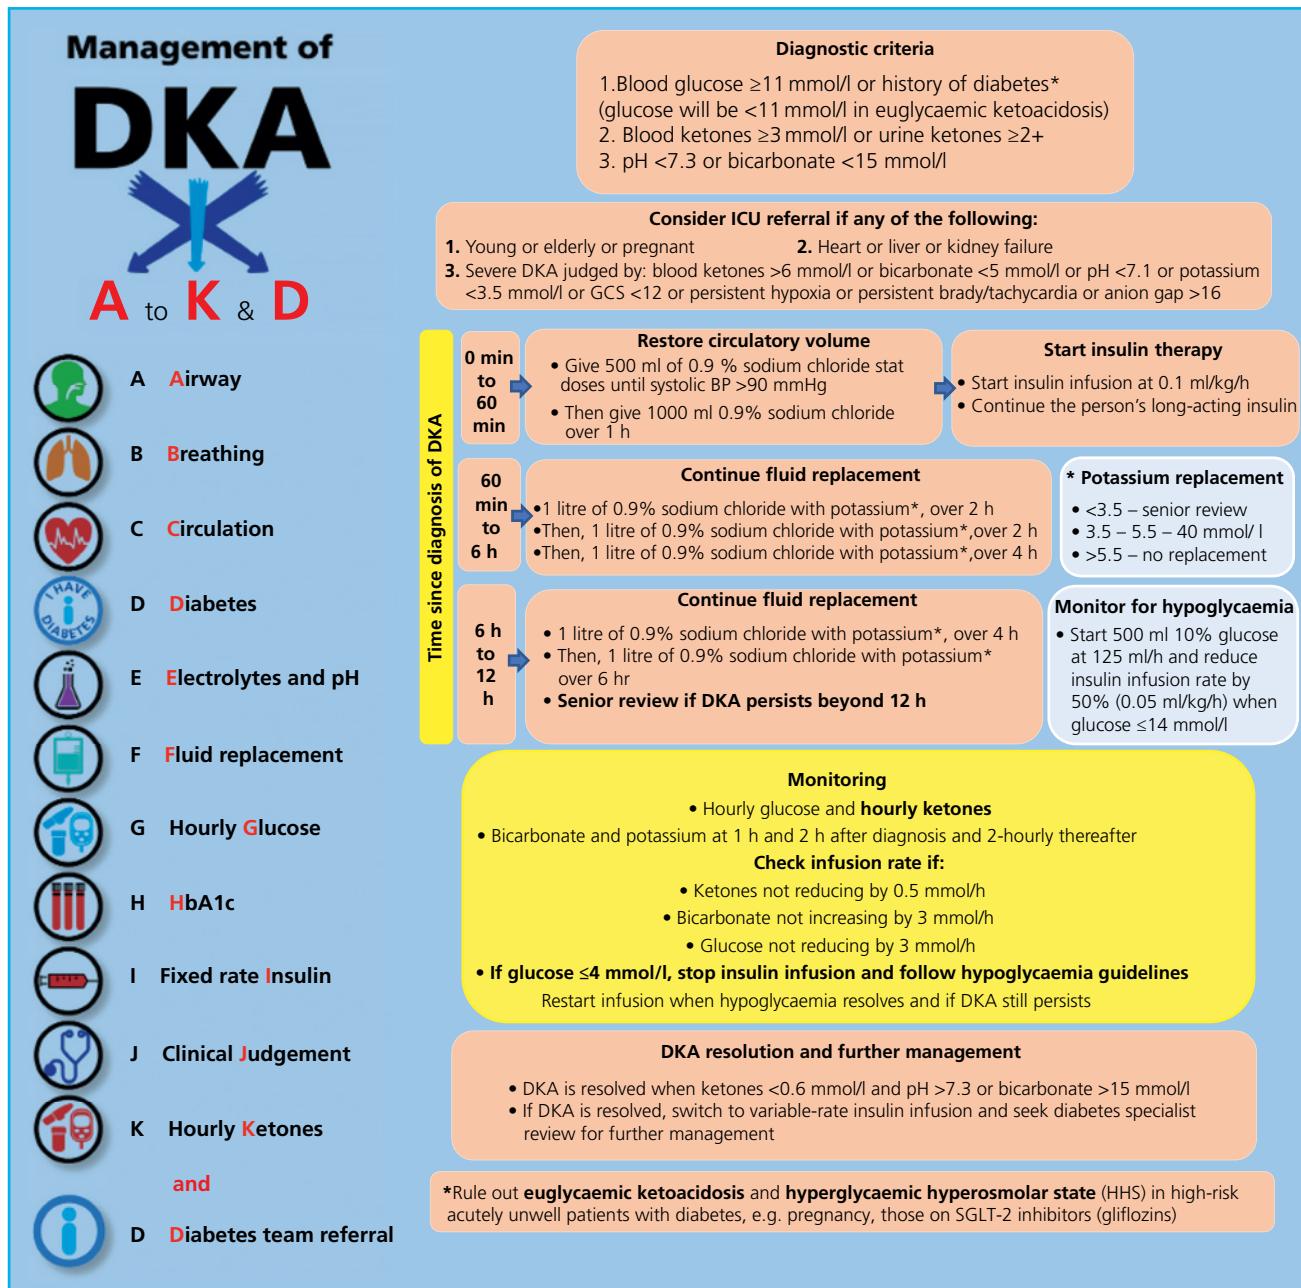

Figure 41.2 Management of diabetic ketoacidosis (DKA). BP, blood pressure; GCS, Glasgow coma score; HbA_{1c}, glycated haemoglobin; ICU, intensive care unit; SGLT-2, sodium–glucose cotransporter 2. Source: Adapted by permission from Kempegowda et al. 2019 [58].

continuation with 0.9% sodium chloride is appropriate at 250–500 ml/h, reducing stepwise as hydration improves. If the serum sodium is elevated, then a reduction of infusion rate to 166–250 ml/h would be suggested, or a switch to 0.45% sodium chloride infused at 250–500 ml/h [3, 27, 46].

Resolution of hyperglycaemia will often occur far quicker than resolution of ketonaemia, therefore to ensure continued adequate insulin administration for DKA resolution, plasma glucose levels should be maintained in a safe range by the addition of glucose infusion fluids. Intravenous 5–10% glucose should be infused additionally when the plasma glucose is approximately 14 mmol/l (250 mg/dL), enabling continued insulin administration until ketonaemia is reduced, while lowering the risk of hypoglycaemia [27].

Insulin therapy

Insulin administration is an essential element of DKA management, as it both increases peripheral glucose utilization and decreases hepatic glucose output. Moreover, it inhibits the release of free fatty acid from adipose tissue and decreases ketogenesis. A common effective practice is to administer an initial intravenous or intramuscular bolus of rapid-acting insulin (0.1 units/kg of body weight), followed by a continuous fixed-rate intravenous insulin infusion of soluble (regular) insulin (0.1 units/kg/h), although there is sufficient evidence to suggest that the initial bolus is not required if there is prompt intravenous access and treatment initiation with a continuous infusion [3, 27, 59]. For DKA associated with Covid-19 infection, it has been reported

that individuals are highly insulin resistant, requiring much higher doses [60]. The reasons for this remain unknown, and the addition of dexamethasone to aid in recovery will increase insulin resistance further.

The UK and American guidelines are now aligned with regard to fixed-rate insulin adjustment when glucose has dropped to $<14 \text{ mmol/l}$ (250 mg/dL), with the updated guidance advising reduction of the insulin infusion rate to 0.05 units/kg/h, alongside initiation of glucose-containing fluids to avoid hypoglycaemia during DKA treatment in response to a national survey of practice [61]. The UK guidance suggests further adjustment of the infusion rate, increasing by 1 unit/h if ketone levels are not falling by 0.5 mmol/l/h [3, 27]. The fixed-rate intravenous insulin infusion should be continued until DKA has resolved, by clinical assessment of ketonaemia and acidosis verified by a venous blood gas. If DKA has resolved, but the person is still unable to eat and drink, they can be converted to a variable-rate intravenous insulin infusion with appropriate concomitant glucose-containing infusion fluids.

Uncomplicated DKA can be managed with subcutaneous rapid-acting insulin (e.g. lispro, aspart, glulisine). Appropriate clinical support must be available for frequent glucose monitoring, as the insulin would need to be administered every 1–2 h [56, 57, 60]. Those already on a basal insulin subcutaneously should continue at their usual dose alongside a fixed-rate intravenous insulin infusion [27]. For those newly diagnosed with type 1 diabetes at presentation, it is recommended that they are initiated on a basal insulin subcutaneously (approximately 0.25 units/kg) to provide a safety net for rebound ketosis and facilitate easier transfer to subcutaneous insulin on DKA resolution [27].

Electrolyte considerations

Potassium

There is an estimated total body potassium deficit of 3–5 mmol/kg of body weight in people with DKA. Despite this, measured serum potassium levels are often at or above the upper limits of normal, due to a shift of intracellular potassium to the extracellular space [4, 15, 22, 30]. Correction of the acidosis and concurrent insulin administration will reduce serum potassium levels through the parallel actions of increased cellular potassium uptake in peripheral tissues and increased urinary excretion. A measured serum potassium concentration of $<5.0 \text{ mmol/l}$ should prompt intravenous replacement of 40 mmol of potassium chloride within each infused litre of fluid, which is usually sufficient to keep the potassium within the normal range of 4–5 mmol/l. Should the potassium fall $<3.5 \text{ mmol/l}$, individuals are likely to require more than 40 mmol/h of potassium, which should prompt a senior clinical review. In this case, if the person is being treated outside an ICU setting, the majority of hospital guidelines do not allow the addition of potassium to fluid bags or for $>40 \text{ mmol/h}$ to be given via peripheral cannulas. The options are to either slow down the rate of insulin per hour (0.05 units/kg/h) to reduce the drive of potassium into the intracellular space or obtain central venous access in an ICU setting where higher concentrations of potassium may be given. Individuals who present with hypokalaemia prior to treatment initiation are difficult to adequately manage outside an ICU setting, because of the likely total body potassium requirements and the likelihood of further serum potassium reduction on treatment initiation with insulin and fluid replacement [27].

Bicarbonate

The administration of intravenous bicarbonate therapy is not routinely recommended, as it does not improve cardiac or neurological function or promote a more rapid rate of recovery from hyperglycaemia and ketoacidosis [62, 63]. Excessive bicarbonate use can increase the risk of hypokalaemia, reduce tissue oxygen uptake (increasing lactate), and potentiate cerebrospinal fluid acidosis due to an increase in CO_2 partial pressure [3, 64]. However, some guidelines and commentaries note that severe acidosis can reduce myocardial contractility and cause cerebral vasodilatation and coma, recommending that with severe metabolic acidosis ($\text{pH} <6.9$) sodium bicarbonate should be administered until the pH rises to 6.9–7.0 [27]. Data from randomized controlled trials to firmly recommend this treatment option are lacking [63, 65].

Phosphate and magnesium

In a process similar to potassium, phosphate will often appear normal prior to DKA treatment initiation, though serum phosphate will decline during treatment due to an overall total body deficit (averaging 1 mmol/kg) [27, 66]. Though severe hypophosphataemia can result in muscle weakness, haemolytic anaemia, and rhabdomyolysis, studies have not shown any benefit of phosphate replacement [66–70]. Hence phosphate replacement should only be suggested for those with cardiac dysfunction, anaemia, and respiratory depression, with a serum concentration $<0.3\text{--}0.5 \text{ mmol/l}$ [3, 27].

Though magnesium deficits are commonly seen in DKA, there is no proven benefit of replacement [71, 72]. Magnesium replacement should be reserved for those with severe hypomagnesaemia and hypocalcaemia, where dose and rate of replacement should follow locally agreed protocols, usually dependent on severity of symptoms.

Complications

Hypoglycaemia and hypokalaemia are the two most common complications during DKA management, but the risk of both can be reduced by careful electrolyte monitoring and the management described previously [61]. Approximately 10–30% of people with type 1 diabetes experience hypoglycaemia during management, most often occurring several hours after intravenous insulin infusion commencement [61]. Omission or delay in appropriate initiation of glucose-containing fluids or where guidelines differ internationally, and not reducing the insulin infusion rate when the glucose level reaches 14 mmol/l (250 mg/dL), are the two commonest causes of hypoglycaemia [3, 61]. Close, frequent glucose monitoring is essential to reduce risk, as many individuals either do not experience the expected typical adrenergic *early-warning* symptoms of sweating, anxiety, hunger, or tachycardia, or those symptoms could be attributed to the stress of the DKA state itself. Acute kidney injury is a common complication of DKA owing to the severe hypovolaemia caused by osmotic diuresis resulting in pre-renal failure [4]. Though cerebral injury is a serious complication seen in approximately 1% of children with DKA, it is rarely reported in adults with DKA [73, 74].

Resolution and prevention

The criteria for DKA resolution include venous $\text{pH} >7.3$, serum bicarbonate $>18 \text{ mmol/l}$, and ideally a plasma glucose level $<11.1 \text{ mmol/l}$ (200 mg/dL) [3, 27]. This is when subcutaneous insulin therapy can be resumed or commenced. If a state of DKA persists for more than 24 hours, other contributing factors should be explored, such as alternative causes of raised anion gap metabolic acidosis or problems with insulin delivery.

Given that the half-life of rapid-acting intravenous insulin is 5–7 minutes, it should be appreciated that any sudden interruption to this infusion could result in rebound hyperglycaemia and ketoacidosis [75, 76]. Hence, on resolution of DKA, an intravenous insulin infusion should be continued for up to 1–2 hours after subcutaneous insulin is commenced. Continuing subcutaneous basal insulin alongside a fixed-rate intravenous insulin infusion during DKA management can prevent rebound hyperglycaemia after the intravenous insulin infusion is discontinued, which is standard practice in UK guidelines [27, 76].

Review by a specialist diabetes team is advised if available. This can help ensure that the individuals' previous insulin regimen remains appropriate in terms of insulin type and doses or advice offered for an insulin-naïve person. Typically, someone new to insulin would be started at a total daily dose of 0.5–0.7 units/kg [3, 27, 77]. This would usually be administered as a *basal bolus* (once- or twice-daily basal insulin alongside rapid-acting insulin with meals) or twice-daily *fixed mixed* insulin regimen (with morning and evening meals) [3, 27, 77].

Pregnancy can increase the risk of developing DKA even with relatively lower glucose levels. It is imperative that in cases of DKA presenting in pregnancy, there is specialist input and joint care from the diabetes and obstetrics teams as soon as possible [4, 78].

Individuals with end-stage renal failure or on dialysis require specialist input as early as possible after presentation, with special attention paid to their fluid balance. Although this is thankfully rare due to the reduced clearance of insulin, it can sometimes be difficult to distinguish from the chronic metabolic acidosis associated with chronic kidney disease. Recent Joint British Diabetes Societies (JBDS) guidance outlines the clinical considerations necessary for the management of fluids, insulin, and potassium replacement, all of which can contribute to a cacophony of complexity in this clinical scenario [79].

It is also important to ensure that all possible actions are taken to help reduce the risk of recurrent DKA. In the case of suspected contributing mental health issues (e.g. deliberate insulin omission as an act of self-harm, eating disorder) or alcohol-associated problems, support from relevant agencies should be offered. Knowledge of sick-day rules and self-care motivation should be reviewed. The individual should have access to appropriate glucose and ketone monitoring equipment. Educational materials and care plans can also be provided for families and carers, with specialist follow-up or access arranged where indicated. The frequency of hospitalization for DKA has been reduced following diabetes education programmes and with access to diabetes nurses or educators [80].

Hyperosmolar hyperglycaemic state

Commonly previously referred to as hyperglycaemic hyperosmolar non-ketotic coma (HONK), HHS is the other major hyperglycaemic emergency in diabetes. It is characterized by severe dehydration, hyperglycaemia, and hyperosmolarity in the absence of significant ketonaemia [3, 81–84]. Though it was associated with a mortality of up to 20%, this has fallen in recent decades, but remains higher than in DKA.

Pathophysiology

The pathophysiology of HHS is illustrated in Figure 41.1 and although similar to that of DKA, there are a few characteristic differences. The predominant picture is of relative insulin deficiency and increased counter-regulatory hormones, which lead to increased gluconeogenesis and reduced glucose uptake in peripheral tissues [1, 83]. There remains enough insulin to prevent hepatic free fatty acid oxidation and significant ketogenesis, but not enough to prevent hyperglycaemia and subsequent osmotic diuresis [7, 85]. The commonly seen severe hyperglycaemia at diagnosis, often developing over several days, results in prolonged osmotic diuresis, leading to a cycle of worsening dehydration, hyperosmolality, and eventually renal impairment, leading to reduced glucose excretion and further haemoconcentration [1]. Fluid losses are severe, with an estimated deficit of 100–220 ml/kg, although individuals may show only mild signs of volume depletion [3]. Biochemically the extreme dehydration will produce a hyperosmolar clinical picture of severe hypernatraemia, hyperuraemia, and hyperglycaemia, although as in DKA there is a total body deficit of sodium (5–13 mmol/kg), potassium (4–6 mmol/kg), and chloride (5–15 mmol/kg) [3]. In up to 50% of cases HHS and DKA can present as a mixed picture, with a metabolic acidosis due to concurrent ketosis and raised serum lactate levels, and mortality reported as higher in this group (8%) when compared to those with either DKA (3%) or HHS (5%) alone [13, 86].

Precipitating factors

HHS is typically a more gradual process that evolves over a number of days to a few weeks, in contrast to DKA that may develop over a few hours. Though most often observed in older people with type 2 diabetes, HHS may also reveal a new presentation of type 2 diabetes in up to 20% of cases [45]. With an increase in the prevalence of obesity, type 2 diabetes is gradually being diagnosed at a younger age and therefore younger adults can also develop HHS, as well as those with type 1 diabetes [87, 88]. Infection is the most common precipitant, with urosepsis and pneumonia accounting for up to 50% of cases [89, 90]. Other acute situations that release counter-regulatory stress hormones such as surgery, trauma, acute coronary syndromes, or acute stroke can also predispose to HHS. Several medications that cause hyperglycaemia by increasing insulin resistance, such as glucocorticoids and second-generation antipsychotics (clozapine, olanzapine), can precipitate HHS, especially if either appropriate monitoring of capillary glucose levels or screening for new-onset diabetes is omitted [91, 92]. Other medications such as phenytoin, thiazide diuretics, protease inhibitors, and β -blockers can also be causative [91] (Table 41.4).

Clinical presentation and diagnosis

The majority of individuals who develop HHS will do so over days to weeks and therefore the progressive onset of symptoms can be difficult to detect until they are severe. The person will often have experienced polyuria, polydipsia, significant dehydration, and a progressive decline in conscious level, ranging from drowsiness to coma. There will be severe dehydration at presentation, usually without signs of acidosis (Table 41.5). The JBDS notes that there is no firm definition of HHS. However, the notable characteristic features would be hypovolaemia, hyperglycaemia (>30 mmol/l; 540 mg/dL), and hyperosmolarity (>320 mosmol/kg), without the

Table 41.4 Causes of hyperosmolar hyperglycaemic state.

New presentation of type 2 diabetes
Medications, e.g. high-dose steroids, second-generation antipsychotics
Alcohol excess
Sepsis/infection
Cerebrovascular disease
Trauma
Long lie following a fall
Reduced fluid intake, e.g. reduced thirst perception in older age
Reduced fluid access

Table 41.5 Diagnostic criteria for hyperosmolar hyperglycaemic state, and definition of resolution.

- Serum osmolality^a >320 mosmol/kg
- Plasma glucose concentration >30 mmol/l (540 mg/dL)
- pH >7.3
- Serum bicarbonate concentration >15 mmol/l
- Plasma ketones <3 mmol/l (30 mg/dL)
- Hypovolaemia
- Definition of resolution:
 - 1) Clinical and cognitive status is back to the pre-morbid state
 - 2) Osmolality <300 mOsm/kg
 - 3) Hypovolaemia has been corrected (urine output ≥0.5 ml/kg/h)
 - 4) Blood glucose <15 mmol/l (170 mg/dL)

^a Calculated serum osmolality = $2[\text{Na}^+]+\text{glucose}+\text{urea}$.

Source: Adapted from Mustafa et al. 2023 [83].

presence of significant ketonaemia (<3 mmol/l) or acidosis (pH <7.3, bicarbonate >15 mmol/l). The American Diabetes Association definition is very similar [3, 83]. Many individuals present with a high anion gap metabolic acidosis alongside HHS, which often resolves quickly on treatment initiation [13].

Management

The treatment principles for HHS are similar to those for DKA, namely correction of hypovolaemia, hyperosmolality, and electrolyte disturbances and addressing the precipitating cause (Figure 41.3) [3, 83]. Due to the extreme dehydration, the initial focus of treatment is fluid and electrolyte replacement to restore circulating volume and electrolyte deficit, subsequently diluting sodium, urea, and glucose levels [83]. The infusion of 0.9% sodium chloride at 1000 ml/h for the first 2–3 h is the usual recommendation due to the need to

replace fluid, sodium, and chloride. Ongoing fluid choice and rate should be clinically reviewed based on osmolarity, urine output, and electrolyte change in the past 12 h. There is no experimental evidence to suggest that using hypotonic 0.45% sodium chloride to reduce osmolarity is preferable, and this can result in a dangerously rapid drop in serum sodium levels (>10 mmol/l in 24 h) [83]. On initiation of treatment, if the glucose levels are extremely high, there is likely to be an increase in sodium levels as glucose levels drop, but this does not indicate the need to switch to hypotonic intravenous fluids.

Increased serum potassium is often seen in HHS for pathophysiological reasons, as in DKA. With the serum potassium deficit estimated at 3–5 mmol/l of body weight, the principles of potassium replacement are also as for DKA, where potassium replacement should be initiated if serum potassium is <5.5 mmol/l. UK guidelines suggest that fixed-rate intravenous insulin infusion treatment should only be commenced at 0.05 units/kg/h when glucose levels stop falling with fluid replacement, or if the person initially presents with ketonaemia suggesting hypoinsulinaemia [83]. The target range for glucose should be 10–15 mmol/l, which may require the addition of intravenous 5–10% glucose as for DKA management. The ongoing need for insulin or alternative diabetes therapy is reviewed when the person has an improved conscious level and can manage sufficient oral intake [3, 83].

Complications

The hypercoagulable state increases the risk of both arterial and venous thromboembolic events in HHS [3, 93]. Formal prophylactic anticoagulation during treatment is recommended by some groups and noted in the UK guidelines [83]. However, routine use of therapeutic anticoagulation is not recommended [94]. There is an increased risk of foot pressure ulcers developing, and so foot-protection measures should be taken and feet re-examined daily. There are reports of concomitant rhabdomyolysis or subclinical rhabdomyolysis in HHS, where there appears to be a linear relationship with the severity of hyperosmolarity and the serum level of creatinine kinase [95, 96]. As rhabdomyolysis and a raised creatinine kinase can cause acute renal failure, consideration should be given to assessing for this, as it will have an impact on decision making around appropriate fluid management to avoid acute fluid overload [95, 96].

Prevention

Improved education around awareness and risk factors for developing HHS are key to reducing future risk. Ensuring that appropriate access to fluids and glucose monitoring are in place, especially in the context of the precipitants outlined, should also help to reduce the risk of HHS developing.

7 Microvascular Complications in Diabetes

Allan Flyvbjerg

Steno Diabetes Center Copenhagen, Copenhagen, Denmark

Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark

Key points

- Microvascular complications affect the capillaries and arterioles in the retina (retinopathy), the kidney (nephropathy), and nerves (neuropathy).
- Microvascular complications are caused by prolonged exposure to hyperglycaemia.
- Microvascular complications are best prevented by strict metabolic management.
- Hyperglycaemia damages cell types that cannot downregulate glucose uptake, causing intracellular hyperglycaemia.
- Persistent consequences of hyperglycaemia-induced mitochondrial superoxide production may also explain the continuing progression of tissue damage after improvement of glycaemic levels (hyperglycaemic memory or the legacy effect).
- Different individual susceptibilities to microvascular complications have been linked to genetic polymorphisms.
- Several proven and potential pathogenic factors linking hyperglycaemia to the development of microvascular complications may be categorized into five groups: metabolic factors, haemodynamic factors, growth factors/cytokines, intracellular factors, and the complement system.
- Incretin drugs, which include glucagon-like peptide 1 receptor agonists and dipeptidyl peptidase 4 inhibitors, and sodium–glucose cotransporter 2 inhibitors have proven cardio-reno-protective effects through mechanisms beyond those that can be explained by the blood glucose and/or body weight lowering effects alone.

Diabetic angiopathy: definition and clinical features

Diabetic angiopathy is characterized by functional and structural organ damage as a result of changes in the vascular system. Diabetic angiopathy is divided into *microangiopathy*, which affects the capillaries and arterioles in the retina (retinopathy), the kidney (nephropathy), and nerves (neuropathy); and *macroangiopathy*, which affects arteries in the brain (cerebrovascular disease), heart (ischaemic heart disease and congestive heart failure), and the lower extremities (peripheral arterial disease) (Figure 42.1). Diabetic angiopathy has a significant impact on the prognosis, life expectancy, and quality of life of people with diabetes. Late diabetes-related complications may occur both in type 1 diabetes and type 2 diabetes, which is the reason all individuals with diabetes should be examined regularly in an appropriate screening programme. Microvascular complications are quantitatively dominant in type 1 diabetes, whereas macroangiopathy dominates the clinical appearance in type 2 diabetes. In the treatment priorities in the prevention of diabetic angiopathy, microvascular complications are best avoided by strict metabolic management of blood glucose, whereas macrovascular complications are best avoided by strict treatment of dyslipidaemia, hypertension, and other risk factors for cardiovascular disease (Figure 42.2).

The pathogenesis of microvascular complications is described in this chapter, followed by a description of diabetic retinopathy in

Chapter 43, diabetic nephropathy in Chapter 44, and diabetic peripheral neuropathy in Chapter 45. The pathogenesis of macrovascular complications, including atherosclerosis in diabetes, is described in Chapter 46, cardiovascular risk factors in diabetes in Chapters 47 and 48, ischaemic heart disease in Chapter 49, heart failure in Chapter 50, cerebrovascular disease in Chapter 51, and peripheral arterial disease in Chapter 52.

A classical morphological feature of diabetes-related microvascular complications (i.e. microangiopathy) is a thickening of the basement membrane in the capillaries and arterioles in the retina, kidney, and nerves. The magnitude of the thickening increases with the duration of diabetes. The thickening of the basement membrane is seen in virtually all individuals with diabetes, but clinically symptomatic organ damage is far less frequent. However, much of the impact of chronic diabetes falls on the microcirculation [1,2]. With long-standing disease, there is progressive narrowing and eventual occlusion of vascular lumina, resulting in impaired perfusion, ischaemia, and dysfunction of the affected tissues. Several processes contribute to microvascular occlusion. One of the earliest is increased vascular permeability, allowing extravasation of plasma proteins that accumulate as periodic acid-Schiff (PAS)-positive deposits in the vessel walls. In addition, extracellular matrix production by perivascular cells such as pericytes (retina) and mesangial cells (glomerulus) is increased, brought about by changes in the synthesis and turnover of its component proteins and glycosaminoglycans. As a result, the basement membrane is thickened in many tissues, including retinal capillaries and the vasa nervorum, along

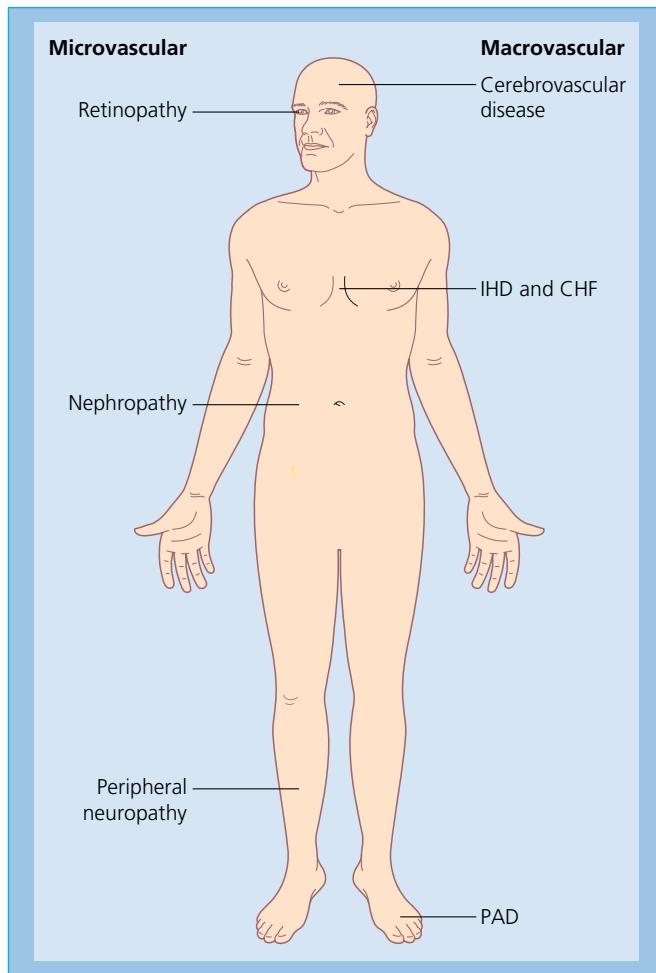

Figure 42.1 Diabetic angiopathy. Diabetic angiopathy is divided into *microangiopathy*, which affects the capillaries and arterioles in the retina (retinopathy), the kidney (nephropathy), and nerves (neuropathy), and *macroangiopathy*, which affects arteries in the brain (cerebrovascular disease), heart (ischaemic heart disease, IHD; and congestive heart failure CHF), and the lower extremities (peripheral artery disease, PAD).

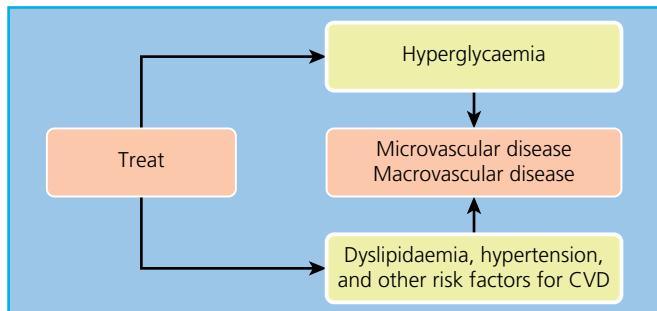

Figure 42.2 Primary priorities in the prevention of diabetic angiopathy. Microvascular complications are best prevented by strict metabolic management of glucose, whereas macrovascular complications are best avoided by strict treatment of dyslipidaemia, hypertension, and other risk factors for cardiovascular disease (CVD). Also read the section in this chapter about the potential mechanisms behind the renoprotective effects of the incretin drugs, glucagon-like peptide 1 (GLP-1) receptor agonists and dipeptidyl peptidase 4 (DPP-4) inhibitors, and sodium–glucose cotransporter 2 (SGLT-2) inhibitors.

with mesangial matrix in the renal glomerulus. Hypertrophy and hyperplasia of endothelial, mesangial, and arteriolar smooth muscle cells also contribute to vessel wall thickening. Finally, increased coagulability and adhesion of platelets and leucocytes to the endothelial surface lead to microthrombus formation and luminal occlusion.

The progressive narrowing and blockage of diabetic microvascular lumina are accompanied by loss of microvascular cells. In the retina, diabetes induces apoptosis of Müller cells and ganglion cells [3], pericytes, and endothelial cells [4]. In the glomerulus, widespread capillary occlusion and declining renal function are associated with podocyte loss. In the vasa nervorum of nerves, endothelial cell and pericyte degeneration occurs [5] and appears to precede functional abnormalities of peripheral nerves [6]. Increased apoptosis of cells in the retina, renal glomerulus, and peripheral neurons is a prominent feature of diabetes-related microvascular tissue damage [4, 7–10] and may also damage adjacent cells.

Pathogenesis of microvascular complications: the role of hyperglycaemia

Overall, diabetes-related microvascular complications are caused by prolonged exposure to high glucose levels. This has been established in large-scale prospective studies, both in type 1 diabetes by the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Study (DCCT/EDIC) [11] and in type 2 diabetes by the UK Prospective Diabetes Study (UKPDS) [12]. Similarly, robust data in type 2 diabetes have been reported by the Steno-2 study [13, 14]. In this section, the potential mechanisms of differences in cell response to hyperglycaemia, the phenomenon of glycaemic memory, and determinants of individual susceptibility to hyperglycaemia-induced damage are described.

Differences in cell response to hyperglycaemia

As every cell in the body of an individual with diabetes is exposed to abnormally high glucose concentrations, it may be asked why hyperglycaemia selectively damages some cell types whereas others are unaffected. The targeting of specific cell types by generalized hyperglycaemia reflects the failure of those cells to downregulate their uptake of glucose when extracellular glucose concentrations are elevated. Cells that are not directly susceptible to hyperglycaemic damage, such as vascular smooth muscle, show an inverse relationship between extracellular glucose concentrations and glucose transport. In contrast, vascular endothelial cells, a major target of hyperglycaemic damage, show no significant change in glucose transport rate when the glucose concentration is elevated, resulting in intracellular hyperglycaemia (Figure 42.3) [15]. These differences are caused in part by tissue-specific differences in expression and function of different glucose transporter (GLUT) proteins [16].

Glycaemic memory or legacy effect

In 1993, the results of the landmark DCCT study showed that, in individuals with short-duration type 1 diabetes, intensive glycaemic management dramatically reduced the occurrence and severity of microvascular complications. After the announcement of the DCCT results, many participants who had been in the standard therapy group adopted more intensive therapeutic regimens,

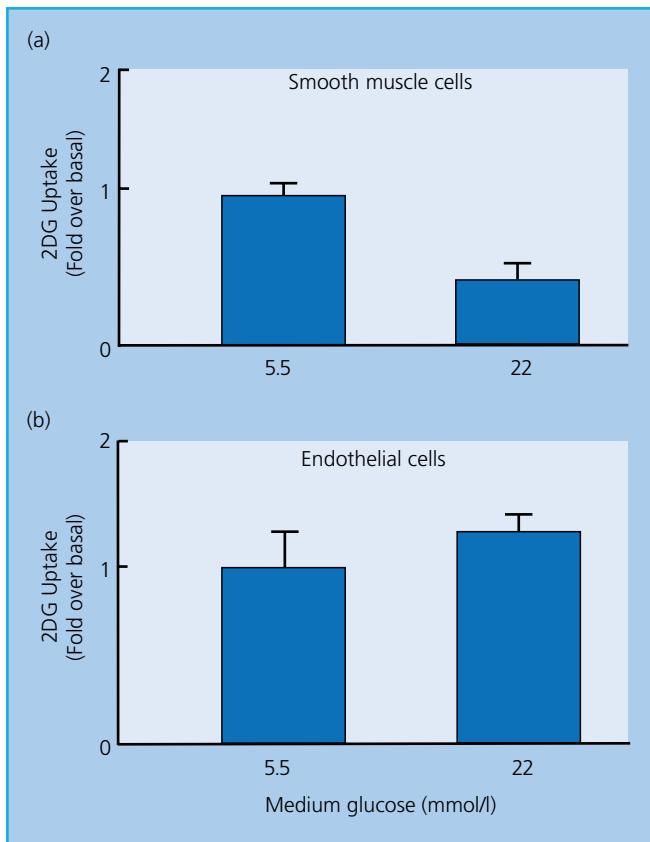

Figure 42.3 Lack of downregulation of glucose transport by hyperglycaemia in cells affected by diabetes-related complications. (a) 2-Deoxyglucose (2DG) uptake in vascular smooth muscle cells pre-exposed to 5.5 or 22 mmol/l glucose; (b) 2DG uptake in aortic endothelial cells pre-exposed to 5.5 or 22 mmol/l glucose.

Source: Data from Kaiser et al. 1993 [15].

and their glycaemic levels improved, as measured by glycated haemoglobin (HbA_{1c}). At the same time, the mean HbA_{1c} worsened for those who had been in the intensive therapy group. The post-DCCT HbA_{1c} values for both groups became statistically identical for the following 14 years of the EDIC study.

Surprisingly, however, the effects of a 6.5-year difference in HbA_{1c} during the DCCT on the incidence of retinopathy and nephropathy persisted and became greater over the subsequent 14 years of follow-up. Individuals in the standard therapy group continued to have a higher incidence of complications, even with an improvement in glycaemia during the 14 years of EDIC, whereas individuals in the intensive therapy group continued to have a lower incidence of complications, even with deterioration in glycaemia during the EDIC years. This phenomenon has been termed *glycaemic memory* or the *legacy effect* (Figure 42.4). Glycaemic memory also occurs in people with type 2 diabetes. The tight glucose management group from the UKPDS demonstrated a continued reduction in microvascular risk and emergent risk reductions for acute myocardial infarction and death from any cause, despite an early loss of glycaemic differences. A continued benefit was evident during the 10-year post-trial follow-up among overweight participants [17–19].

Glycaemic memory has several important clinical implications and recommendations:

- Early and tight metabolic management is required to prevent long-term diabetes-related complications.

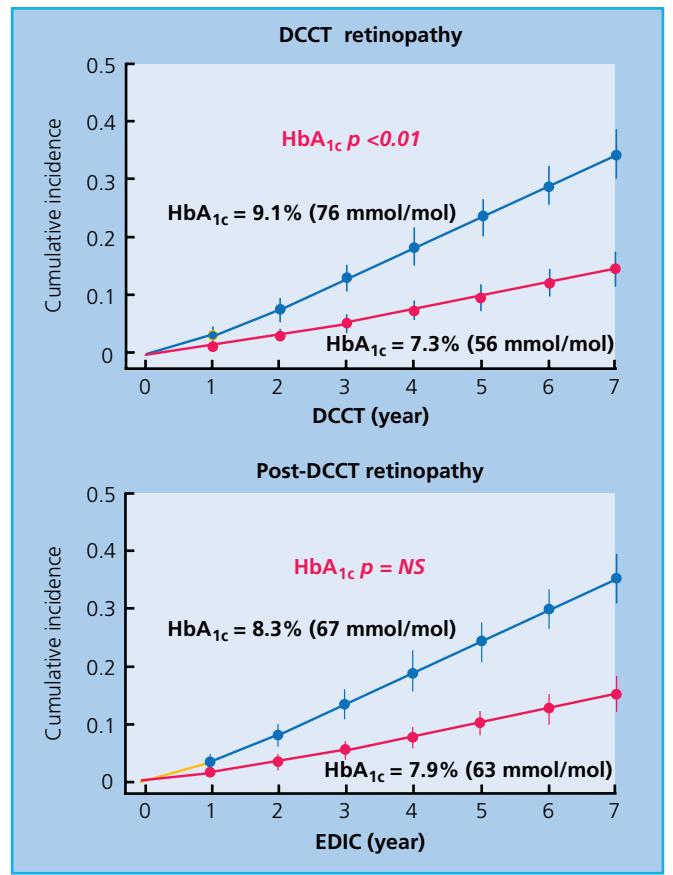

Figure 42.4 Hyperglycaemic memory. Previous higher blood glucose levels make individuals with diabetes more susceptible to damage despite subsequent lower blood glucose exposure. After the end of the Diabetes Control and Complications Trial (DCCT), the group treated with conventional insulin therapy (blue) continued to have a higher incidence of diabetic retinopathy than the intensively managed group (red), even though post-trial glycated haemoglobin (HbA_{1c}) was comparable in the two groups. Reported HbA_{1c} is the mean in each group. EDIC, Epidemiology of Diabetes Interventions and Complications study.

- Tight metabolic management after long-term metabolic dysregulation may not prevent the subsequent development of microvascular complications.
- There is a need for the development of novel therapies that reverse hyperglycaemic memory.

Hyperglycaemia-induced mitochondrial superoxide production may provide an explanation for the continuing progression of tissue damage after the correction of hyperglycaemia (*hyperglycaemic memory*). Post-translational modifications of histones cause chromatin remodelling and changes in gene expression [20–22]. Because these modifications do not involve differences in DNA sequence, they are called *epigenetic* (Figure 42.5a). Transient hyperglycaemia induces long-lasting activating epigenetic changes in the promoter of the Fib-subunit p65 in human aortic endothelial cells (16 hours' exposure) and in aortic cells *in vivo* in non-diabetic mice (6 hours' exposure), which cause sustained increases in p65 gene expression (Figure 42.5b) and in the expression of p65-dependent pro-inflammatory genes. Both the epigenetic changes and the gene expression changes persist for at least six days of subsequent normal glycaemia. Hyperglycaemia-induced epigenetic changes and increased p65 expression are prevented by normalizing mitochondrial superoxide production or superoxide-induced methylglyoxal (Figure 42.5b, c) [23].

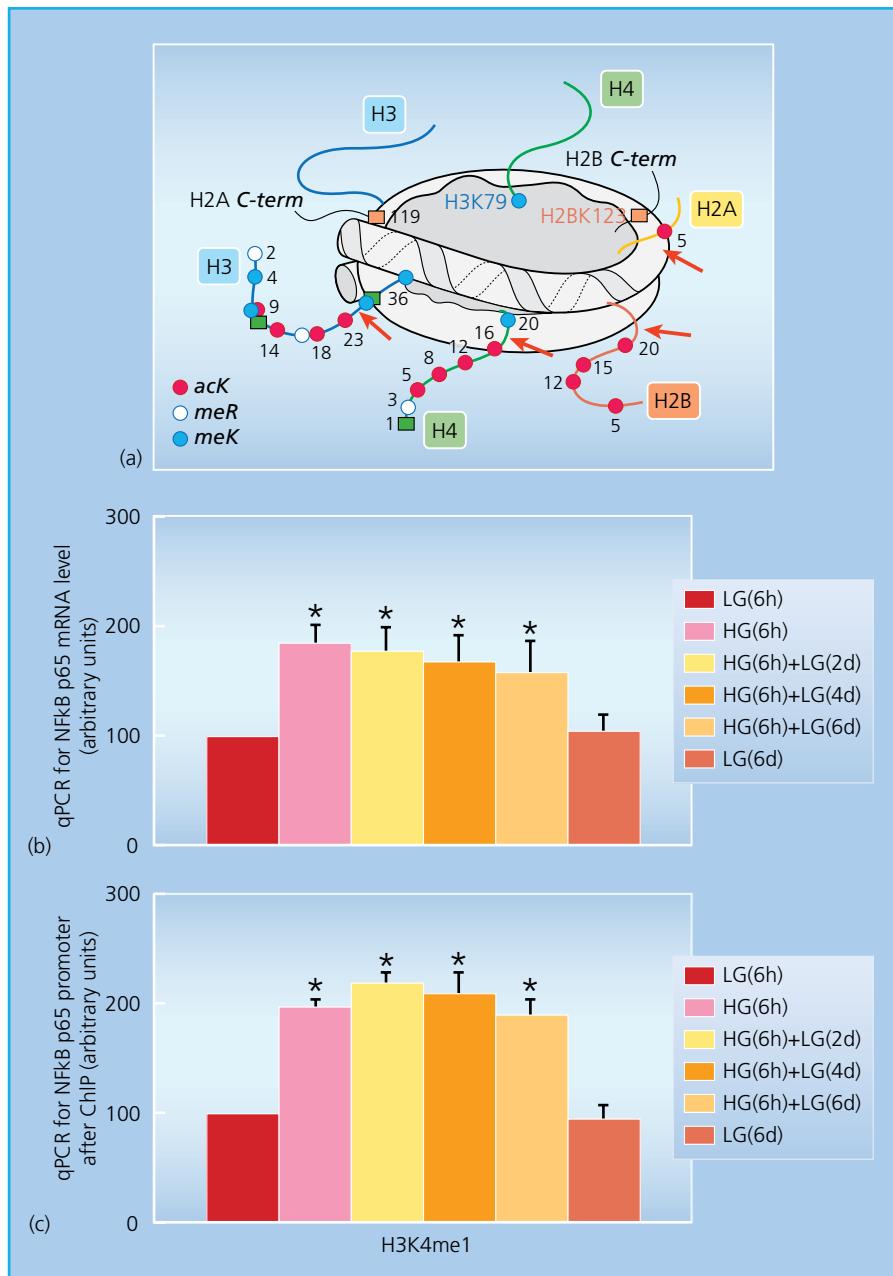

Figure 42.5 Transient hyperglycaemia causes persistent epigenetic changes and altered gene expression during subsequent normoglycaemia. (a) Schematic representation of several histone modifications. (b, c) Transient hyperglycaemia induces persistent increased expression of the NF κ B p65 subunit, caused by persistent epigenetic changes, including histone 3 lysine 4 mono-methylation (H3K4me1) in the proximal promoter of the NF κ B p65 subunit. ack, acetylated lysine; HG, high glucose; LG, low glucose; meK, methylated lysine; meR, methylated arginine; ChiP, chromatin immunoprecipitation. Source: Data from El-Osta et al. 2008 [23].

These results highlight the dramatic and long-lasting effects that short-term hyperglycaemic spikes can have on vascular cells and suggest that transient hyperglycaemic spikes may be an HbA_{1c}-independent risk factor for diabetes complications. Demethylation of another histone lysine residue, H3K9, is also induced by hyperglycaemia-induced overproduction of reactive oxygen species (ROS). This reduces inhibition of p65 gene expression, and thus acts synergistically with the activating methylation of histone 3 lysine 4 [24]. Consistent with these observations, others have shown similar epigenetic changes in lymphocytes from individuals with type 1 diabetes [25] and in vascular smooth muscle cells derived from an experimental mouse model of type 2 diabetes [26].

Determinants of individual susceptibility to hyperglycaemia-induced damage

As with all complex diseases, the occurrence and progression of diabetes complications vary markedly among people with diabetes. Some have type 1 diabetes for over 50 years with minimal complications, whereas others manifest severe disease or death within 15 years after diagnosis. The management of blood glucose, and also blood pressure and lipid profile, is an important factor in predicting the risk of complications, but it only partially explains the risk of complications for an individual. Therefore, genetic factors have been investigated for their influence on the risk of developing complications. An understanding of the genes involved in the susceptibility to or protection from diabetes complications can lead

both to a better understanding of the pathophysiological mechanisms and to new biomarkers and molecular targets for drug development. Familial clustering studies strongly support a role for genetic determinants of susceptibility to hyperglycaemic damage.

In two studies of families that have two or more siblings with type 1 diabetes, if one sibling had advanced diabetic nephropathy, the other sibling with diabetes had a nephropathy risk of 72–83%. By contrast, the risk was only 17–22% if the index sibling did not have diabetic nephropathy [27,28]. Numerous associations have been made between various genetic polymorphisms and the risk of different diabetes complications. These include HLA-DQB10201/0302 alleles [29], polymorphisms of the aldose reductase gene [30], the sorbitol dehydrogenase gene [31], and the promoter of erythropoietin gene [32]. A positive linkage and association with diabetic nephropathy of simple tandem-repeat polymorphisms and single-nucleotide polymorphisms (SNPs) in 20 genes have been demonstrated in families of individuals with type 1 diabetes of white European descent [33]. Three genes code for growth factors or growth factor receptors, five genes code for intracellular factors, three genes code for components of the extracellular matrix, and two genes are involved in its degradation. The remaining genes are likely to be important in kidney function [33]. The DCCT/EDIC trial also reported familial clustering and association with gene polymorphisms. In those with diabetes, the odds ratio for risk of severe retinopathy was 5.4-fold higher in family members of participants with retinopathy than in those without; coronary artery calcification also showed familial clustering [34]. In the same cohort, an association of multiple superoxide dismutase 1 variants was associated with the development and progression of diabetic nephropathy [35].

In the future, the challenge will be to identify specific genes involved in the varying clinical severity of diabetes complications. Recent emphasis in human disease genetics has been on so-called modifying genes; that is, genetic variants that are distinct from disease susceptibility genes but modify the phenotypic and clinical expression of the disease. Studies show that genetic modifiers can be *tipping-point* genes. This means that one gene changes the whole phenotype in an all-or-nothing fashion, in contrast to the incremental effects seen with changes in a large number of non-modifier genes. Many examples of modifier genes are known in model organisms, and several have been identified in humans [36,37].

Beyond hyperglycaemia

It has become increasingly evident that several different pathways play a role as mediators between elevated and fluctuating blood glucose levels and the development of microvascular complications. The number of systems and interactions between these factors are complex, but as described in a review article dealing with the pathogenesis of diabetes-related kidney disease, four important groups of mediators are metabolic factors, haemodynamic factors, growth factors/cytokines, and intracellular factors [38]. Furthermore, there is an important role for the innate immune system. Figure 42.6 provides a schematic depiction of the potential hierarchy and interactions between metabolic, haemodynamic, growth factors/cytokines, intracellular factors, and the innate immune system in the pathogenesis of microvascular complications. In the following section, the five systems and the evidence for their role are described in

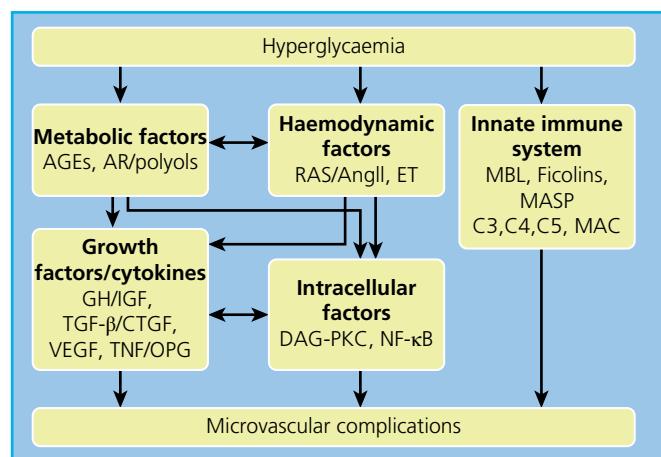

Figure 42.6 Schematic depiction of pathogenetic factors in microvascular complications showing the potential hierarchy and interactions between metabolic, haemodynamic, growth factors/cytokines, intracellular factors, and the innate immune system. AGEs, advanced glycation end-products; AngII, angiotensin II; AR, aldose reductase; C3, C4, C5, complement C3, C4, C5; CTGF, connective tissue growth factor; DAG-PKC, diacylglycerol-protein kinase C; ET, endothelin; GH, growth hormone; IGF, insulin-like growth factor; MAC, membrane attack complex; MASP, MBL-associated serine protease; MBL, mannose-binding lectin; NF-κB, nuclear factor κB; OPG, osteoprotegerin; RAS, renin-angiotensin system; TGF-β, transforming growth factor β; TNF, tumour necrosis factor; VEGF, vascular endothelial growth factor.

more detail. The last part of this section proposes the potential mechanisms behind the renoprotective effect of incretin drugs and sodium–glucose cotransporter 2 (SGLT-2) inhibitors in the treatment of type 2 diabetes (Chapter 44).

Metabolic factors

Among the different metabolic pathways that have impacts on the development of microvascular complications, the roles of advanced glycation end-products (AGEs) and of the aldose reductase/polyol pathway have been studied in most detail.

Advanced glycation end-products

Amadori products are formed when glucose and other reactive carbonyl compounds react non-enzymatically with proteins, lipids, or nucleic acids and Schiff bases. Additional rearrangements and modifications lead to the generation of various forms of AGEs, such as carboxymethyllysine, pentosidine, imidazolone, and pyrraline [38,39]. AGEs interact with specific receptors [39–41]: p60 (OST-48, AGE-R1), p90 (80K-H, AGE-R2), galectin-3 (AGE-R3), the macrophage scavenger receptor type II (ScR-II), and CD36 all regulate the uptake and clearance of AGEs [39,41]. The best-characterized receptor is the receptor for AGEs (RAGE) [39]. AGEs can also act in a receptor-independent way by cross-linking proteins [39,40]. AGEs alter the structure and function of intra- and extracellular molecules, increase oxidative stress, and modulate cell activation, signal transduction, and the expression of cytokines and growth factors through receptor-dependent and -independent pathways [39–41].

Pre-clinical data in support of a role for AGEs in microvascular complications come from studies in diabetic animal models [38,42]. Renal AGE levels are increased in long-term experimental diabetes [43,44]. Furthermore, in models of type 1 diabetes and type 2 diabetes,

the intake of food-derived AGEs accelerates renal changes, whereas a low-AGE diet provides protection against kidney damage [45]. In animal models of both type 1 diabetes [46, 47] and type 2 diabetes, elevated RAGE glomerular podocyte staining has been reported, compared with animals without diabetes [48]. Finally, diabetic transgenic mice overexpressing human RAGE present with kidney and glomerular hypertrophy, increased albuminuria, mesangial expansion, advanced glomerulosclerosis, and increased impaired kidney function, compared with controls [49]. In clinical studies, AGEs have been shown to be elevated in both type 1 diabetes and type 2 diabetes [50, 51]; it is important to note, however, that at these concentrations AGEs are not the major ligand for RAGE. Rather, several pro-inflammatory protein ligands have been identified that activate RAGE at low concentrations. These include several members of the S100 calgranulin family and high-mobility group box 1 (HMGB1), all of which are increased by hyperglycaemia. Binding of these ligands with RAGE causes cooperative interaction with the innate immune system signalling molecule toll-like receptor 4 (TLR-4) [52, 53].

Targeting the advanced glycation end-product system

Various agents have been examined in attempts to interfere with AGE formation or the cross-linking of proteins by AGEs. Agents that block AGE formation by scavenging reactive carbonyl intermediates include aminoguanidine, pyridoxamine, 2,3-diaminophenazine, OPB-9195, and tenilsetam. ALT-711 is an example of an AGE cross-link breaker. Ways to block the signal transduction through RAGE can be achieved by the use of RAGE antibodies, antisense oligodeoxynucleotides (AS-ODNs), or soluble RAGE [38, 42]. Clinical trials have been performed aimed at exploring the clinical effects of pyridoxamine in both type 1 diabetes and type 2 diabetes [54, 55]. In one study of mild to moderate renal impairment, the intervention reduced the slope of creatinine change without having an influence on urinary albumin excretion [54]. In another study of more severe renal impairment, there was no effect of treatment, suggesting that treatment should be administered before the onset of significant pathological organ changes [55].

Aldose reductase/polyol pathway

The polyol pathway is based on a family of aldo-keto-reductase enzymes, which can utilize a wide variety of sugar-derived carbonyl compounds as substrates and reduce these by nicotinamide adenine dinucleotide phosphate (NADPH) to their respective sugar alcohols (polyols). The classic representation holds that glucose is converted to sorbitol, and galactose to galactitol. Sorbitol is then oxidized to fructose by the enzyme sorbitol dehydrogenase, with NAD⁺ being reduced to NADH. The first and rate-limiting step of the polyol pathway is regulated by aldose reductase, which is found in tissues such as nerve, retina, lens, glomerulus, and blood vessel wall. In these tissues, glucose uptake is mediated by GLUT proteins other than GLUT4 and so does not require insulin; intracellular glucose concentrations therefore rise in parallel with hyperglycaemia.

Several mechanisms have been proposed to explain how hyperglycaemia-induced increases in polyol pathway flux could damage the tissues involved. These include sorbitol-induced osmotic stress, decreased cytosolic Na/K⁺-ATPase activity, increased cytosolic NADH/NAD⁺, and decreased cytosolic NADPH. It was originally suggested that intracellular accumulation of sorbitol, which does not diffuse easily across cell membranes, could

result in osmotic damage, but it is now clear that sorbitol levels in diabetic vessels and nerves are far too low to do this. Another early suggestion was that increased flux through the polyol pathway led to decreased phosphatidylinositol synthesis, and that this inhibited Na/K⁺-ATPase activity. The latter abnormality occurs in diabetes, but has subsequently been shown to result from hyperglycaemia-induced activation of protein kinase C (PKC), which increases the production of two inhibitors of Na/K⁺-ATPase, arachidonate and prostaglandin E2 [56].

The reduction of glucose to sorbitol by NADPH consumes the latter. NADPH is a cofactor required to regenerate reduced glutathione; as glutathione is an important scavenger of ROS, this could induce or exacerbate intracellular oxidative stress. Indeed, overexpression of human aldose reductase increased atherosclerosis in diabetic mice and reduced the expression of genes that regulate the regeneration of glutathione [57]. Reduced glutathione is depleted in the lens of transgenic mice that overexpress aldose reductase and in diabetic rat lens compared with non-diabetic lens [58, 59]. Decreased glutathiolation of cellular proteins is related to decreased nitric oxide availability in diabetic rats, which would decrease S-nitrosoglutathione. Restoring the nitric oxide levels in experimental animal models of diabetes increases glutathiolation of cellular proteins, inhibits aldose reductase activity, and prevents sorbitol accumulation. Moreover, hyperglycaemia can also inhibit glucose-6-phosphate dehydrogenase, the major source of NADPH regeneration, which may further reduce the NADPH concentration in some vascular cells and neurons [60]. In diabetic vascular cells, however, glucose does not appear to be the substrate for aldose reductase, because the Michaelis constant (K_m) of aldose reductase for glucose is 100 mmol/l, whereas the intracellular concentration of glucose in the diabetic retina is 0.15 mmol/l [61, 62]. Glycolytic metabolites of glucose such as glyceraldehyde-3-phosphate, for which aldose reductase has much higher affinity, may be the physiologically relevant substrate.

Targeting the aldose reductase/polyol pathway

Several aldose reductase inhibitors have been developed and studied in experimental and clinical studies for their potential effect on microvascular complications [63], but these drugs have not shown convincing clinical effects [64].

Haemodynamic factors

Tight control of blood pressure delays the progression of retinopathy and nephropathy, whereas elevated blood pressure accelerates the onset of nephropathy and its progression [64–66]. Blockade of the renin–angiotensin system, and thereby the effects of the vasoconstrictor angiotensin II (AngII), is gold-standard treatment and a cornerstone in the secondary and tertiary treatment of incipient or overt microvascular complications, in particular retinopathy (Chapter 43) and nephropathy (Chapter 44). In addition to the well-known systemic and locally haemodynamic effects, the renin–angiotensin system and the endothelin (ET) system may exert non-haemodynamic effects through autocrine and paracrine actions. In the following section, the endothelin system and its role in microvascular complications are addressed.

Endothelin

The endothelin system embraces ET-1–3 and two receptors, of which ET-1 is the most potent vasoconstrictor [67, 68]. In mammals, two receptors, ET_A and ET_B, exert their signal mainly through activation of G-proteins. The ET_A receptor is mainly involved in

vasoconstriction and cell proliferation, whereas the ET_B receptor induces nitric oxide release and vasodilation [67,68]. Endothelin acts through paracrine and autocrine actions.

Targeting the endothelin pathway

The effects of endothelins can be blocked by the administration of non-selective endothelin receptor antagonists (e.g. bosentan), selective ET_A antagonists (e.g. avosentan, atrasentan), or ET_B antagonists. As summarized in a recent review [69], endothelin receptor blockade, in particular by the use of selective ET_A blockers, has renoprotective effects in experimental animal models of diabetes, by lowering urinary albumin excretion, podocyte loss, and inflammation. In human diabetes, some renoprotective effects have been reported with bosentan treatment [70] or treatment with selective ET_A blockers [71,72]. However, fluid retention has been a challenge in most studies, which may reduce the future potential for this class of drugs in the treatment of microvascular complications [69].

Growth factors/cytokines

Of the many known growth factors and cytokines, growth hormone (GH) and insulin-like growth factor I (IGF-I) were the first to be implicated in the development of diabetes-related microangiopathy [73–75]. The evidence for a role of GH/IGF-I in its pathogenesis is reviewed elsewhere [38]. So far, no drugs with effects on this axis have yet made it to clinical use. Transforming growth factor β (TGF-β), connective tissue growth factor (CTGF), and vascular endothelial growth factor (VEGF) have been studied intensively over several decades as significant pathogenic factors for diabetic microangiopathy. In recent years, the role of the tumour necrosis factor (TNF) superfamily has been increasingly associated with a pathogenic role in microvascular complications.

Transforming growth factor/connective tissue growth factor

The TGF-β superfamily comprises multifunctional cytokines, where TGF-β1, TGF-β2, and TGF-β3 are involved in extracellular matrix synthesis [76]. The biologically active isoforms are generated after proteolytic activation [76]. Three TGF-β receptors have been identified and TGF-β signal transduction involves at least three subclasses of Smad proteins [76–78]. CTGF is a downstream mediator of TGF-β [37]. There is a huge amount of pre-clinical and clinical evidence that the TGF-β superfamily, including CTGF, may be involved in the pathogenesis of diabetic nephropathy and retinopathy [38,79,80].

Targeting transforming growth factor β and connective tissue growth factor

Clinical studies have been conducted to examine the effects of TGF-β or CTGF blockade. A phase II clinical study has been performed with the application of a TGF-β antibody in individuals with type 1 diabetes and diabetic nephropathy, showing a minor effect on the rise in serum creatinine [81]. Pirfenidone, a compound that blocks TGF-β promoter activity, has been examined in individuals with type 1 diabetes and type 2 diabetes and kidney disease, already on renin-angiotensin system blockade, and demonstrated a beneficial effect on estimated glomerular filtration rate (eGFR) compared with placebo; however, there was a high dropout rate in the pirfenidone-treated participants [82]. In addition to a series of pre-clinical studies showing positive results on kidney variables by blocking the CTGF axis, a single clinical trial has been performed with the application of a human monoclonal antibody

to CTGF (FG-3019) in people with diabetic nephropathy [83]. The treatment was generally well tolerated and reduced urinary albumin excretion [83].

Although the promising renoprotective results from pre-clinical studies have facilitated the first clinical studies in individuals with renal impairment, the safety and efficacy of using TGF-β and CTGF blockers in the clinical management of microvascular complications are still uncertain.

Vascular endothelial growth factor

The VEGF family embraces different isoforms and exists in several homodimeric glycoproteins [84,85]. VEGF increases vascular permeability and has a stimulatory effect on endothelial cell differentiation and proliferation [85]. The two well-described VEGF receptors (VEGFR-1 and VEGFR-2) are high-affinity transmembrane tyrosine kinase receptors [85]. The production of VEGF is regulated by other growth factors and cytokines, including IGF-I [84,85]. Numerous pre-clinical and clinical studies have been published in the last two decades, indicating a pathogenic role of VEGF in both diabetic nephropathy [38,86] and retinopathy [87].

Targeting the vascular endothelial growth factor system

Several VEGF/VEGFR antagonists have been developed, including agents that directly block the VEGF peptide, such as an anti-VEGF aptamer (pegaptanib), a monoclonal antibody fragment (ranibizumab), and a full-length VEGF antibody (bevacizumab). Other agents include a soluble VEGF receptor analogue (VEGF-Trap) and small interfering RNA drugs (bevasiranib and rapamycin). Although anti-VEGF treatment halts the development of renal changes in experimental models of type 1 diabetes and type 2 diabetes [38], anti-VEGF treatment has not yet been introduced in the clinic to prevent nephropathy. By contrast, local application of anti-VEGF agents in the eye is a widely used procedure in the management of proliferative diabetic retinopathy, macular oedema and their associated complications [86,87] (Chapter 43).

The tumour necrosis factor superfamily

The TNF superfamily comprises structurally related proteins involved in processes such as regulation of immune response, inflammation, and cell death [88]. TNF-related apoptosis-inducing ligand (TRAIL; also called TNF ligand superfamily member 10) was initially identified as a third member of the TNF superfamily to induce apoptosis [89]. In contrast to other members of the TNF superfamily, TRAIL binds to a complex system of TRAIL receptors. Different TRAIL receptors have been described in humans, four of which are membrane bound: TRAIL-R1 to TRAIL-R4 [88,89]. A fifth receptor is osteoprotegerin. In addition to being a stimulator of the various TRAIL receptors, TRAIL is also an inhibitor of osteoprotegerin. Osteoprotegerin was originally known as an inhibitor of bone resorption binding to the receptor activator of nuclear factor κB ligand (RANKL) [89–91]. Osteoprotegerin acts as a soluble inhibitor of the interaction between RANKL and RANK and also of osteoclastogenesis. Therefore, osteoprotegerin acts as an inhibitor of both TRAIL and RANKL, and the delicate balance between these three components is important both in normal physiology and in pathophysiology [92].

Research on the role of TRAIL in microvascular complications is in its initial phase [87], while an increasing number of studies have been carried out on the role of osteoprotegerin. It has become increasingly clear that osteoprotegerin may play an important role in vascular dysfunction in diabetes, although it was originally

identified as a bone molecule, with an inhibitory effect on osteoclast formation [89,90]. Some studies, on the one hand, indicate that osteoprotegerin may be involved in the development of vascular calcifications [93–95]. Thus, osteoprotegerin appears to be a survival factor for endothelial cells [96]. In addition, osteoprotegerin knockout mice develop vascular calcifications [97]. However, most studies are in support of a pro-atherosclerotic role for osteoprotegerin in the vasculature, which may be particularly pronounced in diabetes. Accordingly, increased circulating osteoprotegerin levels have been observed in studies of experimental diabetes [98,99], and microarray studies in human diabetes specimens have shown upregulation of osteoprotegerin mRNA levels in kidney samples [100,101]. Plasma osteoprotegerin levels correlate with the presence of renal dysfunction or cardiovascular disease in type 1 diabetes and type 2 diabetes [88], and plasma osteoprotegerin levels are associated with vascular endothelial dysfunction [102]. Several prospective studies have focused on circulating osteoprotegerin as a putative predictor of the progression of end-stage renal disease. In individuals with type 1 diabetes and nephropathy, plasma osteoprotegerin is a powerful and independent predictor of progression to end-stage renal disease, cardiovascular, and all-cause mortality [103].

Intracellular factors

Among many different intracellular factors, there has been a particular focus on the potential role of the activation of the diacylglycerol–PKC pathway in the development of microvascular complications.

Diacylglycerol–protein kinase C pathway

PKC is an important intracellular pathway that can be activated by many upstream factors in the development of microvascular lesions, including metabolic, haemodynamic, and growth factor/cytokine factors. PKC can then be a stimulus for the initiation of several growth factors and cytokines. PKC comprises at least 11 isoforms that are widely distributed in mammalian tissues. The activity of the classic isoforms is dependent on both Ca^{2+} ions and phosphatidylserine and is greatly enhanced by diacylglycerol. Persistent and excessive activation of several PKC isoforms might also operate as a third common pathway mediating tissue injury induced by hyperglycaemia and associated biochemical and metabolic abnormalities. This results primarily from enhanced *de novo* diacylglycerol synthesis from glucose via triose phosphates, whose availability is increased because raised intracellular glucose levels enhance glucose flux through the glycolytic pathway [104–107]. Finally, the enhanced activity of PKC isoforms could also result from the interaction between AGEs and their cell-surface receptors [108]. Hyperglycaemia primarily activates the β and δ isoforms of PKC, both in cultured vascular cells [109–111] and in the retina and glomeruli of diabetic animals [105–107], but increases in other isoforms have also been found, such as PKC- α and PKC- ϵ isoforms in the retina [104] and PKC- α and PKC- δ in the glomerulus of diabetic rats [112,113].

In early experimental diabetes, activation of PKC- β isoforms mediates the diabetes-related decreases in retinal and renal blood flow [114], perhaps by depressing the production of the vasodilator nitric oxide and/or increasing ET-1, a potent vasoconstrictor. PKC overactivity has been implicated in the decreased nitric oxide production by the glomerulus in experimental diabetes [115] and by smooth muscle cells in the presence of high glucose levels [116], and inhibits insulin-stimulated expression of endothelial nitric

oxide synthase (eNOS) in cultured endothelial cells [102]. Hyperglycaemia increases the ability of endothelin-1 to stimulate mitogen-activated protein kinase (MAPK) activity in glomerular mesangial cells, and this occurs by activating PKC isoforms [117]. The increased endothelial cell permeability induced by high glucose levels in cultured cells is mediated by activation of PKC- α [118]; activation of PKC by high glucose also induces expression of the permeability-enhancing VEGF in smooth muscle cells [119]. In addition to mediating hyperglycaemia-induced abnormalities of blood flow and permeability, PKC activation may contribute to the accumulation of microvascular matrix protein by inducing expression of TGF- β 1, fibronectin, and type IV collagen in both cultured mesangial cells [120,121] and in glomeruli of diabetic rats [112]. This effect appears to be mediated through the inhibition of nitric oxide production by PKC [122]. Hyperglycaemia-induced activation of PKC has also been implicated in the overexpression of the fibrinolytic inhibitor plasminogen activator inhibitor 1 (PAI-1) [123], and in the activation of nuclear factor κ B (NF κ B) in cultured endothelial cells and vascular smooth muscle cells [124].

Targeting the diacylglycerol–protein kinase c system

Over the last few decades, several PKC inhibitors have been developed and examined in an attempt to lower PKC activity. Ruboxistaurin mesylate, which is a highly specific blocker of PKC- β isoforms and the most widely studied specific PKC inhibitor, has been examined in diabetic animal models and a few pilot studies in humans [125]. These studies showed some beneficial effects on the development of diabetic renal changes in animals, but studies in humans have predominantly been inconclusive [125]. Therefore, the clinical effects of lowering PKC activity in the prevention of microvascular complications remain unclear at present.

Innate immune system

The innate immune or complement system plays an important role in the pathogenesis of diabetes-related microvascular complications [88,126]. The complement system has a key role in facilitating the clearance of microbes and damaged cells by antibodies and phagocytic cells. Activation of the complement system typically occurs through three pathways:

- The lectin pathway, which is triggered by carbohydrates on cell surfaces.
- The classical pathway, which involves antibody-mediated activation via the C1 complex.
- The alternative pathway, which involves direct activation of C3 through surface-binding or tick-over [126].

Activation of any one of these pathways leads to the production of complement C3 convertase, which activates complement component C3, leading to generation of the opsonic C3b and eventually generation of the membrane attack complex (MAC), which lyses, damages, or activates target cells.

Mannose-binding lectin (MBL) is considered the classic activator of the lectin pathway, although studies have shown that a group of pattern-recognition molecules called ficolins (including H-ficolin, L-ficolin, M-ficolin) can also activate the lectin pathway [126–131]. Initiation of the lectin pathway occurs when MBL binds to glycan-associated mannose or ficolins bind to N-acetylglucosamine, N-acetylgalactosamine, or N-acetylneurameric acid residues on microbial surfaces [127]. Such binding activates MBL-associated serine proteases (MASPs), leading to cleavage of the complement components C2 and C4 and formation of a C4b2b C3 convertase [128]. Activation of the classical pathway

occurs through the formation of an antigen–antibody complex via the C1q domain of complement C1. C1 is a non-covalent complex of three different proteins (C1q, C1r, and C1s) and after the mentioned complex formation C1q subsequently activates C1r and C1s, which then cleave C2 and C4, also leading to formation of the C4b2b C3 convertase. The alternative complement pathway is activated in an antibody-independent manner on foreign surfaces, such as those of viruses, bacteria, and biomaterials, and leads to the subsequent production of a C3bBb C3 convertase. The C3b fragment generated by any of the complement pathways can bind factor B (FB) and, facilitated by factor D (FD), can form the alternative pathway C3bBb C3 convertase, thereby amplifying the complement cascade [129]. Finally, the alternative pathway is constitutively activated at a low level by the continuous hydrolysis of C3, producing an intermediate that forms alternative pathway-initiating C3 convertases with FB and FD via a mechanism known as tick-over. Following cleavage of C3 to C3a and C3b, the three pathways merge to follow a single pathway. The C3b fragments bind to C3 convertases to produce a C5 convertase, which in turn divides C5 further into C5a and C5b. Thus, C6–9 bind to C5b to form the MAC [126, 130].

The evidence for a connection between the complement system and especially renal dysfunction spans decades, and is supported by findings from both experimental and clinical studies [126, 132–135]. Two main mechanisms explain the involvement of complement in the development of nephropathy. First, activation of the lectin pathway occurs following binding of pattern-recognition molecules to proteins that are glycated as a result of exposure to sugars [136, 137]. Second, hyperglycaemia induces glycation of complement-regulatory proteins [138, 139], leading to dysfunction of their regulatory capacity, which in turn might facilitate complement auto-attack; that is, overactivation of complement pathways [137, 139]. These pathophysiological mechanisms are described in further detail in the following sections. In *in vitro* studies, it has been suggested that diabetes-induced alterations in glycoproteins may stimulate complement activation through binding of MBL to neo-epitopes [136, 137]. These diabetes-induced changes may develop either through altered enzymatic protein glycosylation or by a non-enzymatic formation of AGEs [136, 137].

Mannose-binding lectin

Experimental studies have demonstrated a causal relationship between MBL and diabetic nephropathy. Compared to wild-type mice with streptozotocin-induced diabetes (a model of type 1 diabetes), diabetic MBL-knockout mice have less renal damage, with reduced renal hypertrophy, urinary albumin excretion, and collagen IV expression, suggesting a potential pathological role of MBL on the kidney under diabetic conditions [140]. The adverse renal effects of MBL signalling under diabetic conditions have since been confirmed by other studies in mice with streptozotocin-induced diabetes [141–143]. One study that examined MBL levels after the induction of diabetes as well as the half-life of injected recombinant human MBL showed not only a rise in endogenous MBL levels after the induction of diabetes, but also an increase in the half-life of recombinant human MBL, indicating that the elevation in MBL with diabetes is a result of increased MBL production and decreased MBL turnover [144]. One study demonstrated a twofold increase in MBL levels in glomeruli of mice with established streptozotocin-induced diabetes compared to levels in non-diabetic controls [143], indicative of a direct effect of MBL in the diabetic kidney [143].

The clinical relevance of these experimental studies has been confirmed in clinical studies of individuals with type 1 diabetes or type 2 diabetes. A cross-sectional study of normoalbuminuric individuals with type 1 diabetes reported elevated circulating MBL compared with healthy individuals [144]; moreover, MBL levels were positively associated with urinary albumin excretion levels, even within the normal urinary albumin excretion range [145]. Another study reported higher serum MBL levels among individuals with type 1 diabetes and microalbuminuria or macroalbuminuria than in individuals with normoalbuminuria [146]. In addition, genotypes associated with high circulating MBL have been associated with the development of diabetic nephropathy and increased mortality among people with type 1 diabetes [147]. In a cohort of individuals with type 1 diabetes, those with genotypes associated with high MBL had a 50% increased risk of developing nephropathy [145] and significantly greater mortality over 10 years of follow-up than individuals with a *low-expression* MBL genotype [148]. The findings from this study contrast with those from an earlier study that found no association between 19 MBL SNPs associated with MBL concentrations and the presence of type 1 diabetes or diabetic nephropathy [149]. The reason of this discrepancy is still unknown. In a study of individuals with newly diagnosed type 1 diabetes, serum MBL measured shortly after diabetes onset was a robust predictor of incident microalbuminuria over 18 years of follow-up [150]. Additional studies support an association between MBL and diabetic nephropathy among people with type 1 diabetes [144, 149–151], including a large prospective multicentre study, which reported an association between MBL concentrations and progression of renal disease from macroalbuminuria to end-stage renal disease in individuals with type 1 diabetes [144].

Finally, in people with type 1 diabetes and renal failure who received a simultaneous pancreas–kidney transplant, preoperative serum MBL levels predicted grafts and person survival, with low MBL levels associated with improved outcomes [152]. Moreover, study of individuals with type 1 diabetes and diabetic nephropathy who underwent simultaneous pancreas–kidney transplant or kidney transplantation alone [153] found that circulating MBL normalized in individuals who had undergone successful simultaneous pancreas–kidney transplantation, and that normalization mostly occurred in those with a polymorphism in the *MBL2* gene [153]. By contrast, circulating MBL remained elevated among individuals who received a kidney transplant alone, indicating that glycaemia, and not the reversal of end-stage renal disease, is associated with decreased MBL. In support of this proposal, levels of glucose and HbA_{1c}, but not serum creatinine levels or eGFR, correlated with MBL [153].

As in type 1 diabetes, MBL is strongly predictive of worsening urinary albumin excretion and mortality among people with type 2 diabetes [154]. Several studies from the past few years have confirmed the utility of circulating MBL to predict the development of nephropathy in type 2 diabetes [155–157]. One study that assessed the association of *MBL2* polymorphisms with type 2 diabetes and diabetic nephropathy among a Northern Chinese population showed an association between GA and AA genotypes of rs1800450 with type 2 diabetes, but no association between *MBL2* polymorphisms and diabetic nephropathy [156]. Those with the GG genotype of rs1800450 and the CC genotype of rs11003125 had high serum MBL, however, and the researchers reported an association between elevated serum MBL and nephropathy [156].

These studies in people with type 1 diabetes and type 2 diabetes confirm the value of circulating MBL as a robust predictor of

diabetic nephropathy, while the same consistency has not been found for polymorphisms in the *MBL2* gene. Several of the studies have assessed the predictive value of MBL and high-sensitivity C-reactive protein (hsCRP), alone and in combination, for the development of nephropathy [144, 154]. Levels of MBL and hsCRP are not correlated, which most likely is a consequence of the strong genetic influence on circulating MBL. This lack of correlation seems to be the explanation for a stronger association with the progression of nephropathy when combining the prognostic information from the two biomarkers.

Ficolins

A few studies have examined whether ficolins, like MBL, also have a role in the development of diabetic nephropathy. In one study, deletion of the M-ficolin orthologue, B-ficolin, had no effect on the development of diabetes-induced renal damage in mice with streptozotocin-induced diabetes [158]. This finding suggests that unlike MBL, B-ficolin (and potentially M-ficolin in humans) does not have a role in the pathogenesis of nephropathy. The different outcomes associated with the deletion of B-ficolin and MBL in experimental models of diabetes might relate to differences in their specific carbohydrate-binding properties [158].

A prospective 18-year observational follow-up study examined the association between H-ficolin and the risk of nephropathy among an inception cohort of 270 individuals with newly diagnosed type 1 diabetes [159]. Following adjustment for HbA_{1c}, systolic blood pressure, smoking status, and baseline urinary albumin excretion, individuals in the highest quartile for baseline H-ficolin levels had a twofold greater risk of developing worsening urinary albumin excretion than those in the lowest quartile. Thus H-ficolin levels seem to be robustly associated with risk of progression to micro- or macroalbuminuria [159]. In a recent study circulating H-ficolin correlated not only with diabetic kidney disease, but also with mortality and cardiovascular events in individuals with type 1 diabetes [160]. So far no human studies have been published on the potential association between L-ficolin or M-ficolin and the risk of developing nephropathy.

Mannose-Binding Lectin–Associated Serine Proteases

In contrast to the substantial number of studies that have demonstrated a role for MBL in diabetic nephropathy, only one published study has investigated the role of MASPs in diabetes. The investigators compared levels of MASP-1, MASP-2, and MASP-3 in 30 children and 45 adults with type 1 diabetes with levels in individuals without diabetes [161]. Compared to age-matched controls, MASP-1 and MASP-2 levels were significantly higher among adults and children with type 1 diabetes, whereas MASP-3 did not differ between those with and without diabetes. HbA_{1c} level correlated with both MASP-1 and MASP-2, with levels of MASP-1 and MASP-2 levels decreasing as a result of improved glycaemic management. So far no studies have been published on MASP levels in type 2 diabetes.

Complement components C3, C4, and C5

In addition to the increasing body of evidence supporting a role for the lectin pathway in the development of diabetic nephropathy, several studies support a role for downstream components of the complement system – C3, C4, and C5 – in nephropathy. Some, but not all, experimental studies have reported an accumulation of complement component C3 in animal models of diabetes. In studies from the 1970s, the induction of type 1 diabetes in rats by administration of streptozotocin led to an increase in glomerular C3 levels, which

was normalized by transplantation of pancreas islets [162, 163]. Furthermore, transplantation of kidneys from rats with type 1 diabetes into non-diabetic rats led to decreased expression of glomerular C3 and decreased mesangial volume in 50% of transplanted kidneys [164]. One study demonstrated an increase in glomerular MBL in mice with streptozotocin-induced diabetes, but did not find a difference in the glomerular immunofluorescence intensity of complement factors C3, C4, or C9 compared to that of non-diabetic controls; however, circulating levels of the complement activation product C3a were increased in diabetic compared to non-diabetic mice [143]. Whether the apparent disparity in levels of glomerular MBL and glomerular C3 are real or due to methodological issues in that study is not known [143]. In contrast to the study described, elevated C3 have been detected in the kidneys of two other mouse models of type 1 diabetes, the non-obese diabetic mouse [165] and the OVE26 diabetic mouse [166].

Deposition of C3 in glomeruli and glomerular capillaries has also been observed in KK mice, a model of type 2 diabetes [167]. Similarly, a study in Zucker rats, which are a hypertensive, dyslipidaemic, obese, and hyperglycaemic model of type 2 diabetes, found that a single episode of renal ischaemia was followed by a significant increase in renal mRNA encoding C3, C4, C5, C6, C8, and C9, along with notable elevations in renal mRNA encoding C3a and C5a [168].

The role of downstream complement components in nephropathy has also been assessed in clinical studies. Transcriptome and immunohistochemical analyses found a sixfold increase in glomerular C3 in kidney biopsy samples from individuals with overt diabetic kidney disease [169]. In addition, plasma levels of C3 were significantly higher in people with type 2 diabetes and macroalbuminuria than in those with normoalbuminuria [170].

The relationship between complement component C4 and diabetic nephropathy has also been described in a number of clinical studies. In a study of 64 children with type 1 diabetes, 25% of the individuals had low circulating complement C4 levels, with no association with circulating levels of complement C3 fragments in the same group [171]. Another study showed that people with type 1 diabetes and microangiopathy had lower circulating C4 than individuals with normoalbuminuria, and that C4 levels were inversely correlated with the degree of complement activation [172]. This inverse association was not confirmed, however, by another study, which might suggest that low C4 levels might be a result of the diabetes, rather than having a pathogenic role in the disease [173]. Evaluations of C4 allotypes in individuals with diabetes with or without microvascular complications have not shown consistent results [174, 175].

Membrane attack complex

A series of immunohistochemical studies using antibodies directed against the C9 component of MAC [176–178] have localized MAC to the glomerular basement membrane, tubuli, and Bowman capsule in renal tissue from individuals with type 1 diabetes [176–178]. Evaluation of renal tissue from people with varying degrees of renal function demonstrated a correlation between MAC and the magnitude of mesangial expansion among persons with type 1 diabetes. The deposition of MAC in diabetic glomeruli has been confirmed in more recent studies [139, 179]. These results are interesting, as MAC is the end-product of the complement system and the elevated MAC in type 1 diabetes seems to underline the universal activation of the complement system in diabetes ranging from MBL, over MASP and C3, to MAC.

Targeting the complement system

Under normal conditions MBL and ficolins do not bind to their receptors on cell surfaces; however, AGEs in response to hyperglycaemia generate neo-epitopes to which lectin pathway pattern-recognition molecules bind [140, 180]. In addition, increased levels of glycation in diabetes lead to glycation-induced dysfunction or inactivation of complement-regulatory proteins such as CD59, which normally prevents the deleterious effects of complement overactivation by inhibiting MAC [138, 139]. The combined effects of glycation-induced inactivation of CD59 and hyperglycaemia-induced activation of complement signalling have been proposed to increase tissue deposition of MAC, thereby activating intracellular signalling pathways, which in turn release pro-inflammatory cytokines and growth factors. Three different pathways have been proposed to lead to the late complications of diabetes: those that are dependent on the complement system and activation of MAC (for example, activation of the lectin pathway through glycation of receptor carbohydrates in addition to pathways involving CD59); those that are independent of complement (e.g. the polyol pathway); and those pathways that are triggered by either hyperglycaemia and/or MAC, such as PKC and NF- κ B.

A role for the complement system in various diseases has stimulated interest in the development of antibodies, small molecules, and biologics to target this pathway. Although attempts to block complement span more than 50 years, only a few drugs have made it into clinical trials, and even fewer have passed beyond phase 1 clinical trials. Nevertheless, complement therapeutics remains an area of active interest, with new insights from molecular, genomic, and structural studies, as well as the approval and success of some complement inhibitors, such as the C5 inhibitor eculizumab, for diseases such as atypical haemolytic uraemic syndrome, encouraging further research in this field [181].

Approaches to modulate complement signalling can be categorized into five main groups:

- Those that disrupt initiation of the lectin and classical pathways by inhibiting initiating complexes, e.g. MBL-, C1q-, C1s-, or MASP-neutralizing monoclonal antibodies (mAbs); or inhibiting initiating enzymes, e.g. serine protease inhibitors (C1 inhibitor [C1INH] and nafamostat mesilate).
- Those that inhibit activating enzymes of the alternative pathway, e.g. humanized immunoglobulin G1 (lampalizumab) and small-molecule protease inhibitors.
- Those that inhibit C3 convertases and/or C3 activity, e.g. C1INH.
- Those that inhibit C5 convertases and/or C5 activity, e.g. eculizumab, coversin, C5-specific aptamers.
- Those that inhibit MAC function, e.g. soluble recombinant CD59 [181].

Only a few experimental studies have assessed the therapeutic effect of blocking complement signalling in diabetic nephropathy. One study examined the effect of thrombomodulin on the development of renal changes in a diabetic mouse model of type 1 diabetes [182]. Thrombomodulin inhibits coagulation, but also prevents complement activation via its lectin-like domain. Diabetic mice lacking thrombomodulin's lectin-like domain had increased complement activation and more severe nephropathy than diabetic wild-type mice. Inhibition of complement by administration of a low molecular weight heparin (enoxaparin) reduced albuminuria and podocyte injury in the mutant mice. *In vitro* studies demonstrated that the lectin-like domain of thrombomodulin prevented

glucose-induced complement injury of podocytes, suggesting that the lectin-like domain of thrombomodulin protects against diabetic renal damage by limiting glucose-induced complement activation [182].

Two studies have examined the effects of blocking complement C3a receptors [183, 184] and/or C5a receptors [183] in Sprague-Dawley rats with streptozotocin-induced type 1 diabetes [183] and a model of type 2 diabetes, induced by exposing Sprague-Dawley rats to a high-fat diet and low-dose streptozotocin [184]. Blockade of C3a and C5a receptors in the type 1 diabetes model ameliorated endothelial-to-myofibroblast transition through the Wnt/ β -catenin signalling pathway, indicative of a potential protective effect of complement blockade on renal fibrotic changes [183]. Similarly, blockade of C3a receptors in rats with type 2 diabetes improved renal morphology and function by inhibiting cytokine release and TGF- β /Smad3 signalling, again supporting a role for C3a in diabetic renal changes [184].

A study in another rat model of type 2 diabetes (Otsuka Long-Evans Tokushima Fatty Rats) demonstrated that blockade of complement component C5 with the inhibitor K-76COONa diminished the severity of albuminuria and mesangial expansion [185]. Glomerular deposition of C3 was more pronounced in untreated rats with diabetes than in animals with diabetes treated with K-76COONa, supporting a pathogenic role for C5 in diabetes-induced renal damage [185].

At present it is not fully clear which way would be the best to target the complement system in order to block the development of diabetic nephropathy. Several compounds that modify the complement system are already in clinical use for other diseases than diabetic nephropathy. The most promising of these agents should be tested for their ability to prevent or slow down the progression of diabetic nephropathy. However, for future strategies it is important to recall that the complement system has an important role in host defence and, despite the potential benefits of blocking the complement system on diabetes-induced renal damage, any approach to modulate complement signalling carries considerable risks. Individuals who are deficient in components of the lectin pathway or the classical pathway (for example, MBL, MASP-1 and MASP-2, C1 or C4) typically present with recurrent bacterial infections. Individuals with deficient classical pathway signalling can have an impaired ability to clear immune complexes, which in turn increases the risk of lupus nephritis in people with systemic lupus erythematosus [181]. Individuals who have a deficiency in a component of the alternative pathway are at increased risk of developing bacterial infections of Gram-negative origin [181]. Deficiencies in the terminal paths of the complement system increase the risk of meningo-coccal sepsis and/or meningitis [181]. As proposed previously, the best way to minimize the risk of iatrogenic complications is to minimally affect the physiological effects of complement signalling and to block the relevant pathway as downstream as possible. Whether the adverse effects of chronic complement inhibition, as would be required for a disease such as diabetes, are unacceptable remains to be determined.

The potential mechanisms behind the renoprotective effects of incretin drugs and sodium–glucose cotransporter 2 inhibitors

As described in detail in Chapter 44, unexpected cardio-renoprotective effects were shown in the US Food and Drug Administration (FDA)-required safety studies performed before the clinical introduction of incretin drugs and SGLT-2 inhibitors.

These two new classes of glucose-lowering drugs have markedly changed the treatment of type 2 diabetes. In addition to effectively lowering glucose, incretin drugs (glucagon-like peptide 1 [GLP-1] receptor agonists and dipeptidyl peptidase 4 [DPP-4] inhibitors) and SGLT-2 inhibitors can also reduce blood pressure, body weight, the risk of developing or worsening of diabetic kidney disease and/or cardiovascular events, and the overall risk of death [186–191].

Experimental data have identified the modulation of the innate immune system and inflammation as plausible biological mechanisms underpinning the kidney-protective effects of the drugs. In addition, these drugs may block the production of pro-inflammatory cytokines and attenuate oxidative stress [186–191].

Conclusion

Hyperglycaemia is the main driver in the development of microvascular complications in individuals with type 1 diabetes and type 2 diabetes. Accordingly, strict metabolic management is a cornerstone in the primary prevention of the microvascular complications of retinopathy, nephropathy, and neuropathy. Effective treatments of microvascular disease have been developed, in particular against retinopathy (Chapter 43) and nephropathy (Chapter 44). Although many pharmaceutical and technical interventions are available that effectively prevent or delay the development of microvascular complications in diabetes, there is still an ongoing need to develop new biomarkers and therapies for these complications.

43 Diabetic Retinopathy

Toke Bek

Department of Ophthalmology, Aarhus University Hospital, Aarhus, Denmark

Department of Clinical Medicine, Faculty of Health, Aarhus University, Aarhus, Denmark

Key points

- Diabetic retinopathy is one of the most frequent causes of blindness worldwide.
- The pathophysiology of the disease is unknown, but the morphological lesions characterizing the disease indicate that disturbances in retinal vascular function are involved in the disease pathogenesis.
- The early stages of diabetic retinopathy are not accompanied by any subjective symptoms, but the disease can be detected by screening with inspection of the ocular fundus.
- The early changes may develop into one or both of two vision-threatening complications, proliferative diabetic retinopathy and diabetic maculopathy,

each with a different epidemiology, clinical appearance, and site of origin in the retina.

- Proliferative diabetic retinopathy is primarily treated by retinal photo-coagulation, and diabetic macular oedema by intravitreal angiostatic treatment.
- Countries with effective population screening and timely treatment of diabetic retinopathy have managed to reduce the incidence of low vision and blindness secondary to the disease to a negligible level.

Diabetes mellitus is a disease of the intermediary metabolism that may lead to complications in all parts of the body, including the eye [1]. The ocular complications include sudden palsies of external eye muscles resulting in diplopia that normally disappear spontaneously within a few weeks. Individuals with diabetes also have reduced motility of the pupil secondary to autonomic neuropathy, and diabetes may lead to the development of cataract at a much earlier age than in the population without diabetes [2]. However, this condition can be treated by surgery with a low complication rate.

The diabetes-related complication developing in the retina, diabetic retinopathy, is a potentially much more serious condition and constitutes one of the most frequent causes of blindness worldwide [3]. The disease is characterized by morphological lesions in the retina related to disturbances in retinal blood flow [4]. The initial signs of the disease are microaneurysms and haemorrhages in the macular area (Figure 43.1) that may progress to one or both of the two vision-threatening complications, proliferative diabetic retinopathy and diabetic maculopathy. Proliferative diabetic retinopathy is initiated by occlusion of capillaries in the retinal periphery. The consequent ischaemia and hypoxia stimulate the release of growth factors that stimulate the formation of neovascularizations proximally from the ischaemic areas. In diabetic maculopathy, the early changes progress with breakdown of the blood–retina barrier, exudation of plasma proteins, and formation of retinal oedema that may expand to include the foveal region, with a resulting destructive effect on central vision.

Nomenclature

The nomenclature of diabetic retinopathy dates back to the initial descriptions of retinopathy in people with type 1 diabetes. At this time it was important to distinguish the early changes without visual loss termed simplex, background (inside the retinal background), or non-proliferative diabetic retinopathy from proliferative diabetic retinopathy, where neovascularizations grow pre-retinally and may result in vitreous haemorrhage, tractional retinal detachment, and blindness if untreated [5]. The grading of retinopathy on this scale was supplemented with a notation of whether oedema and/or exudates were present or not in the macular area (maculopathy), since such changes can threaten central vision by mechanisms other than those related to proliferative diabetic retinopathy. The surge in the number of individuals with type 2 diabetes has increased the occurrence of diabetic maculopathy to emphasize that this is a complication in its own right.

Therefore, a present-day comprehension of diabetic retinopathy should reflect the fact that early retinopathy changes can develop into one or both of the two vision-threatening complications, diabetic maculopathy and proliferative diabetic retinopathy, with different sites of origin in the retina, different epidemiologies, and different pathophysiologies (Table 43.1).

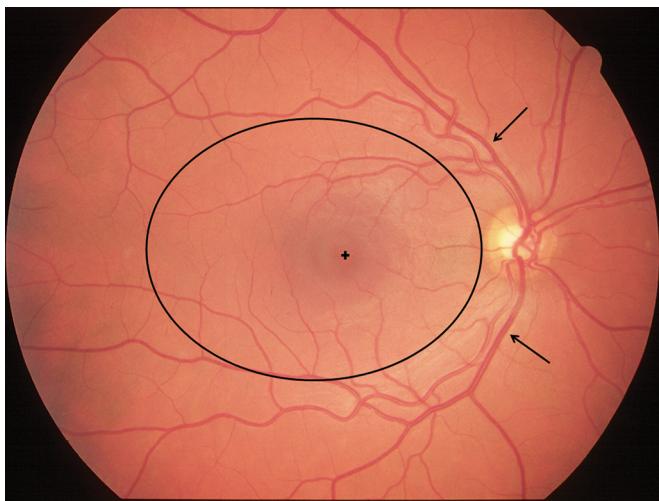

Figure 43.1 Fundus photograph of a normal eye. The retinal vascular tree branches from the optic nerve to the right. Arrows indicate the temporal vascular arcades. The ellipse delimits the macular area and the cross in the centre indicates the fovea.

Table 43.1 The nomenclature used to describe diabetic retinopathy.

Feature	Nomenclature for diabetic retinopathy	
Early changes without vision loss	Simplex retinopathy Older notation that has largely been abandoned	
	Background retinopathy Refers to the fact that lesions are located inside the fundus background	
	Non-proliferative diabetic retinopathy Currently used notation that is somewhat misleading as it does not indicate that these changes also precede diabetic maculopathy	
Transition towards vision-threatening retinopathy	Pre-proliferative diabetic retinopathy	Diabetic maculopathy without central involvement
Vision-threatening diabetic retinopathy	Proliferative diabetic retinopathy	Diabetic maculopathy with involvement of the area in and around the fovea

Pathophysiology

The coupling between diabetic metabolic disturbances and the development of morphological changes characterizing diabetic retinopathy is not known in detail [6]. Consequently, diabetic retinopathy has been studied from several different perspectives, and over the years a number of different hypotheses have been proposed to explain the development of the disease. One of the most productive hypotheses was the proposal of Michaelson that proliferative diabetic retinopathy results from the release of growth factors from ischaemic and hypoxic areas in the retinal periphery [7], which formed the rationale for the development of angiostatic treatment for diabetic retinopathy. Later hypotheses emphasized metabolic disturbances in the retina, such as hyperglycaemia leading to non-enzymatic glycation, shunting via

aldose reductase, or activation of protein kinase C [8]. Other hypotheses have focused on specific anatomical elements as key factors in the pathogenesis of the disease, such as leucocytes, vascular pericytes, basement membranes, endothelial cells, the blood–retina barrier, neuroglia, and elements involved in neurovascular coupling [9–13]. Finally, some hypotheses have emphasized the involvement of specific reaction types such as inflammation in the development of the disease [14]. All these hypotheses can partly explain the pathophysiology of the disease, but have not individually or together been able to fully explain the development of the disease.

It is a particular feature of the retina that the inner vascular supply is devoid of autonomic nerves. This implies that retinal blood flow is autoregulated, and the vascular changes in diabetic retinopathy may be related to impairment of this autoregulation [15]. The disturbances affect both pressure autoregulation, so that retinal resistance vessels contract insufficiently when the systemic blood pressure is increased [16], and metabolic autoregulation, so that the normal dilation of retinal arterioles is reduced when the retinal metabolism increases, such as during exposure to flickering light [17]. Therefore, one of the key issues in the exploration of diabetic retinopathy is to understand the connection between diabetic metabolic dysregulation and disturbances in the regulation of retinal blood flow.

Development

Early changes with no vision loss

The initial morphological changes in diabetic retinopathy are red dots in the macular area representing capillary microaneurysms or dot haemorrhages. These two lesion types often have a similar fundoscopic appearance, presenting as small, round, reddish lesions [18]. A differentiation of microaneurysms from haemorrhages requires fluorescein angiography, where microaneurysms are hyperfluorescent and haemorrhages appear as dark spots [19]. Therefore, the idea of counting microaneurysms based on fundus photographs is conceptually meaningless. However, the clinical significance of microaneurysms and dot haemorrhages is similar, and the two lesion types should be considered together in the grading of retinopathy, just referred to as ‘red dots’.

The initial lesions typically develop in the area temporal from the fovea (Figure 43.2), probably because the intraluminal pressure is particularly high in this area where the capillaries are supplied by dilated arterioles from both the upper and the lower temporal vascular arcades [20]. The presence of a few red dots implies the same risk of progression of the disease as no retinopathy, whereas the risk of progression to a vision-threatening condition increases with higher numbers of red dots [21]. Retinal haemorrhages may also assume shapes other than circular depending on the retinal anatomy at the location where the extravasated blood is distributed. One of the most striking examples is stripe-shaped haemorrhages in the retinal nerve fibre layer. Microaneurysms and haemorrhages show a highly dynamic pattern of development, with continuous new formation and resolution of lesions occurring within days to weeks [22, 23]. Therefore, the progression of the disease with an increase in the total number of lesions over months to years is due to a change in this balance, where the number of newly formed lesions is higher than the number of lesions that are resolved.

The progression of diabetic retinopathy (Figure 43.3) implies an increase in the number of red dots and the occurrence of blot

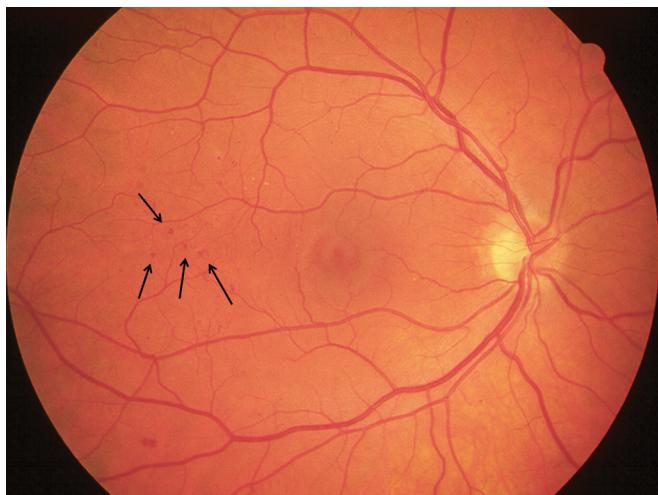

Figure 43.2 Early diabetic retinopathy with red dots (arrows) predominantly located temporally in the macular area.

Figure 43.4 Severe diabetic retinopathy with many whitish cotton wool spots developing during a period with poor metabolic management.

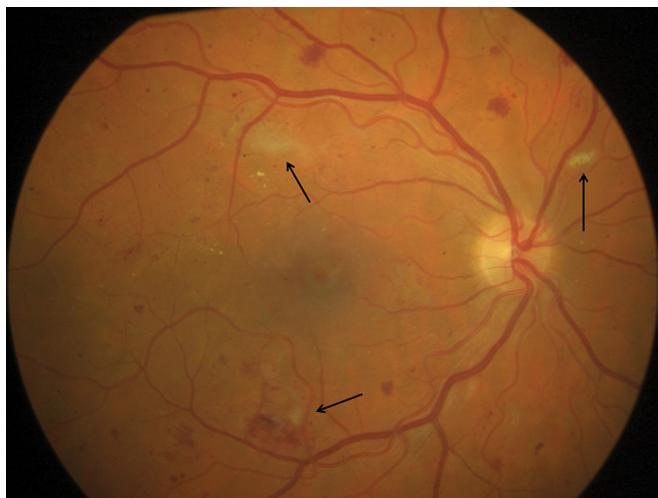

Figure 43.3 Moderate diabetic retinopathy with red dots, larger blot haemorrhages, and cotton wool spots (arrows).

haemorrhages, defined as lesions with a diameter larger than that of the vascular arcades at the crossing of the border of the optic disk [19]. Haemorrhages developing around the larger vascular arcades may indicate that impaired autoregulation has resulted in a higher than normal arterial blood pressure being transmitted to the smaller retinal vessels, with a resulting damage to the capillary system adjacent to these arcades [24].

Diabetic retinopathy may also lead to the development of cotton wool spots, which are localized, whitish lesions about the size of one-third disk diameter located at the inner surface of the retina (Figure 43.4). The lesions represent swellings of the retinal nerve fibres because the axoplasmic transport has been arrested in a focal area, with a consequent intracellular accumulation of the organelles transported to the site of the lesion [25]. Therefore, cotton wool spots are most frequently located in the arcuate areas, where the retinal nerve fibre layer is thick, and never in the foveal area or the retinal periphery, which are devoid of retinal nerve fibres. The lesions develop secondary to disturbed axoplasmic transport in the retinal nerve fibre layer, but do not point to a specific cause of this disturbance. Thus, it is erroneous to refer to the lesions *per se* as

retinal infarctions, although this may be the background for the lesions in some cases. Cotton wool spots have a dynamic cycle of development and disappearance lasting weeks to months and only rarely affect visual function [26]. The development of a single cotton wool spot without any other retinopathy lesions does not imply a risk of progression of the disease, but the development of many cotton wool spots in people with other retinopathy changes (Figure 43.4) may be an indication of unstable regulation of the blood glucose levels and of imminent progression to vision-threatening diabetic retinopathy [27].

Vision-threatening diabetic retinopathy

The early retinopathy changes may progress to one or both of the two vision-threatening complications, proliferative diabetic retinopathy and diabetic maculopathy, each preceded by transitional forms.

Proliferative diabetic retinopathy

Mechanism of development

This complication is assumed to be initiated by occlusion of the capillaries in the retinal periphery. The vascular occlusion is not directly visible by inspection of the ocular fundus. However, retinal ischaemia should be suspected when the retinal fundus has a more yellowish appearance than normal and other causes such as cataract with pronounced nuclear sclerosis that absorbs short-wavelength light have been ruled out. Retinal capillary occlusion can be demonstrated by fluorescein angiography, where the lesions appear as uniform dark areas, probably due to diffuse blocking of light from the choroidal vessels caused by fluid accumulated between the photoreceptor outer segments and the pigment epithelium [28]. Fluorescein angiography may also show localized areas of capillary occlusion at earlier stages, and it has been hypothesized that these changes might be involved in the early development of the disease [29].

Occlusion of the capillary bed initiates the formation of vascular shunts from pre-existing vessels. These shunts are observed as intra-retinal microvascular abnormalities (IRMAs) with a low shunting capacity [30], which are considered to be a sign of pre-proliferative retinopathy. If the capillary occlusion progresses further, the need for shunting increases further, which stimulates the formation of new vessels that grow pre-retinally. This process is stimulated by

vascular endothelial growth factor (VEGF) released from the ischaemic and hypoxic retinal tissue. Since the new vessels are connected to the high-pressure arterial vascular system, there is a risk of spontaneous ruptures of the new vessels leading to vitreous haemorrhage. The new vessels developing from the optic disk are accompanied by a higher risk of progression to result in visual loss than neovascularizations located elsewhere [31], which may be related to a higher intravascular pressure in these vessels. The clinical observation of proliferative diabetic retinopathy as a chronic progressive condition may give the impression that the disease process is irreversible. However, the fact that retinal neovascularizations may disappear a few days after anti-VEGF therapy, and even under certain conditions spontaneously [32], suggests that the natural history of these lesions is a function of changes in the retinal microcirculation and the need for arterio-venous shunting derived therefrom.

Clinical presentation

The presence of pre-proliferative changes with capillary occlusion in the retinal periphery can be suspected when one or more of the following signs (Figure 43.5) are observed [19, 33]:

- The occurrence of many blot haemorrhages temporal to the macular area. These haemorrhages may extend into the foveal region with a consequent reduction in visual acuity, which is one of the few signs of severe diabetic retinopathy that can be noticed subjectively by the individual with diabetes [34].
- IRMAs, which represent dilatations of existing vessels from the retinal microcirculation. On fluorescein angiograms, these lesions are located at the border of areas of capillary occlusion and are therefore assumed to represent shunt formations to bypass the areas of capillary occlusion.
- Many cotton wool spots, probably representing an aggravation of disturbances in blood flow and metabolism.
- Abundant reflexes from the posterior hyaloid membrane visible in younger persons where the optical media are clear. The reflections originate from the vertex of local swellings of the retina, probably reflecting localized areas of subclinical retinal oedema.
- Calibre changes of the larger retinal venules that may develop to resemble beads on a string, so-called venous beading. Under normal

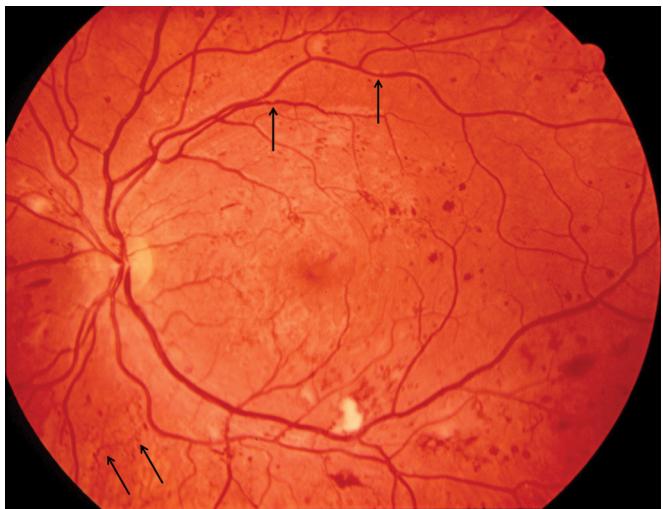

Figure 43.5 Pre-proliferative diabetic retinopathy with blot haemorrhages temporal to the macular area, cotton wool spots, venous beading (upper arrows), intra-retinal microvascular abnormality (IRMA) vessels (lower arrows), and vivid reflexes from the posterior hyaloid membrane in the macular area.

conditions, the diameter of retinal vessels decreases with increasing distance from the optic disk, and therefore a localized increase in the diameter can be considered to be abnormal. The background for this manifestation of diabetic retinopathy is disputed, but it may be related to metabolic acidosis or stagnant retinal blood flow.

The occurrence of neovascularizations (Figure 43.6) is a pivotal event, since this prompts a need for treatment. In clinical practice, it is important to differentiate neovascularizations from shunt vessels. One of the most recently discovered measurements suitable for distinguishing the two types of vascular pathology is retinal oximetry since the oxygen saturation in the venules reflects the degree of shunting in the vessels [18, 30], but retinal oximetry is not yet a routine examination in clinical practice. The following criteria may act as a guide [35] (Table 43.2):

- Retinal neovascularization develops because of proliferation of retinal endothelial cells that penetrate the vascular wall to grow out of the vessel. However, endothelial cell proliferation may also occur inside retinal venules and contribute to the development of venous occlusions slowly enough to allow the formation of shunt vessels to bypass the site of occlusion. These shunt vessels may have the appearance of omega loops or reduplicated bypass channels (Figure 43.7). When these changes are observed, the patient will usually already have or will in the near future develop pre-retinal neovascularizations, and the condition should therefore be handled like any other case of proliferative diabetic retinopathy [36, 37].

Figure 43.6 Proliferative diabetic retinopathy with new vessels blurring the optic disk. A neovascularization at the upper temporal arcade has given rise to a pre-retinal haemorrhage extending towards the fovea.

Table 43.2 The differences between neovascularizations and shunt vessels.

Neovascularizations	Shunt vessels
Extend pre-retinally	Are located intra-retinally
Originate from larger vessels	Originate from smaller vessels
Arterial oxygen saturation	Oxygen saturation between that of arterioles and venules
May cross feeder vessel	Do not cross feeder vessel
May contain connective tissue	Do not contain connective tissue

Figure 43.7 A segment of the upper vascular arcade. An omega loop represents a shunt formed to bypass an occlusion of a larger venule because of intravascular proliferation of endothelial cells. The venule extending peripheral from the loop displays changing calibre.

- Spontaneous haemorrhages emerging from neovascularizations may either be located behind the posterior hyaloid membrane and result in a localized scotoma in the visual field, or may break through to the vitreous body. This expansion of the haemorrhage results in a severe reduction in visual acuity, typically to hand movements, and a severely blurred view of the retinal fundus. If untreated, the vitreous haemorrhage may organize and together with traction from connective tissue in the new vessels the course may result in retinal detachment and total blindness.

Diabetic maculopathy

Mechanism of development

The progression of early diabetic retinopathy may result in the development of retinal oedema and/or exudates representing precipitations of plasma proteins, predominantly in the macular area. These changes are due to breakdown of the blood–retina barrier secondary to structural changes in the retinal vessels and impaired autoregulation, so that a higher than normal blood pressure is transmitted to the capillary system [38, 39]. These factors compromise the tight junctions between the vascular endothelial cells, with a consequent exudation of plasma proteins that precipitate as hard exudates.

Clinical presentation

Diabetic maculopathy is predominantly located in the macular area, but the lesions may extend to a short distance beyond the temporal vascular arcades and nasal from the optic disk. Hard exudates may develop as circular precipitations around focal points of leakage or more randomly in the macular area when the points of leakage are more distributed (Figure 43.8). Retinal oedema has been categorized according to whether it is focal or diffuse [40], which may be an indication of the severity of the condition, but the practical significance of this distinction is disputed [41].

Retinal exudates and/or oedema can progress and potentially threaten central vision. It is defined as clinically significant macular oedema when exudates and/or retinal oedema fulfil one or both of the following (Figure 43.9):

- Extend over an area larger than one disk diameter of which a part is located within one disk diameter from the fovea.
- Are located within half a disk diameter from the fovea [42].

Retinal oedema together with exudates is termed exudative maculopathy and is the commonest type of diabetic maculopathy. However, on rare occasions, macular oedema may be due to an

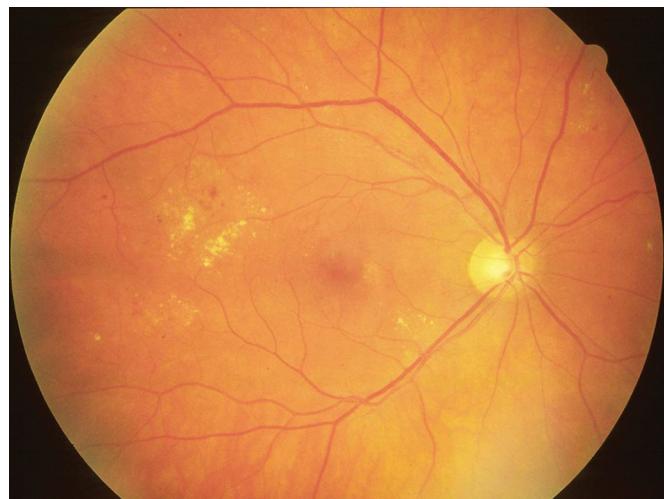

Figure 43.8 Diabetic maculopathy with exudates located temporally in the macular area.

Figure 43.9 Diabetic maculopathy with clinically significant macular oedema. Exudates extend over a larger part of the macular area and involve the foveal region.

extension of capillary occlusion from the retinal periphery to the macular area [43]. The resulting oedema is ischaemic and appears as a yellowish retinal fundus with many haemorrhages, but with no exudates. The two types of maculopathy can be differentiated by fluorescein angiography that can identify the location of respectively leakage and capillary occlusion.

Epidemiology

Diabetes is assumed to affect ~463 million people worldwide, of whom one-third have retinopathy and one-tenth have vision-threatening retinopathy [44]. However, these estimates cover large ethnic, socioeconomic, and genetic variations. The pattern of development of diabetic retinopathy differs among the two types of diabetes and is influenced by the success of the prevention, detection, and therapy of the disease in each country. Thus, in countries with limited access to anti-diabetes medication and lack of systematic population screening, retinopathy changes may develop after a few years of diabetes duration and may be detected so late that

vision-threatening changes have developed. Therefore, the incidence and prevalence of diabetic retinopathy vary considerably, and estimates of the occurrence of the disease mostly refer to countries where data from organized population-based screening and management of diabetic retinopathy are available.

In type 1 diabetes, a few microaneurysms and/or dot haemorrhages may be present at the time of onset of the disease, but these lesions disappear so that the initial signs of diabetic retinopathy in progression appear after ~10 years' duration of diabetes [45]. The prevalence of diabetic retinopathy subsequently increases gradually until ~20 years' duration of diabetes, when almost all people with diabetes have some retinopathy [46]. The incidence of vision-threatening diabetic retinopathy gradually increases until ~25 years' duration of diabetes, after which it declines. This suggests the existence of constitutional factors affecting the risk of developing vision-threatening retinopathy within the first decades' duration of diabetes that overlie the risk of disease progression related to the cumulative exposure to metabolic dysregulation. In populations with comprehensive and organized screening and treatment programmes, half of all individuals with type 1 diabetes develop vision-threatening retinopathy, of whom two-thirds develop proliferative diabetic retinopathy and one-third develop diabetic maculopathy [47].

In type 2 diabetes, the onset of the disease is gradual and it may not be diagnosed for several years after its onset [45], so the occurrence of retinopathy in the undiagnosed population is not negligible [48]. At the time of diagnosis of type 2 diabetes, retinopathy can be observed in a considerable number of individuals, some of whom have already developed vision-threatening retinopathy [49]. After the time of diagnosis, the annual incidence of vision-threatening diabetic retinopathy is constant, and less than 10% of the individuals reach one of the treatment-requiring conditions, proliferative diabetic retinopathy and diabetic maculopathy. Since the number of people with type 2 diabetes is larger than the number of those with type 1 diabetes, the absolute number of individuals developing vision-threatening retinopathy is approximately the same in the two groups.

Prevention

The occurrence and development of diabetic retinopathy are influenced by a number of modifiable and non-modifiable risk factors. Studies of non-modifiable risk factors such as ethnicity [50], gender [51], actual age, and age at onset of diabetes [52, 53] have provided important information about the epidemiology of the disease. However, modifiable risk factors have received much more attention because of the potential for clinical intervention. Thus, the development of diabetic retinopathy correlates with average glucose levels both higher and lower than normal [54], with fluctuations in glycaemia [54], while interventions to improve glycaemic management can reduce the risk of progression of the disease in both type 1 diabetes [55] and type 2 diabetes [56]. Similarly, the development of diabetic retinopathy correlates with the systemic blood pressure [57], and a lowering of the blood pressure can reduce the progression of retinopathy in both type 2 diabetes [57] and type 1 diabetes [58]. Close monitoring of blood glucose and blood pressure can halt the progression of diabetic retinopathy and is especially relevant during pregnancy, where irregularities in metabolic regulation may have detrimental effects on the eye.

It has been suggested that the formation of hard exudates may be related to plasma cholesterol levels [43], but clinical intervention

studies are lacking to document that a reduction in plasma lipids can reduce the risk of diabetic maculopathy. The development of diabetic retinopathy also depends on the type of diabetes and several studies have reported a higher frequency of retinopathy in men than in women, which may be due to men paying less attention to lifestyle [51].

The most recent evidence documents that systemic risk factors contribute differently to the development of proliferative diabetic retinopathy and diabetic maculopathy, suggesting that the overall risk of developing vision-threatening diabetic retinopathy should be calculated from the risk of reaching each of these two complications separately [54].

Screening

Diabetic retinopathy is suitable for screening because the disease fulfils the following criteria [59]:

- *The development and early progression of the disease are not detected by the individual with retinopathy.* Since diabetic retinopathy initially develops and progresses outside the foveal area, the individual will not have subjective symptoms until the late stages when damage to central vision has started. Therefore, a screening examination with inspection of the ocular fundus is needed in order to detect early retinopathy lesions before they become a threat to central vision.
- *The disease is frequent.* Diabetic retinopathy is frequent among individuals in whom diabetes has been diagnosed and therefore justifies screening for diabetic retinopathy in this population [60, 61].
- *The disease can be detected.* Diabetic retinopathy can be detected by inspection of the ocular fundus, which is achievable in all persons unless impeded by cataract or other media opacities.
- *The disease can be treated.* Studies have confirmed the beneficial effect of retinal photocoagulation, intravitreal angiostatic pharmacotherapy, and vitrectomy for the treatment of diabetic retinopathy. This implies that therapeutic benefits can follow the detection of diabetic retinopathy.
- *Screening is cost-efficient.* Health economic analyses have documented that in addition to the beneficial effects for individuals screened for diabetic retinopathy, the procedure is also highly cost-efficient for society [62].

Screening for diabetic retinopathy comprises inspection of the ocular fundus, which may be supplemented with a measurement of visual acuity in order to assess the consequences of the disease for central vision [63]. It is recommended that the fundoscopic appearance is documented by photography, which gives an overview of lesions in all parts of the fundus background, allows retinopathy lesions to be reviewed in order to obtain further opinions, and allows a detailed evaluation of changes in the morphological appearance of the disease over time. It has been a matter of debate whether screening examinations should be performed without dilatation of the pupil (non-mydriatically) in order to allow a faster and more feasible examination procedure for the patient, and the availability of cameras for imaging of the retina through small pupils has facilitated this approach. The disadvantage of this photographic approach is a reduced quality of images from the retinal periphery.

A single fundus photograph provides indirect information about depth relations in the retina, which can only be inferred from differences in focus or from the presence of overlying

structures. However, fundus photography can be supplemented with stereo fundus photography, where duplicate fundus photographs are recorded with the camera moved slightly to each side so that the light path is tangential to the left and right pupil margins. The resulting images have different disparities and when studied binocularly the grader will obtain a stereoscopic view of the retina, which can be used to diagnose macular oedema. However, the evaluation of depth relations in the retina by stereopsis is subjective, and nowadays the evaluation of macular oedema should be performed by optical coherence tomography (OCT) scanning [64].

Fundus photography should cover retinal areas where relevant retinopathy changes can be detected. This can be achieved by seven photographic fields using a 30° field of view as in the US standard [65] or by two wider-field images as in the European standard [63]. Grading of retinopathy is performed by comparing the pattern of retinopathy with a set of standard images representing the different stages of the disease, and is designed so that all levels of retinopathy have the same risk of progression from one level to the next. This semiquantitative grading method considers the type, overall severity, and location of lesions in different quadrants and in relation to the fovea, but the images contain unused information, such as the number, shape, size, detailed location, and dynamics of the lesions. In order to include this information in the evaluation, initiatives have been taken to develop computer algorithms for quantitative analysis of diabetic retinopathy lesions. This work has been challenged by the lack of gold standards for lesion detection. Hence the interpretation of findings in the retina depends on image quality, and even experienced clinicians may disagree about the identification of retinal lesions [66]. The element of pattern recognition in retinopathy grading has stimulated efforts towards developing computerized grading and decision algorithms based on artificial intelligence, and the potential of this approach is under investigation [67].

The immense task of evaluating fundus photographs obtained during population screening for diabetic retinopathy has stimulated the training and certification of non-academic graders to manage this task. The grading of diabetic retinopathy should result in answers to the following two questions:

- What is the time interval to the next screening examination?
- Should the patient be referred for further diagnostic evaluation or treatment?

The time interval to the next screening examination is generally determined by rule-based decision algorithms. On the basis of the diabetes type, diabetes duration, and retinopathy grade, a standard interval is recommended so that the disease will not progress undetected to a vision-threatening stage, even in those with the fastest disease progression [68]. However, this conservative approach implies that the individuals in whom disease progression is slow will experience superfluous examinations, because the disease has not progressed by the time of the following examination. Therefore, new algorithms are being developed with the aim of individualizing the control interval and optimizing screening by reducing the number of unnecessary examinations. These algorithms consider individual risk factors in order to prolong the control interval as much as possible while ensuring that the condition does not progress to vision-threatening retinopathy [69–71]. However, individualized control intervals may be difficult to remember for both the person with diabetes and the doctors and other personnel involved in patient care. This is further complicated if optimized retinopathy screening implies that the examinations are not synchronized with

visits for metabolic regulation and screening for other late diabetes-related complications.

Screening for diabetic retinopathy is a complex challenge that involves ophthalmological, technical, and organizational elements, and should therefore be adapted to the local healthcare system in each country. The potential of such efforts has been proved in countries where screening for diabetic retinopathy has reduced the occurrence of blindness secondary to diabetic retinopathy to a negligible level [72].

Diagnosis

Diabetic retinopathy is defined and diagnosed by inspection of the ocular fundus in order to identify the typical morphological lesions that characterize the disease. Observation of the retina in red-free light may increase the contrast to improve the detection of lesions, but a detailed evaluation of the disease requires information about colour in order to distinguish red lesions from pigmentation. When diabetic retinopathy has progressed to a stage where treatment should be considered, the addition of other imaging techniques may be required.

Fluorescein angiography (Figure 43.10) is a photographic recording of retinal morphology after intravenous injection of fluorescein, where the fluorescent dye is distributed in the systemic circulation and reaches the eye. In order to detect fluorescein in the retina, an excitation filter that transmits short-wavelength light is inserted into the light path that illuminates the retina, and a barrier filter that transmits longer wavelengths is inserted in front of the photographic film. Previously, the method was used routinely for the diagnosis of diabetic retinopathy, but has to a large extent been replaced by less invasive techniques, and at present fluorescein angiography is restricted to special diagnostic cases. The method is unique for detecting leakage of fluorescein from the retinal vessels as an indication of breakdown of the blood–retina barrier [73] and capillary occlusion that appears as well-defined and uniformly black areas delimited by perfused vessels that are often leaky [43]. The method plays a particular role in the differentiation of exudative macular oedema from ischaemic macular oedema, which should be managed differently.

Figure 43.10 Fluorescein angiogram showing focal areas of capillary occlusion and leakage from bordering vessels. Microaneurysms are seen to fill with fluorescein. The hyperfluorescent area to the left represents a neovascularization.

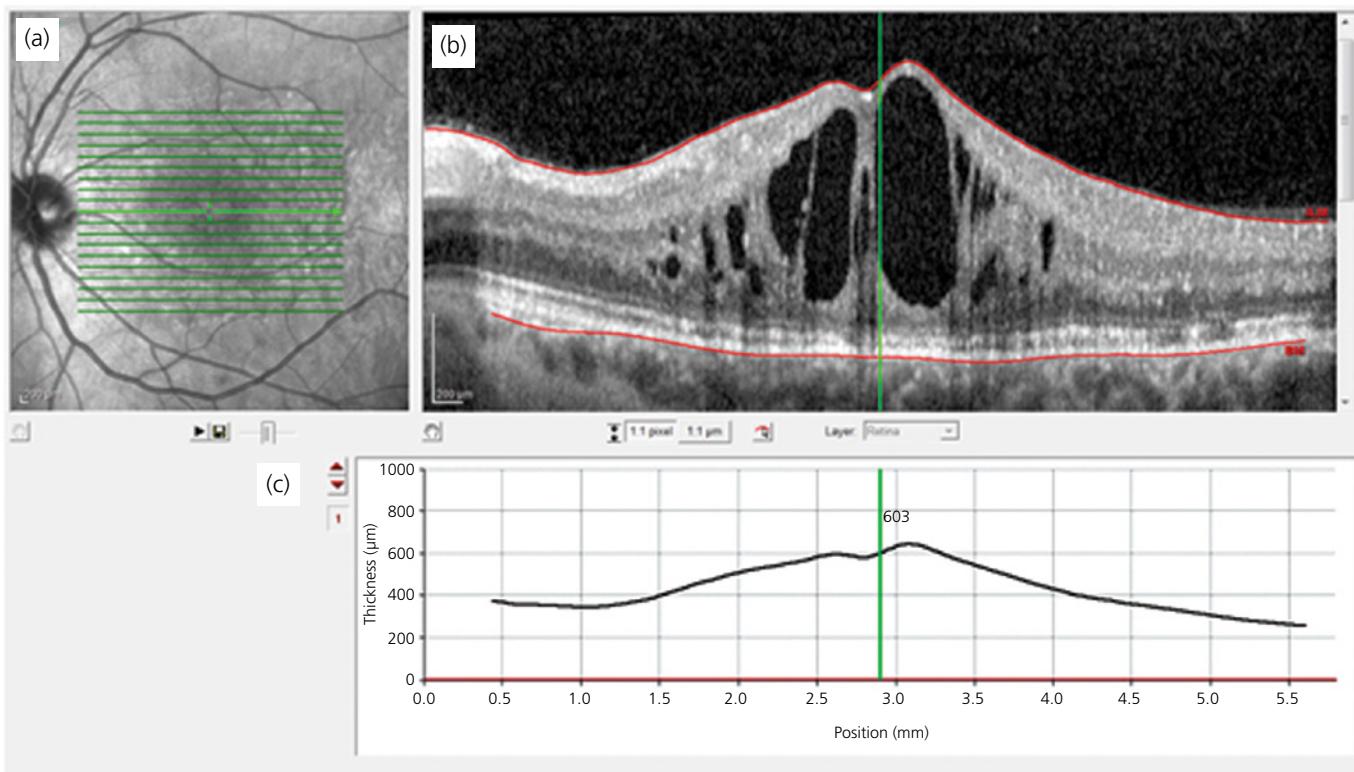

Figure 43.11 (a) Horizontal green lines represent the optical coherence tomography (OCT) scanning lines in the macular area from a person with diabetes. (b) The OCT scan through the fovea shows cystic macular oedema secondary to diabetic maculopathy. (c) The graph represents the profile of the retinal surface along the OCT scan.

OCT scanning records the latency of light pulses reflected from different retinal layers, which is translated to a measure of depth in the retina (Figure 43.11). The method can determine the depth location of individual layers in the retina with an accuracy of less than 10 µm, and is therefore suitable for detecting pathological lesions in the retina not visible by clinical inspection [74] and for quantifying retinal oedema in diabetic maculopathy [75]. This allows monitoring of the effect of treatment of retinal oedema, but the method is also suitable for differentiating diabetic macular oedema from other causes of retinal swelling, such as traction from the posterior hyaloid. At present the potential of OCT angiography for the diagnosis of diabetic retinopathy is under investigation. The technique allows the presentation of perfused vessels and therefore has potential for assessing areas of capillary occlusion [76].

Other techniques are used to study vascular changes in diabetic retinopathy, such as vessel analysis, oximetry, adaptive optics imaging, and flow measurement [77–80]. However, these techniques are research tools and do not at present have a role in daily clinical practice.

treatment are related to the destructive effects on retinal tissue. At the initiation of a treatment session, the patient will have a strong sensation of glare, which often disappears after a while when the retina adapts to the intense light exposure. During the treatment, the applications may induce a distinct feeling of pain, especially when delivered in the retinal periphery corresponding to the horizontal and the vertical meridians. However, this sensation is individual, ranging from no symptoms in some individuals to a need for retrobulbar anaesthesia in order to complete the treatment in very sensitive individuals. After the treatment, it takes a few minutes to adapt to ambient light conditions, and during the following days or weeks the patient may experience blurred vision and flashes in the visual field corresponding to the laser applications. The treatment will induce permanent shrinkage of the visual field and reduce dark adaptation, but in most cases the patient will adapt to this new situation, especially when both eyes have been treated and the brain has adapted to integrate the modified visual inputs from the two eyes.

In proliferative diabetic retinopathy, the treatment is applied outside the macular area extending to the retinal periphery, and the beneficial effect is assumed to be related to the elimination of ischaemic and hypoxic retinal tissue, with a consequent reduction in the release of the growth factors that stimulate neovascularization. The treatment typically requires 2000–3000 applications and is performed in several sessions until the intended clinical response has been obtained (Figure 43.12). The visual prognosis decreases with age and with lower visual acuity before treatment, whereas the number of laser applications necessary to halt the disease has no influence on the visual prognosis [82].

Proliferative diabetic retinopathy may lead to vitreous haemorrhage with a consequent impairment of vision. This condition can

Treatment

Retinal photocoagulation

Retinal photocoagulation was the first available treatment with a documented effect on diabetic retinopathy and still has a central role in the treatment of the disease [81]. The treatment is typically applied through a contact lens, where localized laser burns with a width of 200–500 µm are applied in a grid pattern with spacing corresponding to the width of one burn. The adverse effects of the

Figure 43.12 Fundus photograph one year after panretinal photocoagulation of the case shown in Figure 43.6. The hyperpigmented laser scars extend to the retinal periphery beyond the borders of the image.

be the presenting sign of retinopathy if the patient has not been followed regularly in a screening programme, but may also occur in individuals who have received photocoagulation in whom retinal neovascularization has not regressed. Vitreous haemorrhage leads to a sudden reduction in visual acuity and therefore the patient will be referred to an ophthalmologist. If the patient has not received photocoagulation, it is important to perform ultrasound B-scan examination to rule out rhegmatogenous retinal detachment and other conditions that might indicate surgical intervention. In simple vitreous haemorrhages spontaneous resolution should be awaited for a few weeks to allow inspection and/or treatment of the retina with photocoagulation [83]. If the haemorrhage does not resolve spontaneously, the treatment of choice is vitrectomy with surgical removal of the vitreous opacities [84]. The clearing of the vitreous body may at the same time restore a clear view to the retina to allow retinal photocoagulation. The visual prognosis depends on the damage to the retina induced by the retinopathy hiding behind the opacities. Interestingly, vitrectomy has also been suggested for the treatment of diabetic maculopathy, since the replacement of the vitreous body with saline can improve diffusion and thereby facilitate the exchange of oxygen and other metabolites to the retina [70]. Retinal photocoagulation and vitrectomy will also often lead to regression of new vessels in the iris and the anterior chamber angle of the eye, but if this regression is insufficient the patient may need treatment for neovascular glaucoma.

In diabetic maculopathy, retinal photocoagulation is considered as first choice if exudates or retinal oedema are located outside the foveal area without threatening central vision [85]. The treatment is assumed to facilitate diffusion of oxygen and other nutrients from the choroid, and the elimination of metabolically active retinal tissue induces a contraction of the pathologically dilated retinal vessels [86]. It is a general misconception that focal treatment of microaneurysms is effective. Owing to the fast turnover, the lesions disappear spontaneously whether treated or not [23]. However, the treatment may in general reduce the permeability of the retinal vessels and result in regression of hard exudates that have precipitated in circles around the leaking point [87]. The treatment is applied corresponding to areas with retinal oedema, but sparing the papillomacular bundle and a zone within 500 µm from the fovea, which

can often be achieved by a few hundred applications. People with reduced visual acuity may have extrafoveal fixation, and if photocoagulation is considered, care should be taken not to involve these areas. In ischaemic maculopathy perifoveal capillaries may be occluded so that the foveal avascular zone is enlarged. In these cases, retinal photocoagulation may reduce central vision and is therefore not recommended.

Intravitreal angiostatic treatment

Several new approaches for intravitreal pharmacotherapy have been introduced for the treatment of diabetic retinopathy and retinal vascular diseases in general.

The introduction of intravitreal treatment with anti-VEGF medication has improved the visual prognosis of diabetic retinopathy significantly [88]. The effect of the compound is dual, with a tightening effect on the blood-retina barrier that is beneficial for diabetic macular oedema [89–91] and an angiostatic effect that can reduce neovascularization in proliferative diabetic retinopathy [92]. The advantage of the treatment is the lack of destruction of retinal tissue, but injections should often be repeated at an interval of months, with a consequent cumulation of the risk of adverse effects such as infection, glaucoma, cataract, and retinal detachment. These prospects of life-long repeated intravitreal injections are less attractive in younger people. The treatment comprises a loading phase with three injections separated by one month, followed by regular controls where the treatment can be repeated depending on the clinical response. The treatment is the first choice in those with diabetic maculopathy where the retinal oedema is mainly located in the foveal area, centrally from the zone that is accessible for retinal photocoagulation (Figure 43.13).

Diabetic macular oedema not responding to anti-VEGF treatment may in some cases benefit from intra-vitreal injection with steroid. This treatment may reduce diabetic macular oedema, which supports the hypothesis that inflammation is involved in the disease process. Because of its anti-inflammatory effect, intravitreal steroid injection is also used to treat cystoid macular oedema after cataract surgery. However, the treatment may be accompanied by adverse effects such as glaucoma and cataract, which should be considered in the treatment strategy [88, 93].

The effects of intra-vitreal pharmacotherapy with anti-VEGF compounds and steroid are often transient and should be administered repeatedly, in some cases over years. However, the transient effect of the treatment may provide a time window for the initiation of other therapies with a more permanent effect. Thus, preoperative injection of anti-VEGF compound may reduce the size of retinal neovascularizations, which in turn reduces the risk of haemorrhage during vitrectomy and panretinal photocoagulation [94].

Treatment guidelines

The advent of intra-vitreally administered compounds for treatment of diabetic retinopathy has initiated several clinical trials and implies that the recommendations for treatment are under continuous revision. However, the generally accepted algorithm for treating diabetic retinopathy is as follows [95].

Proliferative diabetic retinopathy:

- Panretinal photocoagulation, optionally preceded by intra-vitreal anti-VEGF compound.
- Vitrectomy if photocoagulation is insufficient or is instituted too late so that unresolving vitreous haemorrhage or retinal traction has developed. The treatment can be preceded by intra-vitreal anti-VEGF compound.

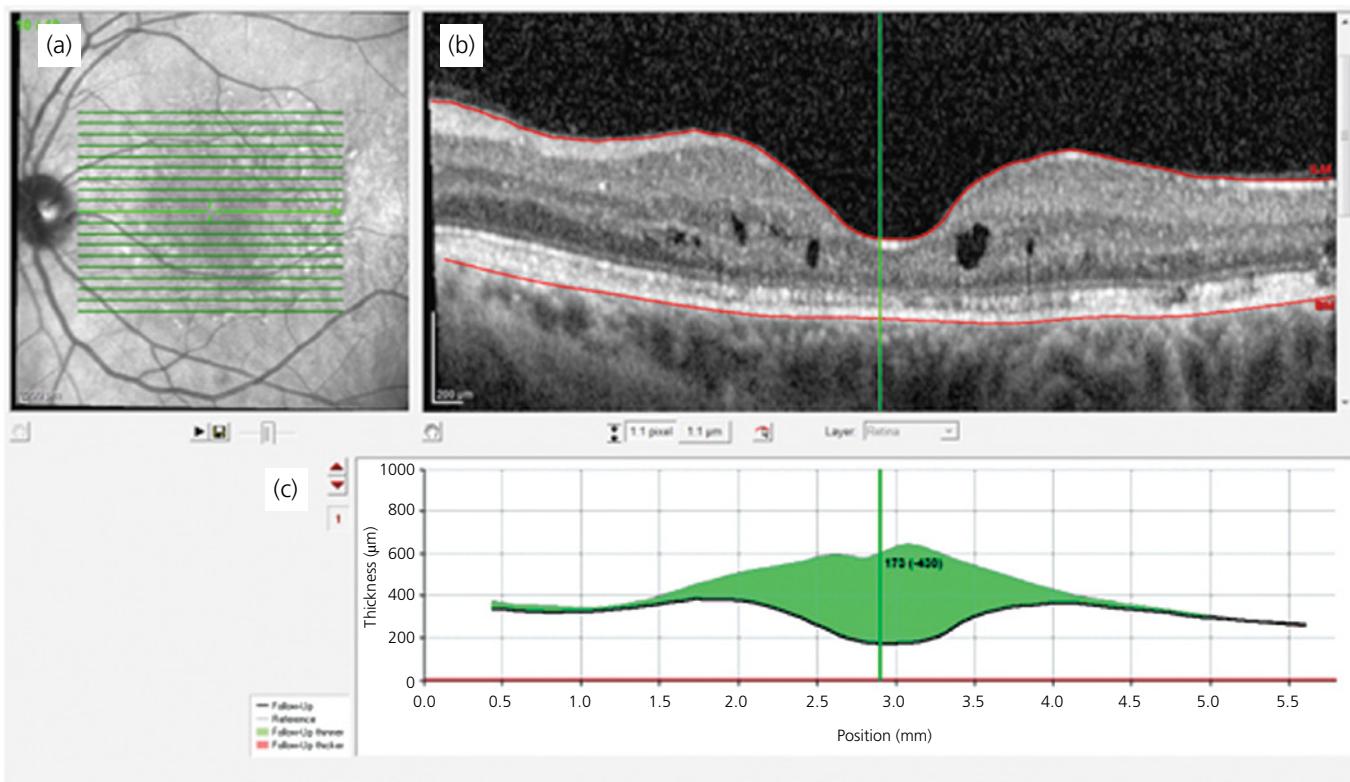

Figure 43.13 (a) Horizontal green lines represent the optical coherence tomography (OCT) scanning lines in the patient shown in Figure 43.11 and recorded three months after intravitreal injections of vascular endothelial growth factor (VEGF) inhibitor. (b) The OCT scan through the fovea shows that the retinal swelling has been reduced to a few cysts and the fovea has been restituted. (c) The graph represents the retinal profile along the OCT scan before and after treatment. The green area represents the reduction in retinal thickness along the scan.

Diabetic macular oedema:

- With central involvement or visual acuity lower than 0.67 assumed to be secondary to diabetic macular oedema, intra-vitreal anti-VEGF compound.
- Without central involvement, retinal photocoagulation, optionally supplemented with intra-vitreal anti-VEGF compound.
- Lack of effect of anti-VEGF compound and during pregnancy: intra-vitreal steroid.

The results of several clinical trials indicate that repeated injections of anti-VEGF compounds may in some cases be an alternative to photocoagulation for the treatment of proliferative diabetic retinopathy, and that vitrectomy may in some cases be beneficial for the treatment of diabetic macular oedema. However, the clinical implications of these trials are disputed, and the results have not yet been incorporated into generally accepted guidelines.

retinopathy, and systematic screening programmes for diabetic retinopathy were initiated worldwide. In the 2000s, intravitreal angiostatic treatment was introduced, based on the discovery of VEGF as a key compound involved in increasing vascular permeability and stimulating neovascularization.

However, there is still a lack of understanding of how the diabetic metabolic dysregulation triggers processes in the retina to initiate and accelerate the development of diabetic retinopathy. Vascular changes resembling early diabetic retinopathy have been induced in small rodents, and more advanced diabetic retinopathy-like changes have been generated in diabetic dogs, pigs, and monkeys. However, the full spectrum of lesions observed in human diabetic retinopathy has not been reproduced in these models, which is a major barrier for studying the pathophysiology of the disease. The lack of clear direction for the investigations has opened for numerous working hypotheses and studies of diabetic retinopathy viewed from different perspectives, depending on the interests and opinions of individual researchers rather than firm knowledge. Being a systemic disease, diabetes affects all elements of the eye, and almost any working hypothesis suggesting a change in a parameter in the eyes of people with diabetes can be confirmed. This implies that the research field of diabetic retinopathy is very open and productive, but leaves no certain cues about which directions of research will contribute to the next breakthroughs in the understanding and management of the disease. Therefore, the art of research in diabetic retinopathy will be to make the right choices for the future experimental strategy to follow.

Investigation of diabetic retinopathy

During the past 50 years, immense efforts have been invested in understanding the pathophysiology of diabetic retinopathy, and several developments have significantly shifted the management of the disease during this period. In the 1960s, the beneficial effect of retinal photocoagulation was discovered by serendipity and once fluorescein angiography had been accepted by the ophthalmological community, this diagnostic method added significantly to the diagnosis and understanding of the disease. In the 1980s, vitrectomy was refined for the treatment of severe proliferative diabetic

Diabetic Nephropathy

Peter Rossing^{1,2} and Allan Flyvbjerg^{1,2}

¹Steno Diabetes Center Copenhagen (SDCC), Copenhagen, Denmark

²Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark

Key points

- Classically, diabetic nephropathy is characterized by gradually increasing urine albumin excretion over many years, accompanied by slowing rising blood pressure and declining glomerular filtration rate (GFR).
- A small number of individuals with type 1 diabetes and about 30% of those with type 2 diabetes who develop chronic kidney disease have a progressive fall in GFR with no or minimal albuminuria. This may be a different form of kidney disease.
- Individuals with nephropathy are at greatly increased risk of other microvascular and macrovascular complications of diabetes.
- The risk of cardiovascular disease increases as albuminuria increases and independently as GFR decreases.
- Approximately 30–50% of white European individuals with diabetes will develop moderately elevated albuminuria; the prevalence is higher in other ethnicities.
- One-third of people with diabetes will progress to severely increased albuminuria and be at high risk of end-stage kidney disease (ESKD).
- Factors most closely associated with progression of nephropathy are sub-optimal glucose and blood pressure management and baseline albuminuria.
- Screening for diabetic kidney disease should be done annually, by measuring the urine albumin-to-creatinine ratio and estimated GFR (eGFR).
- Optimal blood glucose and blood pressure management is key to the prevention of nephropathy.
- If moderately elevated albuminuria or greater is present, an inhibitor of the renin–angiotensin system should be commenced and titrated up to the maximum tolerated dose.
- Maintaining blood pressure at 120–130/75 mmHg, with the addition of other antihypertensive agents as necessary, will reduce the annual rate of decline of GFR from 10 to 12 to 3–5 ml/min/1.73 m².
- Reducing dietary protein intake to 0.8 g/kg body weight/d may slow the deterioration in kidney function.
- Aggressive management of other cardiovascular risk factors and prescription of aspirin reduce the incidence of cardiovascular events and of progression to nephropathy by ~60%.
- Sodium–glucose cotransporter 2 inhibitors slow the progression of kidney disease and reduce cardiovascular events, hospitalization for heart failure, and mortality in people with type 2 diabetes and nephropathy independent of changes in glucose.
- Kidney failure due to diabetes is the commonest single cause of entry to kidney replacement programmes worldwide; the majority of individuals have type 2 diabetes plus major comorbidities.
- People with ESKD and significant comorbidities should be offered dialysis. Fitter individuals benefit from kidney or kidney–pancreas transplantation, but need full cardiovascular assessment and, if necessary, treatment before transplantation.

Worldwide, chronic kidney disease (CKD) remains an important, common complication of diabetes. End-stage kidney disease (ESKD) is devastating to the individual and of enormous financial and social consequences to society. The proportion of individuals commencing kidney replacement therapy in 2018 because of diabetes varied enormously, ranging from 13% in China to 66% in Singapore [1]. In the USA, incidence rates of ESKD in people with diabetes increased by 50% between 1996 and 2006, but have stabilized since then, and in 2018 the rate was ~180 per million per year [1]. The incidence of ESKD in people with type 1 diabetes has remained stable or declined over the last decade, but increased in those with type 2 diabetes [2–5]. Most people with diabetes on kidney replacement therapy have type 2 diabetes.

Definitions

Diabetic nephropathy refers to the chronic condition developing over many years, characterized by gradually increasing urinary albumin excretion (UAE), blood pressure, and cardiovascular risk, falling glomerular filtration rate (GFR) and eventual ESKD. The clinical syndrome is associated with characteristic histopathological features [6]. A small proportion of individuals with type 1 diabetes [7,8], and ~50% of those with type 2 diabetes [9] with progressively declining GFR, have no or minimal albuminuria. We will refer to this clinical phenotype as non-classical diabetic nephropathy. ‘Diabetic kidney disease’ refers to both classical and

non-classical diabetic nephropathy. CKD refers to kidney disease of any aetiology, including non-diabetes-related causes.

Screening for and classification of chronic kidney disease

Guidelines suggest systematic screening as part of the 'annual clinical review'. Albuminuria and GFR should be measured, allowing identification of proteinuric and non-proteinuric disease. Screening should be undertaken when the person is free from acute illness and has stable glucose levels, because many acute illnesses and acute hyperglycaemia increase albuminuria temporarily.

As albuminuria may increase in the upright posture and with exercise, measurements are best made in an early-morning urine sample; however, a spot urine sample is acceptable if there is no alternative. Both urine albumin and creatinine are measured and the albumin-to-creatinine ratio (ACR) is calculated. Because of the high day-to-day variation in UAE, if the first sample is positive further samples should be obtained, ideally within 1–3 months. At least two out of three measurements should be abnormal before a diagnosis of albuminuria is made.

Serum creatinine should be measured annually, using an accredited assay standardized to the recommended isotope dilution mass spectrometry reference method. Most laboratories calculate the estimated glomerular filtration rate (eGFR) with the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation using serum creatinine, age, sex, and ethnicity, which estimates measured GFR more accurately than previous equations, particularly at higher levels of GFR [10]. The CKD-EPI equation also

categorizes risk of mortality and ESKD more accurately than the previous Modification of Diet in Renal Disease (MDRD) equation in a wide range of populations, including those with diabetes [11,12].

The 2012 Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guideline for the Evaluation and Management of CKD advocates that final screening status should indicate both the GFR and UAE status, as in Tables 44.1 and 44.2, along with the cause of the kidney disease [13,14]. The information can then be used as a measure of kidney prognosis (Figure 44.1).

Alternatively, estimations using cystatin C alone or with serum creatinine have been suggested to be slightly more precise [15]. There is no agreement that cystatin C-based estimates of GFR are superior to creatinine-based estimates [16,17]. KDIGO guidelines recommend calculating cystatin-based eGFR in adults whose creatinine-based eGFR is 45–59 ml/min/1.73 m² without other markers of kidney disease [13]. However, we do not know that this approach improves the identification of individuals with progressive CKD compared with frequent measures of creatinine-based eGFR.

Natural history and histopathology

Classical diabetic nephropathy

Gradually increasing UAE over many years is the hallmark of classical diabetic nephropathy (Figure 44.2). At presentation of type 1 diabetes, increased albuminuria may be present. As glucose levels return to normal, so does the albuminuria. In those who will never develop nephropathy UAE remains normal, except during periods of particularly marked hyperglycaemia or during acute intercurrent illness, when a transient increase in UAE may occur. In those who will develop diabetic nephropathy UAE increases gradually, with moderately elevated albuminuria usually appearing within 5–15 years of diabetes. Untreated, the mean increase in UAE is 20% per year. In people with type 1 diabetes, ~1.5–2.5% per annum develop moderately elevated albuminuria [18,19], and 50% develop persistent moderately elevated albuminuria at some point [20,21]. Approximately one-third with moderately elevated albuminuria progress gradually over a further 5–15 years to severely increased albuminuria, one-third will remain at moderately elevated albuminuria, and one-third will revert to normoalbuminuria [22,23]. In the short term, reversion from moderately elevated albuminuria to normoalbuminuria appears common, one study reporting regression in 58% of participants over six years [24]. Short duration of

Table 44.1 Glomerular filtration rate (GFR) categories in chronic kidney disease.

GFR category	GFR (ml/min/1.73 m ²)	Description
G1	≥90	Normal or high
G2	60–89	Mildly decreased ^a
G3a	45–59	Mildly to moderately decreased
G3b	30–44	Moderately to severely decreased
G4	15–29	Severely decreased
G5	<15	Kidney failure

^aRelative to young adult level.

Table 44.2 Albuminuria categories in chronic kidney disease.

Category	ACR (approximate equivalent)			Description	Previous terminology
	AER (mg/24 h)	mg/mmol	mg/g		
A1	<30	<3	<30	Normal to mildly increased	Normal
A2	30–300	3–30	30–300	Moderately increased ^a	Microalbuminuria
A3	>300	>30	>300	Severely increased ^b	Proteinuria

ACR, urine albumin to creatinine ratio; AER, albumin excretion rate.

^aRelative to young adult level.

^bIncluding nephrotic syndrome.

Prognosis of CKD by GFR and albuminuria categories: KDIGO 2012			Persistent albuminuria categories description and range		
	A1	A2	A3		
	Normal to mildly increased	Moderately increased	Severely increased		
	<30 mg/g <3 mg/mmol	30–300 mg/g 3–30 mg/mmol	>300 mg/g >30 mg/mmol		
G1 Normal or high >90

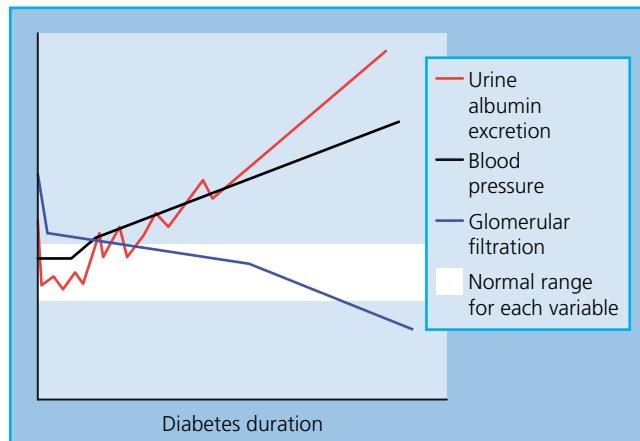

Figure 44.2 Natural history of classical diabetic nephropathy. The white bar represents the normal range for each variable.

moderately elevated albuminuria, and lower glycated haemoglobin (HbA_{1c}), systolic blood pressure, total cholesterol, and triglycerides, were all independently associated with regression. In other studies regression was rarely spontaneous but usually treatment induced [25]. The development of ESKD without albuminuria was rare in a large population-based study in people with type 1 diabetes [26]. The eventual outcome in those who regress, or who do not initially progress, remains unclear. However, they probably remain at increased risk of nephropathy compared with individuals who have never had elevated albuminuria.

Almost all people with type 1 diabetes and severely increased albuminuria eventually progress to ESKD. The use of eGFR rather than serum creatinine has unmasked a decline in eGFR within the normal range in individuals with progressive elevated albuminuria, but eGFR $<60 \text{ ml/min}/1.73 \text{ m}^2$ is rare at this stage. However, in

severely increased albuminuria, the mean annual rate of decline of eGFR is $10\text{--}12 \text{ ml/min}/1.73 \text{ m}^2$ if untreated [27].

One group has suggested that eGFR falls before the onset of albuminuria in type 1 diabetes [8]. Using serial estimates of eGFR derived from serum creatinine and cystatin C, they reported a median annual decline in eGFR of 1.5% per year in individuals with normoalbuminuria and 2.2% in those with moderately increased albuminuria. They argued that albuminuria is therefore not a good guide to diabetic nephropathy [28]. Alternative explanations are suppression of albuminuria by renin–angiotensin system (RAS) inhibitors or that kidney disease with and without albuminuria are different pathological processes, as discussed later. More recently it was highlighted that a subset of individuals with type 1 diabetes have a very fast, almost malignant decline in kidney function and should be identified with novel biomarkers [29].

The natural history of diabetic nephropathy is generally similar in type 2 diabetes. Moderately or severely increased albuminuria may be present at diagnosis and may persist in individuals who have had undiagnosed diabetes for some years. eGFR is usually $>60 \text{ ml/min}/1.73 \text{ m}^2$ at the onset of moderately elevated albuminuria, only declining to CKD stage 3 or more when severely increased albuminuria develops [30, 31].

The characteristic structural changes of classical diabetic nephropathy include basement membrane thickening, progressive mesangial expansion, alteration and loss of podocytes, and tubulo-interstitial fibrosis, eventually leading to glomerulosclerosis [6].

Non-classical diabetic kidney disease

Some 7–22% of individuals with type 1 diabetes [7, 32] and 50% of those with type 2 diabetes [9, 33, 34] who develop progressive CKD do not have preceding albuminuria. Identification of people with non-diabetic kidney changes on the basis of clinical features, including the absence of diabetic retinopathy [35], is difficult. Individuals with type 2 diabetes and CKD stage 3 or more plus moderately or severely increased albuminuria are very likely to have histological features of

diabetic glomerulosclerosis, whereas those with normoalbuminuria are much more likely to have arteriosclerosis [36]. The underlying disease process in non-classical diabetic CKD probably reflects a combination of ageing, hypertension, and atherosclerotic vascular disease in addition to diabetes. Obesity, with ectopic lipid accumulation in the kidney, may also be important [37].

The rate of progression of CKD in the absence of significant albuminuria is slower than in those with albuminuria in both type 1 diabetes [8] and type 2 diabetes [38, 39]. Low eGFR and albuminuria synergistically increase the risk of ESKD.

Changing epidemiology of kidney disease in diabetes

Type 1 diabetes

Recent data suggest that per individual with type 1 diabetes, moderately and severely increased albuminuria and ESKD may be less common than previously, at least in some countries, but the number ending with ESKD is stable or increasing as the population at risk is growing with the prevalence of diabetes going up [40, 41]. Older studies suggested a lifetime risk of developing moderately elevated albuminuria of ~50%, appearing generally after 10–20 years' duration of type 1 diabetes. In the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) cohort, the cumulative incidence of persistent moderately elevated albuminuria (microalbuminuria) was 38% after 30 years in the conventional group and 25% in the intensively treated group [42]. The incidence appeared to plateau in both groups after 25–30 years. Moderately increased albuminuria developed most frequently in the second decade of diabetes in the conventional group, the incidence being blunted particularly during this time in the intensive group.

Older data suggest that the cumulative incidence of severely increased albuminuria is ~40% after 40 years' duration of type 1 diabetes. In the DCCT, after 30 years' duration, 25% of the conventional group and 9% of the intensively managed group had severely increased albuminuria [43]. Several Scandinavian studies also reported low rates of ~13% after 20–25 years' duration [44, 45]. However, in the Pittsburgh cohort, the incidence has remained relatively steady at 32% after 25 years [46].

Several European countries report a current incidence of ESKD in type 1 diabetes of 2.5–7.8% after 30 years of diabetes [47, 48]. The Pittsburgh Epidemiology of Diabetes Complications Study [49] and the WESDR cohort [50] suggested a declining incidence in those diagnosed after 1970. Survival with ESKD may also have improved.

Hence the incidence of all stages of diabetic nephropathy in type 1 diabetes may be declining, at least in some centres. However, in the UK, in the Golden Years cohort of individuals with duration of type 1 diabetes >50 years, 36% had moderately or severely increased albuminuria [51]. In a similar cohort in the USA, the prevalence of albuminuria, defined using a higher cut-off than in the UK cohort, was 13% [52]. Thus, the observed decline in incidence of nephropathy may be a delay rather than true prevention.

Type 2 diabetes

A widely varying prevalence of moderately elevated albuminuria, from 10% to 42%, has been reported. Longitudinal studies suggest that the rate of progression from normo- to moderately elevated

albuminuria grade is 3–4% per annum. One older study demonstrated equivalent cumulative incidence of severely increased albuminuria in type 1 diabetes and type 2 diabetes after 25 years' duration of diabetes [53]. In the Pima, the incidence of ESKD has declined since 1990 [54]. National US survey data reported a prevalence of CKD (eGFR <60 ml/min/1.73 m² or UAE >30 mg/g) of 44% in the overall type 2 diabetes population and 61% in those aged ≥65 years [55]. In the UK, using a similar definition, the prevalence was 42% [56]. The increasing number of individuals with diabetes commencing kidney replacement therapy in many countries is due mainly to type 2 diabetes [1] and is accounted for in part by an increased acceptance of older, sicker individuals for treatment and improved cardiovascular survival.

Risk factors and markers for chronic kidney disease in diabetes

Many factors are associated with CKD in diabetes (Figure 44.3). Some are associated with both classical and non-classical kidney disease, and some with one but not the other phenotype [57]. Associations may be with both albuminuria and eGFR or with one measurement only. Some factors influence initial development of kidney disease and others progression of disease. Duration of diabetes is one of the strongest risk factors for diabetic nephropathy, particularly in type 1 diabetes.

Hyperglycaemia

Recent studies reinforce the importance of hyperglycaemia in the development and progression of diabetic nephropathy. An unselected Swedish cohort of individuals with type 1 diabetes was followed from diagnosis for 20–24 years [58]. No individuals with a long-term weighted mean HbA_{1c} <60 mmol/mol (7.6%) developed moderately elevated albuminuria. In contrast, 23% of those with mean HbA_{1c} >80 mmol/mol (9.5%) did so. There is a strong, graded positive association between HbA_{1c} and incident eGFR <60 ml/min/1.73 m², independent of other risk factors and present even in the absence of albuminuria [59]. Greater variability in HbA_{1c} is associated independently with albuminuria and diabetic nephropathy [60–62].

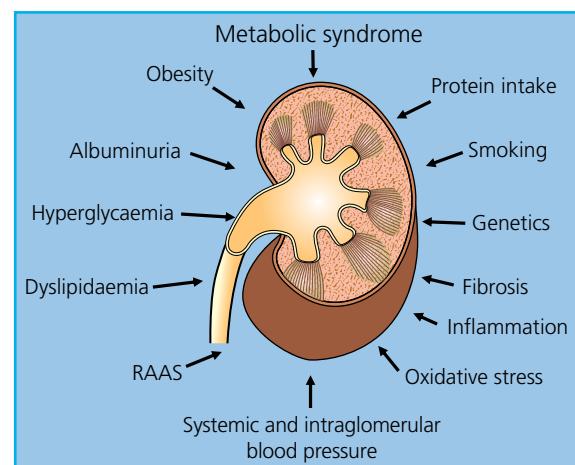

Figure 44.3 Putative promoters of progression of diabetic nephropathy. RAAS, renin-angiotensin-aldosterone system.

Blood pressure

Blood pressure is critical to the development and progression of diabetic kidney disease. The excess prevalence of hypertension in type 1 diabetes is confined to those with nephropathy [63]. In young people with moderately elevated albuminuria, changes in blood pressure are subtle, perhaps manifesting only as reduced nocturnal diastolic blood pressure dipping [64]. Once severely increased albuminuria is present, frank hypertension is present in 80% of individuals, and is almost universal in ESKD. Variability in systolic and diastolic blood pressure independently predicts the development of albuminuria in type 1 diabetes [60, 65].

In type 2 diabetes, the link between hypertension and kidney disease is less striking, because hypertension is so common. Almost all those with moderately elevated albuminuria or worse have hypertension. In people with diabetic nephropathy, variability in systolic blood pressure is independently associated with the development of ESKD [66].

Other metabolic factors

Blood lipids, including triglycerides [51, 67], contribute to the development and progression of nephropathy, although the lipid phenotype alters as nephropathy progresses [68–70]. Insulin resistance increases the risk of albuminuria and a rapid decline in eGFR in type 1 diabetes [71] and of albuminuria in type 2 diabetes [72]. Uric acid predicts the development of severely increased albuminuria [73] and decline in eGFR as well as cardiovascular events [74]. Probably this association is not causal, as reduction in uric acid does not slow the decline in eGFR [75]. Individuals with type 1 diabetes or type 2 diabetes and nephropathy are more likely to have the metabolic syndrome [76–78].

Hyperfiltration

Hyperfiltration is common at the onset of type 1 diabetes and is also present in some individuals at diagnosis of type 2 diabetes. In the majority eGFR returns to normal as glucose levels return to normal, but in some individuals hyperfiltration persists. The hypothesis that individuals with persistent hyperfiltration are most at risk of subsequent diabetic nephropathy remains controversial [79–81]. Sodium–glucose cotransporter 2 (SGLT-2) inhibitors were introduced to lower glucose in type 2 diabetes, but have been demonstrated to slow the progression of kidney disease (see later). A marked effect on hyperfiltration in type 1 diabetes with SGLT-2 inhibitors was suggested to reflect lowering of intraglomerular hypertension and to support lowering of hyperfiltration as an important kidney-protective measure [82]. On the other hand, the results in type 2 diabetes were less clear [83].

Genetic factors

Genetic factors influence susceptibility to diabetic nephropathy [84, 85]. If one sibling with type 1 diabetes has nephropathy, the risk to a second sibling is increased four- to eightfold compared with siblings where neither has nephropathy [86]. The clustering of conventional cardiovascular risk factors and CVD in people with diabetic nephropathy also occurs in their parents [87, 88]. This suggests that the genetic susceptibility to nephropathy also influences the associated CVD. Multiple genes are involved, either protective or deleterious. Different loci may influence albuminuria and GFR separately [89]. Epigenetic modification may also be important [90].

Ethnicity

Albuminuria and CKD stages 4 and 5 are more common in UK Afro-Caribbean and South Asian individuals than in white European people [91, 92]. The prevalence of early CKD (defined as moderately elevated albuminuria or greater and $eGFR < 60 \text{ ml/min}/1.73 \text{ m}^2$) is also higher in Latino and African American individuals than in white people [93]. Albuminuria and CKD are also more common in Pima Indians [94] and in Māoris and Pacific Islanders [95, 96] than in white Europeans. Reasons for this varying prevalence may include differing genetic influences and altered response, or poorer access, to treatments.

Type 2 diabetes developing in young people

Individuals who develop type 2 diabetes at a young age have a high prevalence of hypertension and moderately elevated albuminuria [97]. ESKD and death are particularly common in young people from ethnic minorities [98–100]. However, in some of these populations there is a high prevalence of non-diabetic kidney disease [101].

Albuminuria and estimated glomerular filtration rate

Baseline albuminuria and eGFR independently influence the development and rate of progression of CKD [102, 103]. Baseline albuminuria strongly predicts ESKD [104]. Higher levels of normoalbuminuria [105] and lower eGFR [106] predict a faster decline in eGFR. Conversely, a short-term reduction in albuminuria with intervention reduces the progression of kidney and cardiovascular complications [107, 108].

Other risk factors

Other risk factors for nephropathy include smoking predicting the development of albuminuria [103], pre-eclampsia [109], inflammatory markers [110, 111], cytokines and growth factors [112], periodontitis [113], and serum bilirubin levels [114, 115]. Obstructive sleep apnoea [116] and non-alcoholic fatty liver disease are both independently associated with diabetic nephropathy [117, 118]. Circulating levels of tumour necrosis factor- α receptor 1 are independently associated with the cumulative risk of ESKD in type 1 and type 2 diabetes [119–121].

Association of diabetic kidney disease with cardiovascular disease

The prognosis for people with diabetes and CKD is much poorer than for those without CKD. Both albuminuria and $eGFR < 60 \text{ ml/min}/1.73 \text{ m}^2$ (Figure 44.4) contribute independently and synergistically to the increased all-cause and cardiovascular risk [39, 123–126].

Type 1 diabetes

In type 1 diabetes, the relative risk of premature mortality is 2–3-fold higher in moderately elevated albuminuria, 9-fold in severely increased albuminuria, and 18-fold in ESKD compared with people without diabetes [127]. Individuals with type 1 diabetes and normoalbuminuria do not have a higher risk of premature death [127, 128]. CVD is 1.2-fold more common in people with moderately increased albuminuria [129] and 10-fold higher in those with severely increased albuminuria compared with those with normoalbuminuria [130]. The cumulative incidence of CVD by the age of 40 years is 43% in people with type 1 diabetes

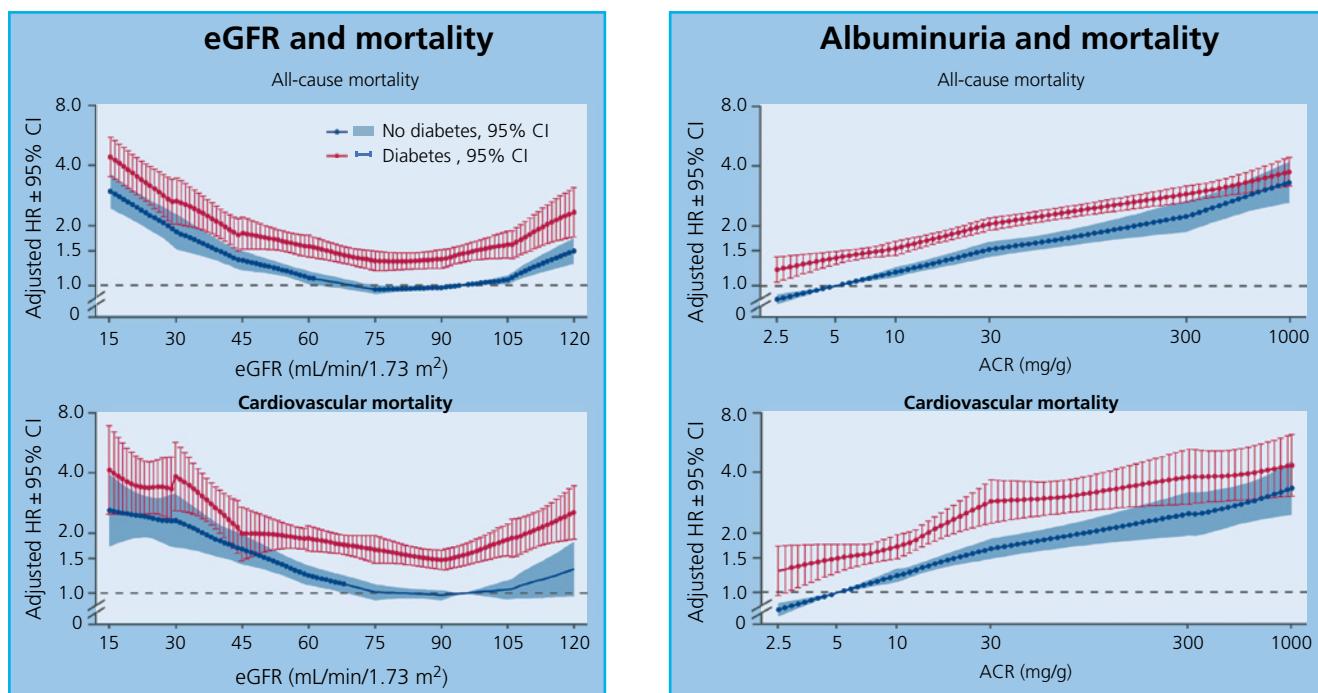

Figure 44.4 Declining estimated glomerular filtration rate (eGFR) and increasing albuminuria are associated with mortality in individuals with and without diabetes. ACR, albumin-to-creatinine ratio; CI, confidence interval; HR, hazard ratio. Source: Reproduced from Fox et al. 2012 [122] by permission of Elsevier.

and severely increased albuminuria, compared with 7% in individuals with normoalbuminuria, with a 10-fold risk of coronary heart disease and stroke. In ESKD, the risk of CVD is even higher. Median survival on kidney replacement therapy is 3.84 years [131].

Type 2 diabetes

In type 2 diabetes, CVD risk is increased 2–4-fold with moderately increased albuminuria [118,132] and 9-fold in severely increased albuminuria [133]. Once serum creatinine is outside the normal range, cardiovascular risk increases exponentially [134]. Median survival from initiation of kidney replacement therapy is 2.16 years [131].

Microvascular complications

People with diabetic nephropathy invariably also have other microvascular complications. Significant retinopathy is almost always present in people with type 1 diabetes and moderately elevated albuminuria or more. Progression of retinopathy and development of nephropathy each increase the risk for the other, supporting the notion of a common aetiology [135]. In people with type 2 diabetes, the relationship is less clear-cut [136]. Those with classical nephropathy and progressively increasing albuminuria usually have significant retinopathy, and indeed moderately elevated albuminuria predicts the development and progression of retinopathy in type 2 diabetes [137,138]. In those with non-classical disease, retinopathy may be absent.

Peripheral neuropathy is also more common in diabetic nephropathy, associated with both albuminuria and declining eGFR [139]. Autonomic neuropathy, reflected in loss of nocturnal blood pressure dipping, occurs frequently [140,141] and predicts kidney function decline [142].

Investigation of kidney disease in diabetes

Excluding other treatable causes of kidney disease

It is uncommon to find a specific treatable cause of CKD if the natural history is classical. However, if there is doubt, ultrasound of the kidney tract, measurement of autoantibodies and immunoglobulins, and kidney biopsy may help.

Monitoring kidney disease

Once UAE is abnormal, the ACR should be measured every 3 months and eGFR 3–6 monthly, depending on the stage of CKD. There is a linear relationship with time and eGFR, which is useful in assessing changes in response to therapy and in predicting when an individual will reach ESKD.

Prevention and management of diabetic kidney disease

Prevention of kidney disease is crucial. Although much can be done to slow progression, it may not be possible to avoid ESKD. The risk of developing diabetic nephropathy is particularly reduced by optimizing blood glucose and blood pressure management. A guideline on management of diabetes in CKD from KDIGO emphasizes management of cardiorenal risk factors that include lifestyle factors (diet, exercise, and smoking cessation), glucose, blood pressure, and lipids, including blockade of the renin-angiotensin-aldosterone system and in type 2 diabetes SGLT-2 inhibition (Figure 44.5) [143].

Glucose management

Glucose management in type 1 diabetes

Among the participants in the DCCT who initially had normoalbuminuria, the relative risk reduction for development of moderately elevated albuminuria was 39% and for grade A3 54% in those allocated to the intensively treated group compared with those in the conventionally managed group over the 6.5-year study [144]. Mean achieved HbA_{1c} was 52 mmol/mol (7.0%) and 76 mmol/mol (9.1%), respectively. There is no HbA_{1c} threshold below which risk is not reduced [145].

In the open follow-up of the DCCT cohort, HbA_{1c} in the previously intensively and conventionally managed groups became similar, ~64 mmol/mol (8.0%). Despite this, the incidence of moderately and severely increased albuminuria grades [146], eGFR <60 ml/min/1.73 m², and ESKD [147] was significantly reduced in those who had previously received intensive management, as summarized in Table 44.3. These results are supported by an observational study of individuals with type 1 diabetes and CKD stages 1–3 with severely increased albuminuria at baseline [148]. The cumulative risk of ESKD after 15 years was significantly lower in those whose HbA_{1c} improved compared with those whose HbA_{1c} remained stable or deteriorated. Hence improving glucose management significantly reduces the risk of development and progression of all stages of diabetic nephropathy in type 1 diabetes. The beneficial effects extend far beyond the actual period of optimal glucose management, a phenomenon termed ‘metabolic memory’. In highly selected individuals undergoing serial kidney biopsies after successful pancreas transplantation, kidney structural changes regressed after 10 but not 5 years [149]. Thus, prolonged periods of ‘normoglycaemia’ are necessary to reverse kidney structural changes. It has been suggested that not only mean glycaemic level as reflected by HbA_{1c} but also time in target glycaemic range is important for the development of renal complications [150]. In a small study insulin pump therapy was associated with less variability

Table 44.3 Kidney benefits of intensive insulin therapy demonstrated by the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Cohort.

Variable	Duration of observation (years)	Conventional insulin therapy	Intensive insulin therapy
Moderately elevated albuminuria	8	15.8%	6.8%
Severely increased albuminuria	8	9.4%	1.4%
eGFR <60 ml/min/1.73 m ²	22	46 (n)	24 (n)
ESKD	22	16 (n)	8 (n)

eGFR, estimated glomerular filtration rate; ESKD, end-stage kidney disease; n, number. Source: Data from Writing Team for the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Research Group 2003 [146], de Boer et al. 2011 [147].

compared to multiple daily insulin injections, and the reduced variability and improved time in range contributed to a decline in albuminuria in type 1 diabetes with increased albuminuria, beyond any change in HbA_{1c} [151].

Glucose management in type 2 diabetes

In the UK Prospective Diabetes Study (UKPDS), although the mean achieved HbA_{1c} in the intensively managed group was 53 mmol/mol (7.0%) compared with 63 mmol/mol (7.9%) in the less strictly managed group, there was a reduction in the relative risk of developing moderately or severely increased albuminuria of 30% after 9–12 years [152]. No threshold of HbA_{1c} and risk

was observed, suggesting that the lower the HbA_{1c}, the lower is the risk of nephropathy [153]. In the open follow-up of the UKPDS cohort, HbA_{1c} was similar in the previously intensively and conventionally managed groups after one year [154]. Despite this, microvascular risk remained lower, confirming the 'metabolic memory' seen in the DCCT/EDIC study. In the Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) study, the HbA_{1c} achieved in the intensively managed group was 48 mmol/mol (6.5%), compared with 56 mmol/mol (7.3%) in the standard care group [155]. In the intensive group there was a 9% relative risk reduction in new-onset moderately elevated albuminuria, a 30% reduction in the development of severely increased albuminuria, and a 65% reduction in ESKD over five years [156]. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study also demonstrated significant reductions in new-onset moderately and severely increased albuminuria and in ESKD with intensive glucose management [157]. Progression of albuminuria was reduced and regression increased. However, in those with CKD at baseline, the risk of all-cause and cardiovascular mortality was significantly increased in the intensive glucose management group [158]. Hence the kidney benefits of extremely tight glucose management are outweighed by the excess mortality. A less tight HbA_{1c} target in individuals with type 2 diabetes and duration >10 years seems sensible.

Glucose management in end-stage kidney disease

Most [159–161] but not all [162] observational studies have demonstrated increasing all-cause and cardiovascular mortality with increasing HbA_{1c} in people with diabetes on kidney replacement therapy. Some also showed a U-shaped relationship, with mortality increasing at low HbA_{1c} levels [159, 163, 164]. However, there have been no studies that demonstrated improved survival by improving glucose regulation.

Glucose-lowering medications and organ protection

Sodium–glucose cotransporter 2 inhibitors

For 20 years RAS blockade was the only treatment for diabetic nephropathy. After many unsuccessful attempts at developing new therapies, the first, and so far most marked, success has been with SGLT-2 inhibitors. When initially tested for safety in cardiovascular outcome trials, empagliflozin did not only show a benefit on the primary endpoint major adverse cardiovascular events [165], a significant benefit on hospitalization for heart failure was also observed. In addition, a reduction in incident or worsening nephropathy occurred (hazard ratio [HR] 0.61; 95% confidence interval [CI] 0.53 to 0.70) [166]. These findings were confirmed in cardiovascular outcome trials with canagliflozin and dapagliflozin. The first study with hard renal endpoints (ESKD, significant loss of renal function) as primary endpoint using an SGLT-2 inhibitor was Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE), which showed a major benefit on renal outcome but also on heart failure and major adverse cardiovascular events in people with type 2 diabetes, urine albumin creatine ratio >300 mg/g, and eGFR 30–90 ml/min/1.73 m² [167]. The primary outcome was a composite of ESKD, a doubling of the serum creatinine level, or death from renal or cardiovascular causes. The study was stopped early showing a benefit of canagliflozin with HR 0.70 (95% CI 0.59 to 0.82). These data were confirmed and extended by the Dapagliflozin and Prevention of Adverse Outcomes in Chronic Kidney Disease (DAPA-CKD) study that included people with CKD with or without diabetes [168] (Figure 44.6).

Whereas SGLT-2 inhibitors were introduced to treat hyperglycaemia, they also provide organ protection in diabetes with eGFR <45 ml/min/1.73 m² where there is no effect on blood glucose, and in persons without diabetes with heart failure and/or CKD. The explanation for the renal and cardiac benefits is not clear, but it may

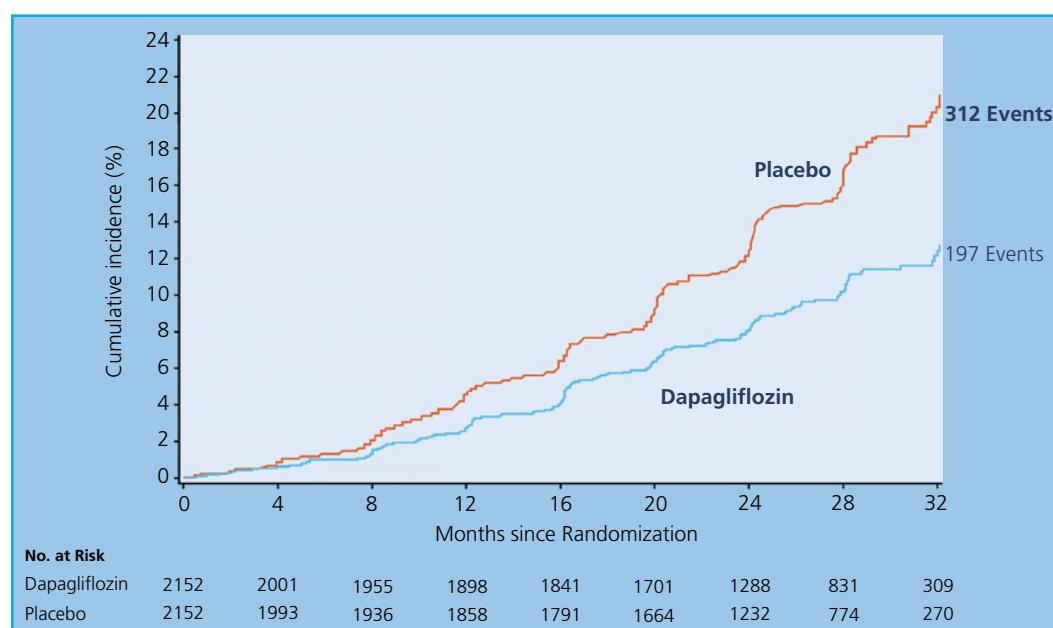

Figure 44.6 Dapagliflozin and Prevention of Adverse Outcomes in Chronic Kidney Disease (DAPA-CKD): sodium–glucose cotransporter 2 (SGLT-2) inhibitor dapagliflozin or placebo in chronic kidney disease with or without type 2 diabetes. Primary outcome: sustained ≥50% estimated glomerular filtration rate (eGFR) decline, end-stage kidney disease, renal or cardiovascular death. Hazard ratio 0.61 (95% confidence interval 0.51 to 0.72), $p < 0.00001$, number needed to treat (NNT) = 19. Source: Modified from Heerspink et al. 2020 [168].

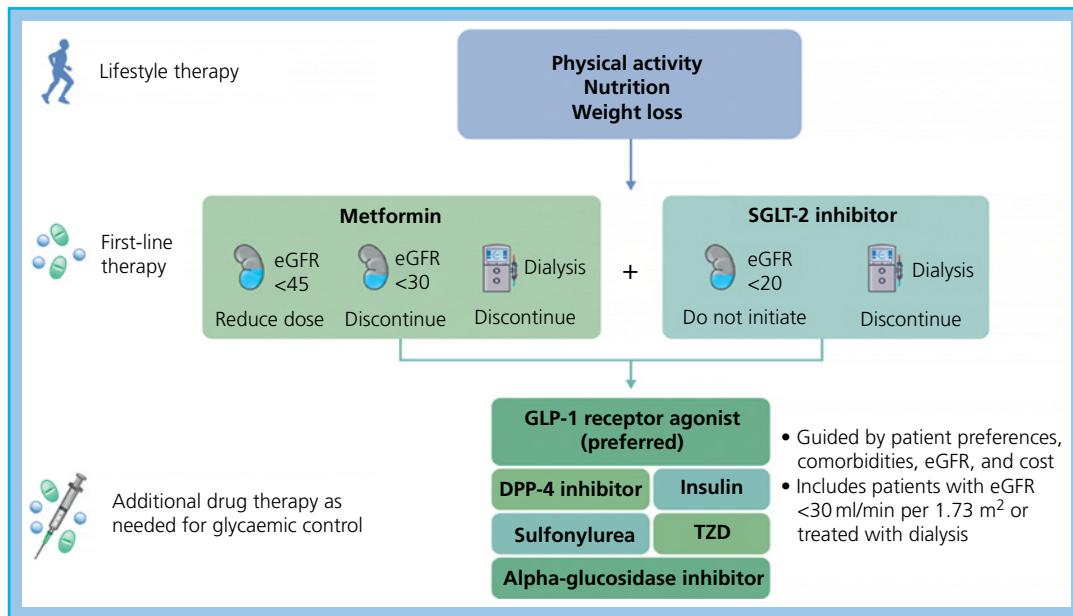

Figure 44.7 Anti-diabetes therapies in people with diabetes and chronic kidney disease. DPP-4, dipeptidyl peptidase 4; eGFR, estimated glomerular filtration rate; GLP-1, glucagon-like peptide 1; SGLT-2, sodium–glucose cotransporter 2; TZD, thiazolidinedione. involve effects on intraglomerular pressure, hypoxia, blood pressure, obesity, and metabolic effects [169]. There are no studies in diabetic nephropathy in type 1 diabetes; the benefit may be as in type 2 diabetes, but the risk of normoglycaemic diabetic ketoacidosis is increased. In people with type 2 diabetes and CKD, metformin is recommended as the first glucose-lowering agent after lifestyle intervention, as in others with type 2 diabetes, and then SGLT-2 inhibitors are recommended independent of HbA_{1c} for their organ-protective effect [143, 170] (Figure 44.7).

Glucagon-like peptide 1 receptor agonists

For some long-acting glucagon-like peptide 1 receptor agonists (GLP-1RAs; liraglutide, semaglutide, and dulaglutide), the cardiovascular outcome trials in type 2 diabetes demonstrated cardiovascular benefits in people with pre-existing atherosclerotic CVD [170]. The benefit on CVD outcomes was also demonstrated in CKD populations, and thus GLP-1RAs are recommended in the treatment of type 2 diabetes with diabetic nephropathy when metformin and SGLT-2 inhibition are not sufficient to obtain optimal glucose regulation (Figure 44.7). Studies also demonstrated positive kidney effects as secondary endpoints, mostly driven by reductions in albuminuria, but also some potential effects on eGFR. A kidney benefit was supported by the AWARD 7 study with dulaglutide in type 2 diabetes with CKD, although the primary endpoint was glycaemia [171]. The FLOW study (NCT03819153) will determine if there are benefits on hard renal outcomes in addition to cardiovascular benefits with semaglutide.

Blood pressure management

Rigorous blood pressure management improves the prognosis in diabetic nephropathy dramatically. Conservative estimates suggest that optimal blood pressure management doubles the time taken from first appearance of severely increased albuminuria to need for kidney replacement therapy from a mean of 9 to 18 years. Improved management in moderately elevated albuminuria may prevent progression and promote regression of normoalbuminuria. Blood

pressure and glucose-lowering effects are independent of one another, but have synergistic effects [172, 173]. In contrast to glucose ‘metabolic memory’, the benefits of blood pressure reduction are lost rapidly when control deteriorates [174].

Type 1 diabetes

RAS inhibitors do not prevent moderately elevated albuminuria in normotensive people with type 1 diabetes [175–177]. There is also no evidence that treating hypertension in type 1 diabetes and normoalbuminuria prevents the progression of albuminuria and decline in kidney function. However, it seems highly likely.

Once moderately or severely increased albuminuria is present, inhibition of the RAS is the backbone of therapy, because it reduces intraglomerular pressure. A meta-analysis summarized the effects of angiotensin-converting enzyme (ACE) inhibitors in people with type 1 diabetes and moderately elevated albuminuria [178]. The odds ratio for progression to severely increased albuminuria was reduced by ACE inhibition to 0.35, and for regression to normoalbuminuria it increased to 3.07, compared with placebo treatment. After two years of treatment, the mean reduction in UAE was 50% with ACE inhibition and was greatest in those with highest baseline levels. However, the response to treatment plateaued with time, suggesting that treatment delays, rather than prevents, progression.

Addition of an ACE inhibitor to non-ACE inhibitor antihypertensive therapy reduced the risk of a doubling of the serum creatinine by 48% and the composite endpoint of death, need for dialysis, or kidney transplantation by 50% in people with type 1 diabetes and with severely increased albuminuria and hypertension [179]. Both benefits were independent of blood pressure. In short-term studies, the effects of angiotensin receptor blockers (ARBs) on blood pressure and UAE were similar to those of ACE inhibitors in type 1 diabetes and severely increased albuminuria [180].

For a similar reduction in blood pressure, there is a greater reduction in protein excretion using ACE inhibitors compared with other classes of antihypertensive agents [181]. This may be beneficial, as the passage of protein across the glomerular filtration

barrier may accelerate the progression of nephropathy [182]. Animal data show that this is due to preferential reduction in intraglomerular pressure with ACE inhibitors [183]. An effect on the filtration barrier has also been suggested [184].

RAS inhibitors should be offered to all individuals with type 1 diabetes and albuminuria, regardless of blood pressure. The dose should be titrated up to the maximum recommended or tolerated, to maximize the antiproteinuric effect. If blood pressure remains >125/75 mmHg on a maximum dose of RAS inhibitors, antihypertensive therapy should be intensified. Lower blood pressure reduces the rate of decline of GFR from 10 to 12 ml/min/year untreated to <5 ml/min/year [185]. Regression from severely to moderately increased albuminuria can be achieved, with the fall in GFR reduced to <1 ml/min/year [186]. The choice of agent should be made on an individual basis, as there is no evidence in type 1 diabetes that any one add-on agent is better than any other. Often multiple agents are needed in CKD stage 3 and beyond.

Type 2 diabetes

Optimizing hypertension management reduces the risk of developing moderately or severely increased albuminuria [187–190]. There may be a particular benefit of RAS inhibition in prevention of nephropathy [191–193], but lowering blood pressure sufficiently is the key. Achieved blood pressure in these studies was generally ~140/80 mmHg, but most guidelines now suggest a blood pressure target of 130/80 mmHg in type 2 diabetes.

As with type 1 diabetes, there is good evidence in type 2 diabetes that inhibition of the RAS should be the backbone of therapy if albuminuria is elevated. RAS blockade reduces the progression of moderately elevated albuminuria to severely increased albuminuria [188, 194] and increases regression to normoalbuminuria [194]. The benefits are at least partly independent of blood pressure lowering. In more advanced diabetic nephropathy, RAS inhibition with ARBs reduces progression, defined as doubling of serum creatinine, ESKD, or death [195, 196]. Hence people with type 2 diabetes and moderately or severely increased albuminuria should be prescribed a RAS inhibitor, titrated to the maximum tolerated dose [197]. Hyperkalaemia is common in individuals with type 2 diabetes and nephropathy taking an ARB and is associated with increased risk of kidney failure [198]. General steps to lower potassium such as dietary advice, diuretics, consideration of potassium-increasing medication, dietary supplements, or potassium binders should be considered before stopping RAS blockade [143]. Introduction of a RAS inhibitor often leads to an acute decline in GFR, which then stabilizes. Individuals with the greatest initial fall in GFR have the slowest subsequent decline in kidney function [199].

Most people with type 2 diabetes and albuminuria will require additional antihypertensive therapy. The choice of additional agents should be made on an individual basis, with diuretics and calcium channel blockers often being appropriate. In resistant hypertension with preserved renal function, mineralocorticoid receptor antagonists (MRAs) may be useful [200].

In the UKPDS, there was no blood pressure level below which risk of developing moderately elevated albuminuria or beyond increased; that is, no 'J-shape' [201]. The ADVANCE study explored the effects of reduction of blood pressure below the currently recommended targets of 130/80 mmHg in individuals with normal or moderately increased albuminuria and 125/75 mmHg in those with severely increased albuminuria [202]. Over four years, the risk of kidney events was reduced by 21%, mainly because of reduced risk

of developing moderately or severely elevated albuminuria. However, an achieved systolic blood pressure below 120–130 mmHg was associated with increased mortality and ESKD [203]. Therefore, extremely tight blood pressure should be avoided.

Dual blockade of the renin–angiotensin system

Addition of an ARB to an ACE inhibitor [204, 205] or of the direct renin inhibitor aliskiren to an ARB reduces blood pressure and albuminuria more than each agent individually. However, in the longer term, dual blockade increases the risk of hyperkalaemia, hypotension, and acute, irreversible kidney failure [206–209]. Hence dual blockade is not recommended.

Mineralocorticoid receptor antagonism

Prevention of diabetic nephropathy was attempted with spironolactone in the PRIORITY trial including people with type 2 diabetes and normoalbuminuria. High risk for progression to CKD/moderately elevated albuminuria was identified with a urinary proteomic-based risk score (CKD-273). High-risk individuals were randomized to spironolactone or placebo, and although the biomarker predicted progression of kidney disease, spironolactone did not reduce progression compared to placebo over three years [210].

Short-term studies in established diabetic nephropathy revealed ~30% reduction in albuminuria with the steroid MRA spironolactone or eplerenone [211]. Preventing overactivation of the mineralocorticoid receptor reduces inflammation and fibrosis, but due to potassium problems diabetes with kidney disease became a contraindication for these agents. Non-steroidal MRAs have been developed and may cause fewer potassium issues. The non-steroidal MRAs esaxerenone and finerenone reduced moderately elevated albuminuria in type 2 diabetes in short-term studies [212, 213]. The FIDELIO-DKD study tested finerenone and included 5734 participants with CKD and type 2 diabetes (urine ACR $\geq 30\text{--}5000 \text{ mg/g}$, eGFR $\geq 25\text{--}<75 \text{ ml/min}/1.73 \text{ m}^2$) and the primary endpoint (kidney failure, sustained decrease of eGFR $\geq 40\%$, or kidney death) was reduced with HR 0.82 (95% CI 0.73 to 0.93, $p = 0.001$). The key secondary outcome (cardiovascular death, myocardial infarction, stroke, or hospitalization for heart failure) was also reduced (HR 0.86; 95% CI 0.75 to 0.99; $p = 0.03$). The incidence of hyperkalaemia-related treatment discontinuation was higher with finerenone than placebo (2.3% and 0.9%, respectively) [214]. FIGARO-DKD support the findings from FIDELIO-DKD, but in type 2 diabetes with less advanced CKD, and has CVD as a primary outcome [215].

Sodium intake

Short-term dietary sodium restriction (target sodium intake 50 mmol Na⁺ per day), added to RAS blockade, reduces albuminuria [216]. The treatment effects of ARB are greater in individuals with lower rather than higher dietary sodium intake [217]. Hence dietary counselling to reduce sodium intake is essential and an intake of <2 g of sodium per day (or <90 mmol of sodium per day, or <5 g of sodium chloride per day) is recommended [143].

Non-classical diabetic kidney disease

There is no specific evidence for the use of RAS inhibition in individuals without albuminuria. However, optimizing blood pressure remains crucial to slow progression. Ongoing studies are investigating the effect of the SGLT-2 inhibitor empagliflozin on CKD, including low eGFR ($20\text{--}45 \text{ ml/min}/1.73 \text{ m}^2$) but normal UAE [218].

Endothelin receptor antagonists

Atrasentan is an endothelin receptor A antagonist that lowers proteinuria without significant oedema [219]. Previously oedema had been a concern with this class of agents [220]. The Study Of diabetic Nephropathy with AtRasentan (SONAR) study tested atrasentan in people with type 2 diabetes and severely increased albuminuria, with progression of kidney disease, ESKD, and mortality as the primary outcome [221]. Although stopped early for concern of futility, the study eventually showed a kidney benefit of the same magnitude as with SGLT inhibitors, but without effect on major adverse cardiovascular events and with a tendency to increased risk of heart failure. The primary endpoint was a composite of doubling of serum creatinine (sustained for ≥ 30 days) or ESKD (eGFR < 15 ml/min per 1.73 m^2 sustained for ≥ 90 days, chronic dialysis for ≥ 90 days, kidney transplantation, or death from kidney failure). The HR for atrasentan compared to placebo was 0.65 (95% CI 0.49 to 0.88; $p = 0.0047$). The mode of action may relate to an effect on inflammation, but also an effect on podocytes and endothelium and glycocalyx has been proposed from experimental data [222].

Low-protein diet

A meta-analysis concluded that such a diet significantly improves GFR but not albuminuria, across all subtypes of diabetes and stages of nephropathy [223]. A randomized trial of 82 people with type 1 diabetes and severely increased proteinuria and progressive loss of kidney function demonstrated reduced mortality and ESKD (relative risk 0.23; 95% CI 0.07 to 0.72) for individuals assigned to a low-protein diet targeting 0.8 g protein/kg body weight/d compared to usual diet [224]. Protein intake should not be restricted to less than 0.7 g protein/kg body weight/d because of concerns about malnutrition in ESKD. In line with recommendations for the general population, a protein intake of 0.8 g protein/kg body weight/d is recommended for people with diabetes and CKD, except for those on peritoneal dialysis where a higher intake (1.0–1.2 g protein/kg body weight/d) is recommended [143].

Lipids

Lipid-lowering medications are recommended to reduce the risk for CVD, but there is some evidence that lipid-lowering agents are beneficial to the kidney. In a *post hoc* analysis of the Collaborative Atorvastatin Diabetes Study, the rate of decline of eGFR was significantly less in those individuals taking atorvastatin 10 mg daily compared with placebo. Fibrates also reduce albuminuria, although they reversibly increase serum creatinine [225].

Cardiovascular risk: other factors

Smoking increases the likelihood of developing diabetic nephropathy, as discussed earlier, but there have been no good trials of smoking cessation. However, smoking cessation should clearly be encouraged. There are no studies in diabetic kidney disease with aspirin evaluating long-term benefits, although short-term studies suggest no effect on UAE or GFR [226]. In many individuals with established CVD or high risk for CVD, aspirin should be considered for prevention of cardiovascular events. There is an increased risk of atrial fibrillation in diabetes and in CKD, and higher morbidity and mortality associated with thromboembolic events including stroke in diabetes with atrial fibrillation [227]. Where diabetes coexists with atrial fibrillation, anticoagulation is often recommended, and direct oral anticoagulants are usually preferred

compared to vitamin K antagonists. In addition to a reduced risk of bleeding and similar or better effects on reducing risk of thrombosis, observational studies suggest reduction in progression of CKD. Thus, a recent study using a health claim database included persons with non-valvular atrial fibrillation and diabetes with newly initiated rivaroxaban ($n = 10017$) or warfarin ($n = 11665$) [228]. The participants were matched using propensity scores. In comparison to warfarin, rivaroxaban was associated with lower risks of acute kidney injury events (HR 0.83; 95% CI 0.74 to 0.92) and development of stage 5 CKD or need for haemodialysis (HR 0.82; 95% CI 0.70 to 0.96) [228]. The mechanism could be reduced vascular calcification, but that needs to be confirmed in randomized controlled trials.

Weight loss

In a trial comparing intensive lifestyle intervention with diabetes support and education in type 2 diabetes, individuals randomized to intensive lifestyle modification were less likely to develop CKD over eight years [229]. The effect was partly attributable to reductions in body weight, HbA_{1c}, and systolic blood pressure. Low-carbohydrate, Mediterranean, and low-fat diets have similar beneficial effects on change in eGFR and albuminuria over two years [230]. In individuals with type 2 diabetes who have undergone bariatric surgery, moderately and severely increased albuminuria regresses to normoalbuminuria [231]. Similar benefits were described in a five-year study in severely obese adolescents with and without type 2 diabetes [232].

Further management of chronic kidney disease stages 3–5

Monitoring anaemia and bone chemistry

In progressive CKD from stage 3 onwards, bone chemistry, full blood count, and iron stores should be assessed 3–6 monthly.

Monitoring glucose levels

Red blood cell and protein turnover are abnormal in CKD, making the interpretation of HbA_{1c}, glycated albumin, and fructosamine results difficult, particularly in people with CKD 4+. Thus, more reliance should be placed on self-monitoring of blood glucose and continuous glucose monitoring, particularly if treatment can cause hypoglycaemia [143].

Glucose-lowering agents

Metformin and its metabolites are excreted mainly by the kidney. In kidney failure, they accumulate and inhibit lactate oxidation. Metformin should therefore be used cautiously in those with eGFR < 40 ml/min/ 1.73 m^2 , and stopped completely when eGFR < 30 ml/min/ 1.73 m^2 [233].

The sulfonylureas glibenclamide, gliclazide, and tolbutamide are excreted predominantly renally and accumulate in CKD. Their dose, and indeed the dose of any sulfonylurea, may need to be reduced as CKD progresses. Only ~10% of the meglitinides, repaglinide and nateglinide, is renally excreted, making them suitable alternative agents. The thiazolidinediones rosiglitazone and pioglitazone, are predominantly metabolized in the liver. However, their use in ESKD may be limited by fluid retention.

Insulin is also excreted by the kidney so that reduced dosage, and perhaps a switch to shorter-acting preparations, may be required.

The dose of some, but not all, dipeptidyl peptidase 4 (DPP-4) inhibitors and GLP-1RAs may need to be reduced as kidney function deteriorates. The SGLT-2 inhibitors become less effective as GFR falls. For further details see Table 44.4.

Anaemia

Anaemia is common in people with diabetes and CKD stage 3 or poorer [234]. Full investigation of iron-deficiency anaemia may be needed to exclude a non-kidney cause. Those with anaemia have higher mortality, higher rates of hospital admission with heart

failure, and poorer quality of life. Iron stores should be repleted, with oral or parenteral iron as necessary, and erythropoietin replacement commenced if indicated. The Trial to Reduce cardiovascular Events with Aranesp (darbepoetin alpha) Therapy (TREAT) investigated if treatment of anaemia in people with type 2 diabetes and CKD would improve renal or cardiovascular outcome, but showed no benefit [235].

Table 44.4 Glucose-lowering agents in chronic kidney disease.

Drug	Comment
Metformin	Risk of accumulation and possibly lactic acidosis Caution when eGFR <45 ml/min/1.73 m ² Stop when eGFR <30 ml/min/1.73 m ²
Sulfonylureas	Glibenclamide, gliclazide, and tolbutamide predominantly renally excreted; may need to reduce dose
Meglitinides	~10% excreted via kidney; usually safe
Thiazolidinediones	Predominantly hepatic metabolism; use may be limited by fluid retention
Dipeptidyl peptidase 4 inhibitors	Dose may need to be reduced in some agents
Glucagon-like peptide 1 receptor agonists	Few data when eGFR <15 ml/min/1.73 m ²
Sodium–glucose cotransporter 2 inhibitors	Protect kidney and heart down to eGFR >25, but ineffective at reducing glucose at eGFR <45 ml/min/1.73 m ²
Insulin	Excreted by kidney; may need to reduce dose and/or switch to shorter-acting preparations

eGFR, estimated glomerular filtration rate.

When to refer to nephrology

Individuals who begin dialysis as an emergency do less well than those in whom treatment is planned [236]. Referral to nephrology should be made when eGFR is declining rapidly (>5 ml/min/1.73 m²/year) or when eGFR is <30–45 ml/min/1.73 m². This allows structured physical and psychological preparation for kidney replacement therapy. Earlier referral may be necessary in particular circumstances (Box 44.1). The need for kidney replacement therapy should be discussed with all individuals and those who wish it should have access. People without significant comorbidities will usually be offered transplantation. Full cardiovascular assessment and treatment are essential before transplantation.

Box 44.1 Indications for referral to nephrology

- Diagnosis uncertain
- Hypertension difficult to control
- Fluid overload
- Anaemia unresponsive to oral iron
- Abnormal bone chemistry
- eGFR 30–45 ml/min/1.73 m²
- Nephrotic syndrome
- eGFR fall >5 ml/min/1.73 m² per year

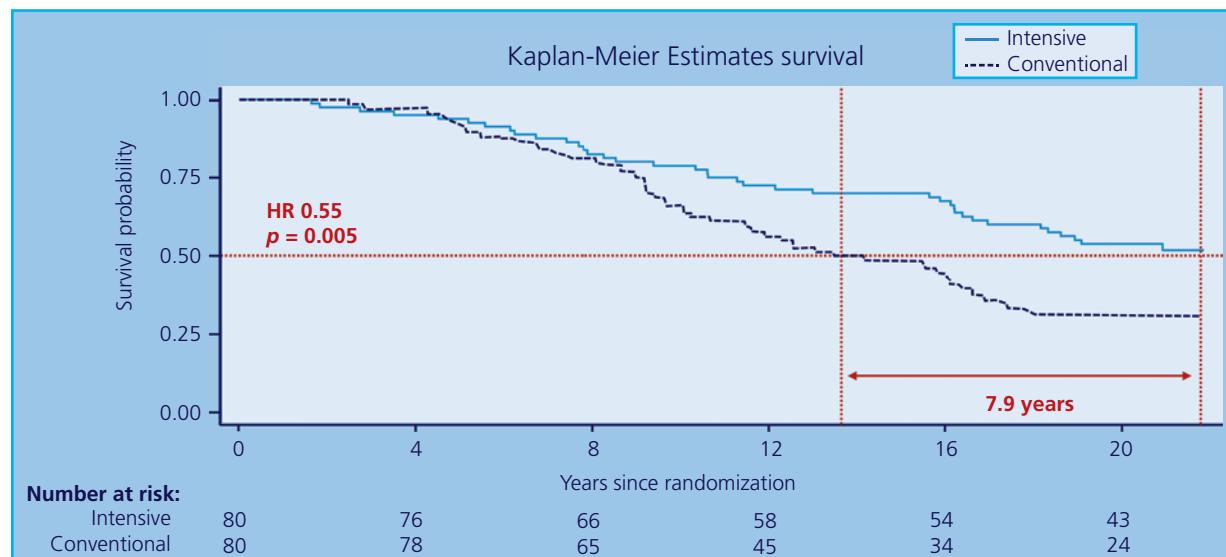

Figure 44.8 Steno-2 post-trial: 21 years' sustained effect of intensive multifactorial intervention compared to standard of care for eight years targeting lifestyle and heart and kidney risk factors. Source: Data from Gaede et al. 2016 [241].

Organization of care

Structured care, delivered by trained specialists working to clear protocols with specific, multiple treatment goals for all the variables described in this chapter, reduces the incidence of moderately elevated albuminuria [237,238] and provides greater kidney and cardiovascular benefits than routine care for individuals with type 2 diabetes and CKD [143,239,240]. Progression to ESKD or death, need for laser therapy, and cardiovascular endpoints including stroke and heart failure are all reduced by such multifactorial intervention [241–244]. When structured intensive multifactorial intervention targeting lifestyle factors (diet, exercise, smoking) and heart and kidney risk factors (blood glucose, blood pressure, lipid management) compared to usual care was started in type 2 diabetes with moderately elevated albuminuria, long-term follow-up of the Steno-2 study demonstrated that eight years of intervention translated into almost eight years of extended median survival (Figure 44.8) [241].

Pregnancy in women with diabetes and chronic kidney disease

Women with diabetic nephropathy have poor pregnancy outcomes [245]. They remain at increased risk of hypertension, pre-eclampsia, abnormal fetal growth, and preterm delivery [246]. In a recent series, the prevalence of diabetic nephropathy and moderately elevated albuminuria in early pregnancy was similar in women with type 1 or type 2 diabetes, and pregnancy outcomes were comparable regardless of the type of diabetes [247]. Women with any evidence of CKD should therefore be counselled pre-pregnancy. RAS inhibitors should be stopped and therapies safe in pregnancy, such as methyldopa, labetolol, and nifedipine, substituted. In women with type 1 diabetes, maintenance of blood pressure <135/85 mmHg and proteinuria <300 mg/24 h with methyldopa improves outcomes [200,248].

²Department of Cardiovascular and Metabolic Medicine, Institute of Life Course and Medical Sciences, University of Liverpool, Liverpool, UK

³Department of Medicine, Weill Cornell Medicine-Qatar, Doha, Qatar

Key points

- Diabetic neuropathies are a 'heterogeneous group of disorders affecting multiple aspects of the nervous system' that can be divided into rapidly reversible neuropathies, persistent symmetrical polyneuropathies, and focal/multifocal neuropathies.
- At least one in three individuals with diabetes is affected by diabetic sensorimotor polyneuropathy, which may present with excruciating neuropathic pain and/or sensory loss leading to foot ulceration and amputation.
- Neuropathic pain markedly reduces the quality of life, by interfering with sleep and daily activities.
- Experimental studies have identified multiple pathogenetic targets for diabetic sensorimotor polyneuropathy and autonomic neuropathy, but to date no disease modifying therapies have been approved by the US Food and Drug Administration.
- Epidemiological data indicate that traditional cardiovascular risk factors such as pre-diabetes, visceral obesity, hypertension, hyperlipidaemia, and smoking play a role in the development and progression of diabetic neuropathy.
- Treatment of diabetic sensorimotor polyneuropathy is based on (i) multi-factorial risk intervention targeting weight, glycaemia, blood pressure, and lipids; and (ii) symptomatic treatment of painful and autonomic symptoms.
- The management of painful diabetic sensorimotor polyneuropathy requires careful dose titration based on efficacy and side effects. Combination therapy may be useful, and potential drug interactions have to be considered given the frequent polypharmacy in people with diabetes.
- Diabetic autonomic neuropathy can cause multiple symptoms and has limited treatment options.

Classification of diabetic neuropathy

Diabetic neuropathy, as defined by the international position statement of the American Diabetes Association (ADA), is a 'heterogeneous group of disorders affecting multiple aspects of the nervous system and result[s] in a multiplicity of manifestations' [1]. Diabetic neuropathy should be actively diagnosed in people with diabetes after the exclusion of other causes of peripheral neuropathy. It may be readily apparent based on symptoms and clinical examination, or it may be demonstrated by undertaking a more detailed assessment of the somatic and/or autonomic nervous system [1]. The classification proposed by P.K. Thomas, based on anatomical and pathophysiological features, is widely used in the classification of diabetic neuropathy [2]. It distinguishes the manifestations of diabetic neuropathies into (Table 45.1):

- Rapidly reversible neuropathies.
- Persistent symmetrical polyneuropathies.
- Focal/multifocal neuropathies.

Epidemiology and clinical impact of diabetic sensorimotor polyneuropathy

The prevalence of diabetic sensorimotor polyneuropathy ranges from 20% to 90%, depending on the patient population studied and the definition of neuropathy used. Diabetic sensorimotor polyneuropathy is the most prevalent clinical manifestation in people with diabetes. In the landmark French prospective study conducted by Pirart et al. between 1947 and 1973, of 4400 adults with diabetes followed over 25 years, 50% developed diabetic sensorimotor polyneuropathy [3]. Pre-diabetes is also a risk factor for sensorimotor polyneuropathy and cardiac autonomic neuropathy [4]. In a large population-based study in the Augsburg region of Germany, the prevalence of polyneuropathy was 13.0% in participants with impaired glucose tolerance, 11.3% in those with impaired fasting glucose, and 28.0% in those with diabetes compared to 7.4% in those with normal glucose tolerance [5]. The annual incidence of diabetic sensorimotor polyneuropathy is ~2% in people with type 2 diabetes

Table 45.1 Classification of diabetic neuropathies.

Type	Neuropathy
Rapidly reversible	Hyperglycaemic neuropathy
Persistent symmetric polyneuropathies	Distal somatic sensory/motor polyneuropathies involving predominantly large fibres
Focal/multifocal neuropathies	Autonomic neuropathies Small-fibre neuropathies Cranial neuropathies/ Thoracoabdominal radiculopathies/ Focal limb neuropathies/ Proximal neuropathies Compression and entrapment neuropathies

(UK Prospective Diabetes Study, UKPDS) and people with type 1 diabetes (Diabetes Control and Complications Trial, DCCT) [6].

Based on natural history studies, risk factors for the progression of diabetic sensorimotor polyneuropathy in type 1 diabetes and type 2 diabetes include suboptimal glycaemic management, age, duration of diabetes, visceral obesity or body mass index (BMI), height, hypertension, smoking status, hypoinsulinaemia, and dyslipidaemia, particularly hypertriglyceridaemia [6–10]. The major clinical manifestations of diabetic sensorimotor polyneuropathy include neuropathic pain, sensory loss, and impaired gait [11], which are associated with depressive symptoms [12]. Vibration perception threshold and nerve conduction velocity predict mortality [13, 14] and foot ulceration [15]. Foot ulceration is a common cause of hospital admission in people with diabetes and 80% of lower-limb amputations occur as a direct consequence of non-healing foot ulcers (Chapter 53).

In the Early Treatment Diabetic Retinopathy Study (ETDRS), mortality in individuals with type 2 diabetes was related to the presence of macrovascular disease, worsening microvascular disease, and diabetic sensorimotor polyneuropathy [16]. In a community-based study from the UK, diabetic sensorimotor polyneuropathy defined by reduced touch or pressure sensation was associated with incident non-fatal myocardial infarction, need for coronary revascularization, congestive cardiac failure, transient ischaemic attack and stroke, and, indeed, the addition of diabetic sensorimotor polyneuropathy in a model based on standard cardiovascular disease risk factors improved cardiovascular risk prediction [17]. The presence of neuropathy in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial was the strongest predictor of mortality in people with type 2 diabetes allocated to intensive glycaemic management with a glycated haemoglobin (HbA_{1c}) <6.0% (42 mmol/mol) [18]. Myocardial ischaemia detected using sestamibi single-photon emission computed tomographic imaging was strongly associated with diabetic sensorimotor polyneuropathy [19]. In a prospective cohort study of people without diabetes from the USA, neuropathy was independently associated with mortality [20].

Diabetic sensorimotor polyneuropathy remains underdiagnosed by physicians and underreported by people with diabetes. In a study from Japan, physicians were only aware of painful diabetic neuropathy in ~36.4% of the individuals with the condition [21]. In a population-based survey (KORA F4) from Germany, 77% of people with diabetic sensorimotor polyneuropathy were unaware of the diagnosis and a quarter had not had a foot examination [22]. In the PROTECT study, painful and painless diabetic sensorimotor polyneuropathy were undiagnosed in 57% and 82% of people with type 2 diabetes, respectively [23], and in a follow-up study 33% of

people with painful diabetic neuropathy had not received treatment [24]. In two studies from Qatar, despite a high prevalence of diabetic sensorimotor polyneuropathy (23%) [25] and painful diabetic sensorimotor polyneuropathy (34.5%) [26], 80% of the individuals had not been previously diagnosed [27].

Neuropathic pain is often the primary complaint that motivates people to seek medical advice. It has a significant impact on sleep and interferes with daytime social functioning and work [11]. Despite severe symptoms it is frequently unreported and inadequately treated [28]. A UK-based study demonstrated that 13% had never reported their symptoms of painful diabetic neuropathy to their treating physician and ~40% had never received treatment [28]. In a large population-based study in the North West of England, one-third of all community-based people with diabetes had painful neuropathic symptoms [29]. In another community-based study in Augsburg, Germany (MONICA/KORA Augsburg Surveys S2 and S3), the prevalence of painful neuropathy was 13.3% in people with diabetes, 8.7% in impaired glucose tolerance, and 4.2% in impaired fasting glycaemia compared to 1.2% in those with normal glucose tolerance [30]. People with ischaemic heart disease also have excess neuropathic pain [31]. Risk factors for neuropathic pain include age, obesity, and low physical activity [26]. Pain treatments include antidepressants (~44%), anticonvulsants (~17%), opiates (~39%), or other drugs (~30%) [28]. Opiates are of considerable concern, given their limited efficacy for painful diabetic neuropathy and risk of long-term dependency and misuse [21, 32]. A 30–50% reduction in pain is considered adequate, whereas a ≥50% improvement in pain is considered a good outcome [33]. Neuropathic pain tends to persist to some degree in the majority of individuals with diabetes.

Clinical manifestations of diabetic neuropathy

Diabetic sensorimotor polyneuropathy

Diabetic sensorimotor polyneuropathy is defined as a ‘symmetrical, length-dependent sensorimotor polyneuropathy which occurs as a consequence of metabolic and microvascular alterations due to chronic hyperglycaemia of diabetes (or prediabetes) and cardiovascular risk factors’ [34]. The onset of diabetic sensorimotor polyneuropathy is usually insidious and without early intervention there is progression to more advanced stages with a poor prognosis. It is length dependent, with the terminal portions of the axons being more vulnerable with initial involvement of the toes and feet followed by the fingers and hands (*glove and stocking distribution*), and it is associated with height (Figure 45.1) [35]. In more advanced diabetic sensorimotor polyneuropathy, the anterior abdominal wall and lateral trunk may also be affected. Peripheral nerves comprise large-fibre myelinated ($A\alpha$, $A\beta$ fibres), thinly myelinated ($A\delta$ fibres), and small-fibre unmyelinated (C fibres) nerves. At present, the general consensus is that small fibres are involved first, followed by large-fibre dysfunction. Studies in both type 1 diabetes and type 2 diabetes have demonstrated pathological reductions in small nerve fibres with normal nerve conduction studies [36, 37]. The early involvement of small nerve fibres is based on individuals presenting with pain and hyperalgesia ($A\delta$ and C fibres) and reduction in corneal and intraepidermal nerve fibres prior to abnormalities of nerve conduction in adults with type 1 diabetes and type 2 diabetes [38], those with impaired glucose tolerance [39], and children with type 1 diabetes [40].

Sensory ataxia (ataxic gait) may occur in diabetic sensorimotor polyneuropathy with a loss or reduction in touch, pressure, and vibration sensation, although this represents a more severe end of the spec-

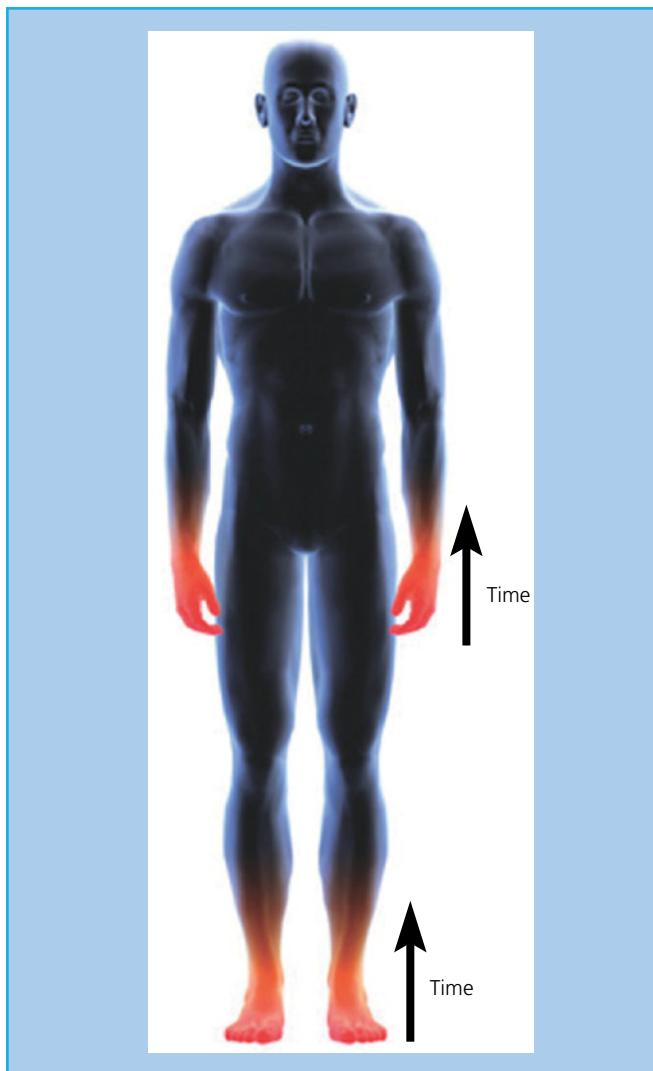

Figure 45.1 The typical 'glove-and-stocking' distribution of diabetic distal symmetrical sensory or sensorimotor polyneuropathy.

trum. The distribution of sensory deficits classically seen in diabetic sensorimotor polyneuropathy is shown in Figure 45.2. Symptoms are often defined as *positive* sensory symptoms (paraesthesia, dysaesthesia, and characteristic neuropathic pain) or *negative* symptoms (reduced sensation); however, these symptoms may coexist. There are several variants of diabetic sensorimotor polyneuropathy, including acutely painful small-fibre or pseudosyringomyelic syndromes and an ataxic syndrome (tabes dorsalis).

Neuropathic pain may be continuous or episodic and characteristically worsens at night, resulting in disturbed sleep [41]. Neuropathic pain may also improve during exercise or walking, which can help to differentiate it from ischaemic pain [42]. Nocturnal exacerbation with increased pain intensity, especially when tired or stressed, is also a typical phenotypic feature of painful neuropathy [43]. Pain from diabetic sensorimotor polyneuropathy may continue over many years [28, 44], resulting in considerable morbidity [11], but it may improve partially or entirely in some, despite worsening nerve function [45]. The prevalence of pain is higher in individuals with worse neuropathy [29], with recent studies showing greater small-fibre damage in those with painful

Figure 45.2 A typical example of the distribution of sensory deficits in a person with distal symmetrical sensorimotor polyneuropathy. Dots, reduced thermal sensation; lines, reduced pain sensation; crossed lines, reduced touch sensation.

compared to painless diabetic neuropathy [46, 47]. Pain remission is associated with a shorter duration of pain or diabetes and lesser severity of diabetic sensorimotor polyneuropathy [45].

It is important to exclude other pathologies that may present with symptoms similar to diabetic sensorimotor polyneuropathy by taking a detailed history and careful examination [48]:

- The pain of *intermittent claudication* is typically exacerbated by walking, while it is relieved in diabetic polyneuropathy, and can occur in the thighs and buttocks, unless it is diabetic lumbosacral plexopathy.
- The pain of *Charcot neuroarthropathy* occurs with collapse and deformity of the foot bones, with increasing warmth in the foot due to inflammation in the presence of a severe neuropathy.
- The pain of *plantar fasciitis* occurs with each heel step and is associated with exquisite tenderness in the sole of the foot.
- The pain of *osteoarthritis* occurs in the feet and hands, is associated with morning stiffness, exacerbated with joint movement and/or exercise, and improves with ambulation during the day.

Overt motor neuropathy is less frequent and most often restricted to the distal lower limbs. Ankle reflexes are frequently reduced or absent with motor involvement. Muscle atrophy and weakness occur in tandem and are largely present at the toes and feet [49], leading to abnormal loading (foot pressures) that is a risk factor for

ulceration [50]. However, significant reductions in strength with lower-limb muscle atrophy have been demonstrated in individuals with impaired glucose tolerance [51] and mild diabetic neuropathy [52], leading to altered gait and walking strategy [53].

The loss of the protective sensation (insensate feet), muscle atrophy, and autonomic involvement with reduced sweat production results in dry skin with callus, which increases the risk of ulceration. Foot complications can be severe and potentially life-threatening as a consequence of ulceration, Charcot neuroarthropathy, and osteomyelitis, with non-healing ulcers leading to lower-limb amputation [54]. Lower-limb amputation rates are 15 times higher in people with diabetes compared to those without diabetes [54]. The active detection of diabetic sensorimotor polyneuropathy is imperative, given that a large proportion of individuals are asymptomatic or remain undiagnosed [26]. Unfortunately, current guidelines [1] advocate the use of simple tests such as the monofilament, which can only detect advanced diabetic sensorimotor polyneuropathy and those at high risk of foot ulceration [55].

Acute painful neuropathy

Acute painful neuropathy occurs in both type 1 diabetes and type 2 diabetes and has been described as a separate clinical entity to diabetic sensorimotor polyneuropathy [56]. The characteristic presentation is of continuous burning pain, particularly on the plantar aspect of the feet, with nocturnal exacerbation. It is often described as being 'like walking on burning sand'. A typical phenotypic picture includes predominantly positive symptoms such as hypersensitivity to tactile stimuli (allodynia), such as pain on contact with bed sheets, and hyperalgesia. Erectile dysfunction and depression are common comorbid conditions. Motor function tends to be preserved with a paucity of sensory loss. Severe weight loss may precede its onset and was originally coined *diabetic cachexia* by Ellenberg [57]. Weight loss improves with better glycaemic management, and severe manifestations subside within 10–12 months, with no recurrence observed on follow-up over six years [56].

In 1933 Caravati [58] coined the term *insulin neuritis* after he described a case of acute painful neuropathy following the initiation of insulin treatment and rapid improvement in glycaemic levels. The terminology of this disorder has now changed to treatment-induced neuropathy in diabetes, whereby a sudden improvement in glycaemic levels in people with marked hyperglycaemia manifests as small-fibre neuropathy with neuropathic pain and varying degrees of autonomic neuropathy [59]. Gibbons et al. [60] showed that the absolute risk of treatment-induced neuropathy in diabetes increased with the degree of decline in HbA_{1c}:

- Reduction in HbA_{1c} of 2–3% (22–33 mmol/mol) over three months = 20% absolute risk.
- Reduction in HbA_{1c} of >4% (44 mmol/mol) over three months >80% absolute risk.
- Reduction in HbA_{1c} of >5% (55 mmol/mol) over three months >90% absolute risk.

The extent of HbA_{1c} reduction was also related to the distribution and severity of pain and autonomic dysfunction, retinopathy, and microalbuminuria [60]. Histopathological studies have demonstrated severe nerve fibre loss with unmyelinated fibre degeneration and regeneration in sural nerve biopsies [61] and epineurial arteriovenous shunting with neovascularization similar to proliferative diabetic retinopathy, which we proposed may have occurred as a consequence of endoneurial ischaemia [59]. Reassuringly, the painful symptoms tend to improve over 3–8 months while maintaining optimal glycaemic levels.

Focal and multifocal neuropathies

Focal and multifocal neuropathies occur in older people with a longer duration of diabetes. They tend to be self-limiting, with either partial or complete recovery and resolution of pain [62]. These individuals should be reassured that recovery will occur with conservative treatment.

Cranial neuropathy

A large registry study from the Middle East and North Africa region showed that the prevalence of ophthalmoplegia secondary to diabetes was ~0.32% [63]. Third nerve palsy was the most common (~53%) and was painful in about 50% of cases [63]. It is characterized by sudden-onset retro-orbital and supra-orbital pain, which may precede ptosis and diplopia (with pupillary dysfunction in 14–18% of cases). Ophthalmoplegia can persist for a number of weeks, with full recovery occurring usually within 12 weeks [64]. The 4th, 6th, and 7th cranial nerves can also be affected. The most important risk factors are age over 45 years, diabetes duration greater than 10 years, male sex, and presence of retinopathy and nephropathy [63].

Mononeuropathy of the limbs

The ulnar, median, radial, and peroneal nerves and to a lesser extent truncal nerves are affected and can be acutely painful. Entrapment neuropathies, such as carpal tunnel syndrome, are also more common in people with diabetes. Carpal tunnel syndrome is associated with painful paraesthesia in the hand, but can extend to the shoulder [65].

Diabetic truncal neuropathy

Diabetic thoracoabdominal neuropathy or radiculopathy presents primarily in middle-aged or older individuals and is characterized by sudden onset of pain or dysaesthesia, occasionally accompanied by hyperaesthesia. Pain may be described as burning, tearing, jabbing, and boring and is usually worse at night. Diabetic truncal neuropathy is almost always unilateral, half encircling the trunk in a root-like distribution. Peak pain occurs a few days after onset, but may continue for weeks to months. Depending on the site of the pain, it may be confused with a pulmonary, cardiac, or gastrointestinal origin for the pain. Abdominal muscle herniation is a rare feature and occurs predominantly in middle-aged men, involving 3–5 adjacent nerve roots between T6 and T12 (Figure 45.3a). Weight loss is a recognized phenomenon, with 7–18 kg loss occurring in >50% of cases [66]. This should alert the physician to exclude underlying malignancy. The prognosis of truncal neuropathy is good, with remission usually within 16 weeks [67].

Diabetic amyotrophy

Diabetic amyotrophy, also known as proximal motor neuropathy, proximal diabetic neuropathy, diabetic lumbosacral plexopathy, or femoral neuropathy, commonly presents with unilateral proximal muscle weakness and wasting of the obturator, iliopsoas, adductor, and quadriceps muscles (Figure 45.3b). The pain is constant, severe, deep, aching, and burning, with nocturnal exacerbation, and is often refractory to standard analgesia including high-dose opiates. Characteristically, it occurs in the lower back or buttock on the affected side, or may be felt as extending from the hip to the knee [68]. There is frequently associated cachexia with substantial weight loss, which tends to be regained during the recovery phase [69].

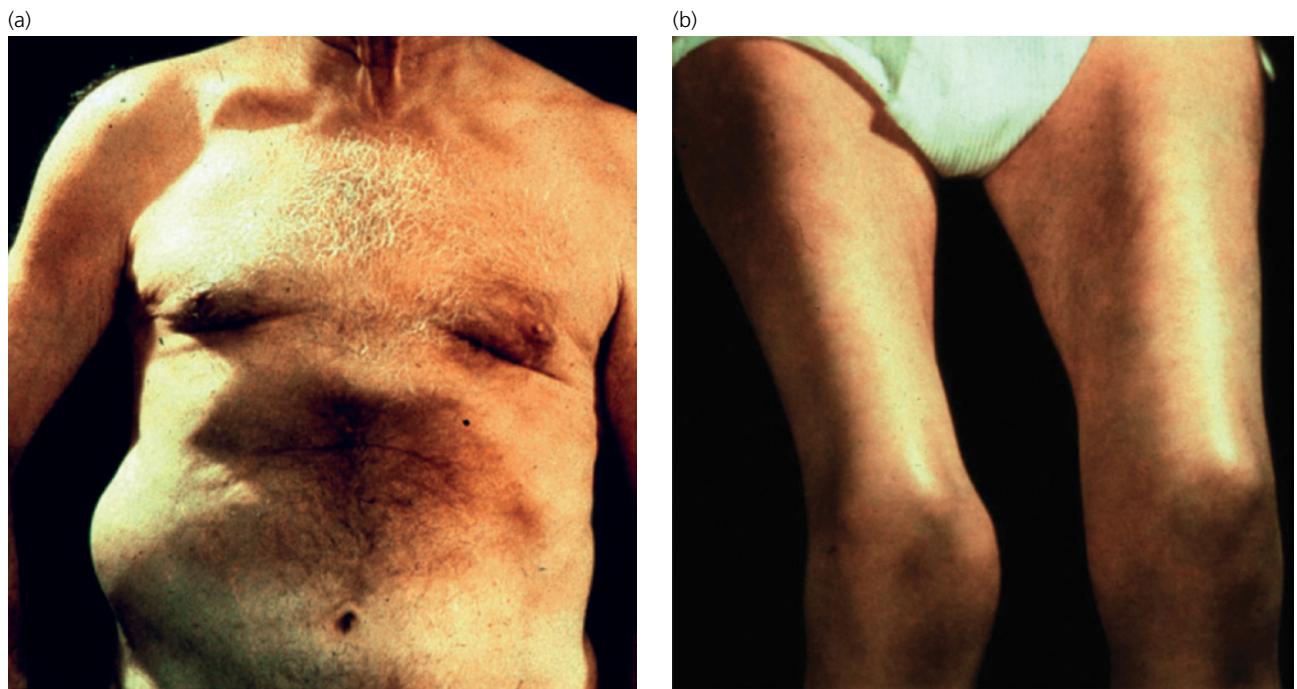

Figure 45.3 (a) Diabetic truncal neuropathy (thoracoabdominal neuropathy or radiculopathy) leading to herniation of the oblique abdominal muscle. (b) Diabetic amyotrophy (proximal neuropathy): pronounced bilateral atrophy and paresis of the quadriceps muscle.

Central nervous system abnormalities in structure and function

Early post-mortem studies demonstrated extensive neurodegeneration in the cerebral cortex, midbrain, and cerebellum [70, 71]. *In vivo* brain imaging has confirmed widespread structural and functional alterations in the brain of individuals with diabetic sensorimotor polyneuropathy without overt cerebrovascular disease [72–76]. Anatomical and functional changes within the somatosensory cortex [73] and spinal cord [77] and a reduction in spinal cord cross-sectional area at C4/5 and T3/4 have been demonstrated in individuals with diabetic sensorimotor polyneuropathy [78]. Magnetic resonance imaging has also shown an excess of subcortical and brainstem lesions in people with type 1 diabetes and diabetic sensorimotor polyneuropathy [79]. In a functional magnetic resonance imaging (fMRI) study, peripheral thermal stimulation was associated with increased activation in somatosensory (right insula, left caudate nucleus, frontal gyrus, and cingulate cortex) and cognition-related (right temporal lobe, left hippocampus, and left fusiform gyrus) cerebral areas of people with diabetic sensorimotor polyneuropathy [80]. Individuals with painful diabetic neuropathy demonstrate enhanced limbic and striatal activation, suggesting a central nervous system contribution to the development and maintenance of neuropathic pain [81]. A study utilizing fMRI and quantitative sensory testing showed altered functional connectivity in the ventrolateral periaqueductal grey of individuals with painful diabetic neuropathy [82].

The Maastricht study showed that people with pre-diabetes had increased lacunar infarcts and white matter hyperintensities independent of major cardiovascular risk factors, which was comparable to 2.1 years of brain ageing [83]. A larger population-based study confirmed that pre-diabetes was associated with smaller total and white matter volume and pre-diabetes and diabetes were both independently associated with accelerated cognitive decline [84]. Weinstein et al. [85] showed reduced occipital grey matter volume and white matter integrity in adults with pre-diabetes. We have

recently also shown that corneal nerve loss is associated with the presence of white matter hyperintensities [86] and cognitive decline in individuals with mild cognitive impairment and dementia [87, 88].

Several studies have assessed central nervous system function utilizing event-related potentials, evoked potentials in response to stimulation of peripheral nerves and neuropsychological assessment. Zeigler et al. [89] showed somatosensory afferent pathway dysfunction in people with type 1 diabetes, which was related to the severity of diabetic neuropathy and characterized by neuroplasticity and alteration of the cortical sensory complex and peripheral rather than spinal or supraspinal deficits [89]. Zeigler et al. [90] have also utilized positron emission tomography (PET) and [¹⁸F]-2-deoxy-2-fluoro-D-glucose (FDG) to show a reduction in cerebral glucose metabolism in individuals with type 1 diabetes and diabetic sensorimotor polyneuropathy compared to individuals with newly diagnosed type 1 diabetes and healthy volunteers. The thalamus modulates information from the periphery to the somatosensory cortex, with ascending sensory pathways in the spinal cord terminating within the ventroposterior lateral thalamic subnucleus before high-order sensory projections are sent to the cortex [91]. Proton magnetic resonance spectroscopy studies have demonstrated abnormalities in brain metabolites with a lower N-acetyl aspartate-to-creatinine ratio, suggesting thalamic neuronal dysfunction in diabetic sensorimotor polyneuropathy [92].

Pathogenesis of diabetic sensorimotor polyneuropathy

The pathogenesis of diabetic neuropathy is multifactorial [1, 93, 94], with interactions between metabolic and vascular factors:

- Increased flux through the polyol pathway, leading to accumulation of sorbitol and fructose, myo-inositol depletion, and reduction in Na⁺K⁺-ATPase activity.

- Disturbances in n-6 essential fatty acid and prostaglandin metabolism, altering nerve membrane structure and lead to microvascular and blood flow abnormalities.
- Endoneurial microvascular disease with hypoxia, generation of reactive oxygen species (oxidative stress), activation of the redox-sensitive transcription factor NFkB, and increased activity of protein kinase C (PKC).
- Reduced expression of neurotrophic factors such as nerve growth factor (NGF), neurotrophin-3 (NT-3), and insulin-like growth factor (IGF) and alterations in axonal transport.
- Accumulation of non-enzymatic advanced glycation end-products (AGEs) on nerve and/or vessel proteins.
- Immunological processes with autoantibodies to the vagal nerve, sympathetic ganglia, and adrenal medulla.
- Cytokine activation with increased interleukin 2 (IL-2), IL-6, tumour necrosis factor α (TNF- α), and inflammation.

Diagnosis of diabetic sensorimotor polyneuropathy

The assessment of diabetic neuropathy must include a careful and focused history. The symptomatology of diabetic sensorimotor polyneuropathy depends on the type of nerve fibre involved, with large-fibre dysfunction leading to numbness, tingling, or poor balance, whereas small-fibre neuropathy leads to paraesthesia and burning, stabbing, or electric shock-like pain in the feet [28, 30]. Alternative aetiologies of neuropathy should be actively diagnosed and treated, including chronic inflammatory demyelinating polyneuropathy (CIDP), vitamin B₁₂ deficiency, hypothyroidism, and uraemia [95]. Screening for neuropathy should begin from diagnosis in people with type 2 diabetes, and after five years in those with type 1 diabetes and in people with prediabetes and neuropathic symptoms [1].

There are several tests for the assessment of diabetic sensorimotor polyneuropathy (Table 45.2). The Neuropathy Disability Score (NDS) is a reliable and reproducible screening tool to identify the presence and severity of neuropathy (Figure 45.4). It involves testing sensory modalities including pain sensation (pin-prick), temperature perception (using hot and cold rods), vibration (128 Hz tuning fork), and tendon reflexes, with an NDS of >6/10 being an independent risk factor for foot ulceration [96]. All individuals should undergo an annual 10 g monofilament and pedal pulse evaluation to assess for the risk of foot ulceration [1]. However, a normal response to the 10 g monofilament should not be used to exclude diabetic sensorimotor polyneuropathy, as it only detects advanced neuropathy. In a recent systematic review it had a very poor diagnostic utility, with a sensitivity of 88% and specificity of only 55%, when nerve conduction was used to diagnose diabetic neuropathy [97]. The alternative 1 g monofilament may be better for detecting earlier neuropathy [98].

Diagnostic definitions

In 2010 the Toronto Diabetic Neuropathy Expert group [34] defined diabetic sensorimotor polyneuropathy as:

- Confirmed* – abnormal nerve conduction and a symptom or sign of neuropathy.
- Probable* – two or more of the following: neuropathic symptoms, decreased distal sensation, or decreased/absent ankle reflexes.
- Possible* – any of the following symptoms: decreased sensation, positive neuropathic sensory symptoms (e.g. numbness while

Table 45.2 Tests to assess diabetic peripheral neuropathy.

	Advantage	Disadvantage	Type of nerve
Nerve conduction studies	Sensitive, specific, reproducible, and easily standardized	Must be done by trained professional Only assesses large-fibre damage	Large fibre
Quantitative sensory testing	Reproducible and reliable	Subjective	Large and small fibre
Skin biopsy	Gold standard, reliable, and reproducible	Invasive procedure Needs specialized laboratory service	Small fibre
Corneal confocal microscopy	Rapid, reproducible, non-invasive Can detect small-fibre damage and track progression	Must be done by trained professional	Small fibre
Sudoscan	Non-invasive, easy to perform, and very quick (<5 min) No specialist training of assessor required	Low specificity	Small fibre
Laser Doppler imaging FLARE	Non-invasive Sensitive, specific	20 min to perform the procedure due to heating of the skin	Small fibre

sleeping, prickling/stabbing, burning or aching pain) predominantly in the toes, feet, or legs, OR signs of symmetrical decrease of distal sensation or decreased/absent ankle reflexes.

Small-fibre abnormality can be diagnosed using the following criteria [34]:

- Definite* – presence of length-dependent symptoms, clinical signs of small-fibre damage, normal sural nerve conduction, and reduced intra-epidermal nerve fibre density at the ankle and/or abnormal thermal thresholds at the foot.
- Probable* – presence of length-dependent symptoms, clinical signs of small-fibre damage, and normal sural nerve conduction.
- Possible* – presence of length-dependent symptoms and/or clinical signs of small-fibre damage.

Neuropathy symptoms

Questionnaires are a subjective method to assess and quantify the severity of neuropathic symptoms and pain. The McGill Pain Questionnaire is widely used to evaluate neuropathic pain [99]. There are also other questionnaires specifically developed to quantify neuropathic pain, which include the Brief Pain Inventory (BPI) [100], Neuropathic Pain Questionnaire (NPQ) [101], Neuropathic Pain Symptom Inventory (NPSI), and Douleur Neuropathique 4 (DN4) [102]. The Neuropathic Symptom Profile (NSP) has been validated to stage the severity of neuropathy [103].

Quantitative sensory testing

Quantitative sensory testing is a psychophysical method used to quantify somatosensory function in response to controlled stimuli [104]. It is a sensitive method of detecting small-fibre neuropathy, particularly in those individuals with normal nerve conduction studies [105], and may be used where no definitive quantitative structural

Figure 45.4 Measurement of temperature sensation using cold and warm rods (a), Achilles tendon reflex (b), pain sensation using a Neurotip (c), and vibration perception using a tuning fork (d).

assessment of small nerve fibres such as skin biopsy or corneal confocal microscopy (CCM) can be undertaken, as well as for monitoring of somatosensory deficits, and of evoked pain, allodynia, and hyperalgesia. When performing quantitative sensory testing, it has been recommended to use predefined standardized stimuli and instructions, validated algorithms for testing, and reference values corrected for anatomical site, age, and sex. The interpretation should always take into account the clinical context, individuals with language and cognitive difficulties, and anxiety [68, 104].

Vibration perception threshold

Vibration perception threshold can be assessed using a hand-held biothesiometer and correlates with the severity of diabetic neuropathy. A vibration perception threshold of $>25\text{ V}$ is a strong predictor for incident foot ulceration [106].

Nerve conduction studies

Nerve conduction studies (Figure 45.5) are an objective, sensitive, specific, and reproducible method to assess the severity of diabetic sensorimotor polyneuropathy [107]. However, they only evaluate large myelinated nerve fibres and cannot detect early small-fibre neuropathy and have relatively high intra-individual variability based on electrode placement and limb temperature [108].

Skin biopsy

Skin biopsy can be used to quantify intra-epidermal and dermal nerve fibres and autonomic nerve fibres. It enables direct visualization of thinly myelinated and unmyelinated nerve fibres, which are

Figure 45.5 Nerve conduction studies.

the earliest to be affected in diabetic polyneuropathy (Figure 45.6). The European Federation for Neurological Societies recommends a punch skin biopsy at the distal leg or proximal thigh for the diagnosis of small-fibre neuropathy [109]. For diagnostic purposes in peripheral neuropathies, the guideline recommends performing a 3 mm punch skin biopsy at the distal leg and quantifying the linear density of intra-epidermal nerve fibres (IENF) in at least three 50 µm thick sections per biopsy, by bright-field immunohistochemistry or immunofluorescence with anti-protein gene product 9.5 antibodies (PGP 9.5) (Figure 45.7). The assessment of IENF and their densities (IENFD) is currently advocated in the assessment of idiopathic small-fibre neuropathy (ISFN) [110].

Corneal confocal microscopy

Corneal confocal microscopy (CCM) (Figure 45.8) is a rapid, non-invasive, objective, and reproducible ophthalmic imaging technique used to evaluate corneal nerve morphology and has been established

as a surrogate marker for peripheral neuropathies [111]. CCM allows direct visualization of peripheral nerves [112, 113], with high sensitivity and specificity to diagnose [38, 114, 115] and predict the development [116] and progression [117] of diabetic sensorimotor polyneuropathy (Figure 45.9) and repair after intervention [118–120]. CCM correlates with IENFD [114] and has comparable sensitivity and specificity to IENFD for the diagnosis of diabetic sensorimotor polyneuropathy [37, 121]. The parameters used to quantify the corneal sub-basal nerve plexus include corneal nerve fibre length (CNFL), corneal nerve branch density (CNBD), and corneal nerve fibre density (CNFD) [122]. CCM has been extensively used to identify small nerve fibre damage in a range of peripheral neuropathies including diabetic neuropathy [123, 124], HIV neuropathy [125], chemotherapy-induced peripheral neuropathy (CIPN) [126], CIDP [127], Fabry's disease [128], and ISFN [129]. CCM can detect subclinical small nerve fibre damage in those with impaired glucose tolerance [130] and children with type 1 diabetes [131].

tes [40]. A reduction in corneal nerve fibres is also associated with the development of neuropathy [131] and foot ulceration with Charcot foot [132]. CCM may be an ideal technique to monitor progression of diabetic neuropathy as it is non-invasive and hence reiterative [133].

Optical coherence tomography

Optical coherence tomography is an imaging technique commonly available in most ophthalmology clinics and was developed for *in vivo* assessment of the retina to assess macular oedema. It has been used to quantify retinal nerve fibre layer loss in individuals with multiple sclerosis [134, 135]. Retinal nerve fibre layer loss has been reported in increasing severity of diabetic neuropathy [136] and was greater in individuals with compared to without diabetic neuropathy over four years [137]. Longitudinal and prognostic as well as interventional studies using optical coherence tomography as a surrogate marker of axonal loss are required before routine use of this modality can be recommended to assess diabetic neuropathy.

Sudoscan

Sudoscan uses galvanic principles [138, 139] by applying a low-voltage current to measure sweat gland function based on sweat chloride concentrations using reverse iontophoresis and chronoamperometry [140] to measure the electrochemical skin conductance on the hands and feet. It is non-invasive and easy to perform within five minutes in a clinical setting [138] and has been suggested as a potential screening tool for diabetic sensorimotor polyneuropathy and cardiac autonomic neuropathy during annual assessment in a diabetes clinic [138, 141].

Laser doppler imaging FLARE

Laser Doppler imaging FLARE (LDI FLARE) measures axon-mediated neurogenic vasodilatation using laser Doppler imaging in response to heating the skin on the dorsum of the foot to 44 °C [142]. It is sensitive and specific for early small-fibre neuropathy in diabetes [142, 143]. The main disadvantage of LDI FLARE is that it takes 20 minutes to undertake the procedure [142].

Management

Intensive diabetes therapy and metabolic factors

Several landmark studies have shown that intensive glycaemic management can prevent or delay the progression of neuropathy in people with type 1 diabetes [144]. HbA_{1c}, smoking status, and high-density lipoprotein cholesterol are associated with neuropathy [145, 146]. The Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR) reported a 20% decrease in the incidence of diabetic sensorimotor polyneuropathy for a 2% (22 mmol/mol) decrease in HbA_{1c} over 4 years of follow-up [147]. The DCCT showed a 64% risk reduction for incident diabetic sensorimotor polyneuropathy with intensive glucose management over 6.5 years of follow-up [148]. The EDIC study confirmed the role of metabolic memory as, despite HbA_{1c} in the two groups being similar (8.1% vs 8.2%; 65% vs 67 mmol/mol) at 5 years after close-out of the DCCT, the prevalence and incidence of diabetic sensorimotor polyneuropathy and cardiac autonomic neuropathy remained significantly lower in individuals on intensive compared to standard therapy [149].

However, in people with type 2 diabetes, the situation is more complex and the evidence for the role of improved glycaemic management in slowing down progression of neuropathy is limited [150–152]. Although the ACCORD trial showed a significant reduction in loss of sensation to light touch after five years of intensive glycaemic management (HbA_{1c} < 6.5%; 48 mmol/mol), this was only one of four neuropathy endpoints that improved [151]. Furthermore, the intensive glucose-lowering regimen was associated with increased overall mortality (hazard ratio 1.22, 95% confidence interval [CI] 1.01 to 1.46, p = 0.04) [153]. Self-reported diabetic sensorimotor polyneuropathy conferred a higher risk of mortality in the intensive glycaemic management group than higher HbA_{1c} and those on aspirin [18].

There is an association between plasma triglycerides and remnant lipoproteins and the risk of diabetic sensorimotor polyneuropathy [8]. Statins, ezetimibe, and fibrates may reduce the progression and severity of diabetic neuropathy [154, 155].

Diet and behavioural interventions

The Diabetes Prevention Program demonstrated that behavioural changes and treatment with metformin reduced the incidence of diabetes in those with impaired glucose tolerance [156]. In the Impaired Glucose Tolerance Causes Neuropathy study, diet and exercise counselling according to the Diabetes Prevention Program protocol in those with impaired glucose tolerance resulted in increased IENFD and an improvement in neuropathic pain [157].

Weight loss

Incretin-based therapies have valuable effects on diabetes-related complications, independent of their glucose-lowering abilities, mainly mediated by their anti-inflammatory and anti-oxidative stress properties [158]. In a pilot study of people with type 2 diabetes and mild to moderate diabetic sensorimotor polyneuropathy, 18 months of treatment with exenatide, compared with glargine, had no effect on the Michigan Neuropathy Screening Instrument and IENFD [159]. However, a recent randomized controlled trial (RCT) has shown that once-weekly exenatide and pioglitazone or basal bolus insulin resulted in a ~3% (33 mmol/mol) reduction in HbA_{1c} and corneal nerve regeneration, despite a ~4 kg weight gain [160].

In a meta-analysis of 10 studies, there was greater remission and lower risk of microvascular and macrovascular disease and

mortality over five years in individuals undergoing bariatric surgery [161]. Bariatric surgery is associated with corneal nerve regeneration within 12 months in those with morbid obesity, both with [120] and without diabetes [162].

Disease-modifying treatment

Pancreas transplantation for type 1 diabetes improves nephropathy and retinopathy [163, 164]. A 10-year follow-up of neuropathy post-transplantation showed an improvement in sudomotor function in the hand and foot within one year, which was maintained throughout 10 years. However, there was no impact on nerve conduction velocity or autonomic function [165, 166]. We initially showed regeneration of corneal nerves within six months of simultaneous pancreas and kidney transplantation in individuals with type 1 diabetes and severe diabetic sensorimotor polyneuropathy [118, 167]. Recently we have shown that the early improvement in small nerve fibres is followed by an improvement in symptoms at 24 months and nerve conduction at 36 months [119]. Islet cell transplantation also improves nerve conduction velocity and amplitude scores [168]. This highlights the need for an adequate trial duration or more sensitive endpoints such as CCM for clinical trials of disease-modifying treatment for diabetic neuropathy.

Treatment based on pathogenetic concepts

Over the last 40 years we have witnessed the failure of multiple clinical trials of numerous pathogenetic treatments of diabetic sensorimotor polyneuropathy [169]. Although some drugs showed promising results in phase II trials, none made it past phase III to gain US Food and Drug Administration (FDA) approval as disease-modifying treatments for diabetic neuropathy [114, 170]. It is conceivable that drugs interfering with the pathogenesis of diabetic neuropathy may be most effective in early phases of the disease to prevent rather than reverse and repair nerves. Equally, the endpoints advocated by the FDA may not be sufficiently sensitive to detect nerve repair within the duration of most phase III trials lasting 12–24 months (Table 45.3).

Alpha-lipoic acid

Alpha-lipoic acid is an antioxidant and is claimed to be a disease-modifying therapy for diabetic neuropathy. However, it has never been approved by the FDA or endorsed by the ADA [1], as pivotal phase III studies failed to show efficacy in diabetic sensorimotor polyneuropathy [171]. A meta-analysis of all the major trials of alpha-lipoic acid including Symptomatic Diabetic Neuropathy (SYDNEY), Alpha-Lipoic Acid in Diabetic Neuropathy (ALADIN) I and II, and Neurological Assessment of Thiocotic Acid in Diabetic Neuropathy (NATHAN) showed that 600 mg of intravenous alpha-lipoic acid over three weeks significantly improved neuropathic symptoms, but without long-term benefits on symptoms, quantitative sensory testing, or nerve conduction velocity [171].

Aldose reductase inhibitors

Increased aldose reductase enzyme activity causes an accumulation of sorbitol and fructose and aldose reductase inhibitors block the polyol pathway. Aldose reductase inhibitors have been tested in phase III clinical trials, but have not been approved by the FDA due to lack of efficacy or toxicity [172, 173]. Epalrestat is marketed in Japan and India based on the Aldose Reductase Inhibitor-Diabetes Complications Trial, which showed a delay in progression of diabetic neuropathy over three years in Japanese individuals with mild neuropathy [174]. Ranirestat showed a significant improvement in

Table 45.3 Treatment options for painful diabetic neuropathy.

Approach	Compound/measure	Dose per day	Remarks	NNT (95% CI)
Optimal glycaemic management	Behavioural modification, OAD, insulin	Individual adaptation	Target HbA _{1c} ≤ 6.5–7% (48–53 mmol/mol)	–
Pathogenesis-oriented treatment	α-Lipoic acid (thioctic acid) ^a	600 mg IV infusion 600–1800 mg orally	RCT duration 3 wk FSP; RCT duration 4 yr	6.3 ^b 2.8–4.2 ^b

summed motor nerve (peroneal, tibial, and median) conduction velocity over 36 months without a significant effect on sensory nerve function [173].

Vascular endothelial growth factor

Vascular endothelial growth factor (VEGF) has an adverse effect on retinopathy by inducing angiogenesis and macular oedema, but is also thought to be neuroprotective [175]. Quattrini et al. showed a reduction in VEGF associated with intraepidermal nerve fibre loss in skin biopsies from individuals with diabetic sensorimotor polyneuropathy [176]. A double-blind RCT of 50 individuals showed an improvement in neuropathic symptoms, but no improvement in quantitative sensory testing or nerve conduction [177].

Angiotensin-converting enzyme inhibitors and calcium channel blockers

Given that microangiopathy is associated with a reduction in nerve conduction velocity and loss of myelinated nerve fibres [178], we randomized normotensive individuals with mild diabetic sensorimotor polyneuropathy to trandolapril or placebo and showed a significant improvement in nerve conduction velocity, amplitude, and F-wave latency over 12 months [179]. Subsequently we also showed

that candesartan improves endothelial function and myogenic tone of resistance vessels in people with type 2 diabetes [180]. The Delapril and Manidipine for Nephroprotection in Diabetes (DEMAND) trial randomized 140 individuals to a combination of manidipine and delapril, delapril alone, or placebo [181]. After three years the development of diabetic sensorimotor polyneuropathy was lowest in individuals on manidipine and delapril (23.5%) compared to delapril (28.9%) and placebo (38.6%). Furthermore, of 60 individuals with diabetic sensorimotor polyneuropathy at baseline, 33.3% showed regression of neuropathy in the manidipine and delapril group compared to 28.9% on delapril and 8.3% on placebo [181].

Treatment of painful diabetic neuropathy

Although tight glycaemic management may prevent the progression of diabetic neuropathy, there is no evidence that improved glycaemic levels improve pain in diabetic sensorimotor polyneuropathy. A therapy that achieves ~30–50% pain relief is considered to be moderately effective, while >50% pain relief is considered a good outcome [182]. A recent systematic review has concluded that duloxetine, venlafaxine, pregabalin, oxcarbazepine, tricyclic antidepressants, atypical opioids, and botulinum toxin were more effective than placebo for relieving neuropathic pain, but quality of

life was poorly reported, studies were short term, and the drugs had substantial dropout rates of ~10% [183].

The limited benefit of any one agent alone reflects the complex aetiology of neuropathic pain. There is increasing recognition that *one size does not fit all* and, rather than blindly trying different therapies until one works, we should consider better clinical phenotyping and targeted therapies [184]. Superficial clinical phenotyping in relation to symptomatology does not improve the response to therapy [185]. However, more detailed phenotyping using quantitative sensory testing has shown that individuals with an irritable nociceptor compared to a non-irritable nociceptor phenotype had a significantly greater response to oxcarbazepine and reduced the overall number needed to treat (NNT) from 6.9 to 3.9 [186]. In a smaller study the relative efficacy of 5% lignocaine was assessed in 15 individuals with irritable nociceptors and 25 individuals without irritable nociceptors; it showed a greater effect in those with irritable nociceptors, on pain paroxysms and deep aching pain [187]. Rate-dependent depression of the spinal H reflex has been suggested as a marker for spinal disinhibition in painful diabetic neuropathy [188]. This measure differentiates individuals with type 1 diabetes and painful diabetic neuropathy in relation to their response to duloxetine compared to pregabalin, potentially ushering in a personalized medicine approach in the treatment of painful diabetic neuropathy [189].

Neurological pathways implicated in mood disorders share neurotransmitters with pathways associated with pain processing [190]. It is therefore unsurprising that there is a dual utility in alleviating neuropathic pain.

Tricyclic antidepressants

Tricyclic antidepressants indirectly modulate the opioid system in the brain via serotonergic and norepinephrine neuromodulation, among other properties [191–193]. Tricyclic antidepressants require uptitration to effective doses, often over a period of 6–8 weeks before reasonable effects are noted, hence medication persistence may sometimes be compromised [194]. Tricyclic antidepressants remain first- or second-line therapies in all five international guidelines on pain management in diabetic sensorimotor polyneuropathy, with most citing amitriptyline as the tricyclic antidepressant of choice. A joint report on painful diabetic neuropathy from the American Academy of Neurology, the American Association of Neuromuscular and Electrodiagnostic Medicine, and the American Academy of Physical Medicine and Rehabilitation concluded that amitriptyline has the greatest efficacy among tricyclic antidepressants [195]. There is currently insufficient evidence for the routine use of imipramine [196]. Tricyclic antidepressants are contraindicated in people with orthostatic hypotension, unstable angina, myocardial infarction within six months, heart failure, history of ventricular arrhythmias, significant conduction system disease, and long QT syndrome, and should be used with caution, particularly in older people [1].

Serotonin–norepinephrine reuptake inhibitors

Serotonin–norepinephrine reuptake inhibitors primarily exert their effect via inhibiting serotonin and norepinephrine reuptake resulting in the excitation of inhibitory descending pathways [197]. Duloxetine is approved by the FDA for the treatment of painful diabetic neuropathy and both 60 mg and 120 mg doses have been found to be effective [198], with a 50% pain reduction by 12 weeks (NNT = 5; 95% CI 4 to 9) [199]. Duloxetine has a superior safety profile compared to amitriptyline owing to the comparably lower

rates of anticholinergic side effects. The most frequent side effects of duloxetine (60/120 mg/d) include nausea (16.7/27.4%), somnolence (20.2/28.3%), dizziness (9.6/23%), constipation (14.9/10.6%), dry mouth (7.1/15%), and reduced appetite (2.6/12.4%). A *post hoc* analysis of three pooled double-blind, placebo-controlled trials evaluating the use of duloxetine in older individuals (aged >65 years) showed good safety and efficacy [200]. Venlafaxine has shown efficacy in painful diabetic neuropathy (NNT 3.1) with superiority to duloxetine in some studies, but there is a lack of larger trials showing this effect [201–203]. It is not approved by the FDA for the treatment of diabetic neuropathy. Desvenlafaxine has shown efficacy in a single RCT [204].

Anticonvulsants

Carbamazepine has been widely used for many years in the treatment of neuropathic pain, especially in the management of trigeminal neuralgia. However, Cochrane reviews of carbamazepine [205] and oxcarbazepine have shown limited efficacy in painful diabetic sensorimotor polyneuropathy [206]. There is also limited evidence to support the use of topiramate [207], lamotrigine [208–210], or lacosamide [210, 211] in painful diabetic neuropathy.

Alpha 2 delta ligands

Gabapentin is a lipophilic analogue of gamma-aminobutyric acid (GABA) that binds to the α -2/ δ -1 subunit of the voltage-gated calcium channel on the presynaptic membrane and reduces excitability of chiefly glutaminergic neurones [212]. A significant improvement in pain scores can be seen eight weeks after starting gabapentin [213]. A systematic review of 35 studies in 727 individuals with neuropathic pain found that gabapentin was effective in alleviating pain, but its effectiveness was questionable at the low doses (300 mg twice a day) that are commonly prescribed [214]. There is a reasonable balance between safety and efficacy for the treatment of painful diabetic neuropathy [215].

Pregabalin, another analogue of GABA, has higher potency and FDA approval based on several RCTs showing efficacy in the treatment of painful diabetic neuropathy [216–218]. Somnolence is a common side effect of pregabalin, although in healthy volunteers it enhances slow-wave sleep, which is deep sleep and associated with consolidation of memory. Pregabalin improves subjective sleep and quality of life in individuals with painful diabetic neuropathy [219–221]. Side effects include oedema and mood disturbance and sudden discontinuation have been linked to the development of seizures, cerebral oedema, and encephalopathy [222].

Opioid analgesia

Tramadol is a centrally acting synthetic non-selective agonist with affinity at Mu, Delta, and Kappa opioid receptors, preferential for the Mu receptor, and also inhibits norepinephrine and serotonin reuptake [223]. The efficacy of tramadol in neuropathic pain has been determined in small, largely inadequate studies with a potential risk of bias [223]. A meta-analysis showed an NNT of 4.4 (95% CI 2.9 to 8.9) for 50% pain reduction, but it concluded that there were insufficient data of adequate quality to endorse tramadol as an effective therapy for neuropathic pain [223].

Tapentadol is a novel, centrally active analgesic with a dual mode of action: Mu-opioid receptor agonist and norepinephrine reuptake inhibitor. A 12-week open-label study demonstrated a 30% pain reduction in 65% of the individuals examined and a 50% pain reduction in 34.9% of enrolled individuals [224]. These findings

were confirmed in a 12-week study, leading to FDA approval in 2012, of modified-release tapentadol for the treatment of neuropathic pain [225].

Topical medications

The use of topical treatments may be particularly useful for persons who cannot tolerate systemic therapies due to adverse effects [226]. Furthermore, the risk of drug–drug interactions is also significantly reduced, making topical therapies more attractive for a growing number of individuals with multiple comorbidities and polypharmacy.

Capsaicin

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) is a selective transient receptor potential vanilloid 1 (TRPV1) agonist, which is expressed on small nerve fibres. The activation of TRPV1 and release with depletion of substance P are claimed to reduce peripheral painful stimuli [227, 228]. A double-blind placebo-controlled trial using 0.0075% topical capsaicin found a significant reduction in pain as measured by physicians' global evaluation and visual analogue scales [229]. However, the use of topical capsaicin is limited by the frequency of application (four times daily) and burning pain frequently induced on application. It is of concern that a topical capsaicin patch increases thermal thresholds and reduces IENFD, with total denervation in some cases, which could increase the risk of diabetic foot ulceration [230].

Capsaicin is currently recommended as third-line therapy by the UK National Institute for Health and Care Excellence and as second-line therapy by the American Academy of Neurology for the treatment of neuropathic pain. In a 12-week double-blind trial in individuals with painful diabetic neuropathy, the 8% capsaicin patch improved both pain and sleep quality significantly [231]. In a 52-week RCT, up to seven consecutive 30-minute treatments with the 8% capsaicin patch as add-on to standard care was associated with sustained pain relief without apparent adverse effects on sensory function. In July 2021, the FDA approved the 8% capsaicin patch for the treatment of painful diabetic neuropathy.

Lidocaine

Lidocaine plasters (5%) applied for 18 hours per day provide effective relief in painful diabetic neuropathy. A systematic review of 38 studies found significant pain reduction using the 5% lidocaine patch, comparable to amitriptyline, capsaicin, gabapentin, and pregabalin [226]. The lidocaine patch is associated with fewer and less clinically significant side effects compared to systemic agents [226].

Isosorbide dinitrate

Impaired nitric oxide (NO) synthesis plays a role in the pathogenesis of diabetic neuropathy. Nitroglycerin releases NO, suggesting a potential role for people with diabetic neuropathy [161]. Additionally, the release of neuronal NO synthase in dorsal root ganglion cells and the spinal cord may contribute to spinal sensory processing and neuronal plasticity with pain relief [232]. A small double-blind trial ($n = 22$) found a significant reduction in pain intensity [233]. A further case series ($n = 18$) reported that individuals treated with glyceryl-trinitrate (GTN) patches showed a reduction in pain scores [234]. Topical lidocaine and GTN patches may be used in combination to provide 24-hour pain cover with alternating 12-hour application of each therapy.

Intravenous lidocaine

Intravenous lidocaine has been used for many years in the treatment of pain produced by nerve injury. Intravenous novocaine was used successfully to provide analgesia to burns individuals as early as 1943 [235]. Lidocaine modifies sodium channel expression, reducing peripheral nociceptive sensitization [236], and possesses anti-inflammatory properties equivalent to traditional anti-inflammatory drugs [237]. Inflammatory cytokines play a role in secondary hyperalgesia and the sensitization of the central nervous system to inappropriate pain signals [238]. A small double-blind placebo-controlled trial in 15 individuals with intractable painful diabetic neuropathy, refractory to standard treatment, showed significant analgesic effect with an intravenous lidocaine infusion that persisted for up to 28 days, without significant side effects [239].

Combination therapy

The response rates to analgesic monotherapy in painful diabetic neuropathy are limited. Combination pharmacotherapy is required in individuals who have only partial response or in whom the drug cannot be further titrated owing to intolerable side effects. In some trials, combined treatment showed superiority over monotherapy, but in others improved benefit or tolerability was not seen [240].

The only two medications with both FDA and European Medicines Agency approval for the treatment of painful diabetic neuropathy are pregabalin and duloxetine. The Combination vs Monotherapy of pregabalin and duloxetine in Diabetic Neuropathy (COMBO-DN) study was a multinational randomized double-blind, parallel-group trial designed to compare the efficacy and tolerability of high-dose monotherapy to standard-dose combination therapy with both pregabalin and duloxetine in individuals with painful diabetic neuropathy, with a limited response to standard-dose monotherapy [241]. There was no significant difference in the Brief Pain Inventory (BPI) score between the standard-dose combination therapy and high-dose monotherapy in those who did not achieve adequate pain relief on standard-dose duloxetine or pregabalin [241]. An exploratory *post hoc* analysis showed that high-dose monotherapy was more efficacious in individuals with severe pain, while combination therapy was more beneficial in those with moderate and mild pain [242]. Furthermore, the individuals who received duloxetine (60 mg/d) as initial therapy had a better response to combined duloxetine and pregabalin for evoked or severe tightness, but a greater benefit for paraesthesia or dysaesthesia with high-dose (120 mg/day) duloxetine [242, 243].

Non-invasive neuromodulation

A recent systematic review and meta-analysis assessed the potential benefits of non-invasive neuromodulation in 20 trials (18 RCTs and 2 quasi-experiments) with 1167 people with diabetes. There was a significant reduction in pain scores with central (effect size [ES] -0.75 , 95% CI -1.35 to -0.14), but not peripheral techniques (electrical and electromagnetic; ES -0.58 , 95% CI -1.23 to 0.07) [244].

Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation (TENS) modulates afferent transmission, increases the nociceptive flexion reflex threshold, and changes somatosensory evoked potentials. Individuals with painful diabetic neuropathy were treated three times weekly with micro-TENS therapy or placebo over four weeks and showed no significant difference in the percentage of individuals with $>30\%$ pain relief (micro-TENS 23% vs placebo 25%) [245]. Acupuncture-like

TENS and traditional TENS showed no significant reduction in individuals with painful diabetic neuropathy [246].

Percutaneous electrical nerve stimulation

Percutaneous electrical nerve stimulation (PENS) is an electroanalgesic therapy that combines the benefits of TENS and electroacupuncture and works by placing acupuncture-like needles in the skin to stimulate sensory nerves in the region of neuropathic pain. The only prospective crossover sham-controlled study is now over 20 years old and showed that over three weeks PENS provided short-term relief of pain and improved mood and physical activity, while reducing the need for oral analgesics [247].

Frequency-modulated electromagnetic neural stimulation

The frequency-modulated electromagnetic neural stimulation (FREMS) technique stems from the TENS family, but has a more distinct and novel mechanism of action with the delivery of a sequence of stimuli, which vary automatically in terms of pulse frequency, duration, and voltage amplitude. In a randomized study of individuals with painful diabetic neuropathy, FREMS was associated with a significant reduction in day and night pain immediately after each treatment session, and an improvement in cold sensation threshold with no change in vibration and warm sensation thresholds or nerve conduction velocity [248].

Electrical spinal cord stimulation

A systematic review comparing medical therapy with tonic spinal cord stimulation and dorsal root ganglion stimulation showed an improvement in pain after 12 months by 56% (95% CI 39 to 73) and 55% (96% CI 22 to 87), respectively. The rate of failed therapeutic stimulation was 16%, infection at the site of insertion was 4%, and problems with the lead requiring corrective surgery was 4% per year [249].

Low-intensity laser therapy

This technique is postulated to work by increasing the release of serotonin and endorphins and may have an anti-inflammatory effect. In a randomized, double-masked, sham therapy-controlled trial in 50 individuals with painful diabetic neuropathy, both groups showed a decrease in weekly mean pain scores, with the laser therapy group showing an additional non-significant reduction in weekly mean pain scores, but no effect on the Toronto Clinical Neuropathy Score, nerve conduction studies, sympathetic skin response, or quantitative sensory testing [250]. A recent study has shown an improvement in the healing of foot ulcers [251].

Acupuncture

Acupuncture involves the insertion of fine needles into the skin of predefined areas with stimulation of sensory nerves leading to pain relief. In a study comparing dragon-tiger fighting needling therapy to pregabalin 75 mg twice daily over two weeks, needling therapy showed a significant improvement in painful symptoms, quality of life, and, surprisingly, nerve conduction velocity [252]. In a recent systematic review that included 10 studies (three RCTs, two pilot RCTs, three uncontrolled clinical trials, one quasi-RCT, and one prospective case series) and 432 participants, there was an improvement in painful symptoms, but the risk of bias was high or unclear in the majority of studies [253].

Emerging therapies for painful diabetic sensorimotor polyneuropathy

Many putative treatments for diabetic neuropathy have failed in phase III trials. However, there are emerging treatments that may shift the pharmacological paradigm in the treatment of neuropathic pain.

Dextromethorphan

Dextromethorphan is a *N-methyl-D-aspartate* (NMDA) receptor antagonist and serotonin reuptake inhibitor. When administered as monotherapy, dextromethorphan has limited bioavailability due to rapid catabolism by hepatic cytochrome P4502D6, and therefore must be administered with a potent P4502D6 inhibitor such as quinidine. Shaibani et al. evaluated two doses of dextromethorphan/quinidine (DMQ) 45/30 mg or DMQ 30/30 mg in a double-blind placebo-controlled trial ($n = 379$) and showed that DMQ was significantly superior to placebo with a reasonable safety profile [254].

EMA401

EMA401 is a highly selective angiotensin II type 2 receptor antagonist. A phase 2 multicentre placebo-controlled double-blind trial in 183 individuals with post-herpetic neuralgia showed a significant reduction in a 11-point numerical rating scale with EMA401 (100 mg twice daily) over 28 days [255]. Two phase 2b multicentre, randomized, double-blind studies of EMA401 in people with post-herpetic neuralgia (EMPHENE; randomized 1:1:1 to either placebo, EMA401 25 mg, or EMA401 100 mg twice daily) and painful diabetic neuropathy (EMPADINE; randomized 1:1 to placebo or EMA401 100 mg twice daily) have demonstrated a non-significant reduction in pain score over 12 weeks [256]. However, both studies were prematurely terminated due to pre-clinical hepatotoxicity with long-term dosing observed in other ongoing studies and only enrolled 129/360 (EMPHENE) and 137/400 (EMPADINE) participants.

Cabinetide

Cabinetide is a non-haematopoietic peptide of erythropoietin that interacts selectively with the innate repair receptor mediating tissue protection [257], as well as being an antagonist of the TRPV1 receptor [258], mediating a disease-modifying and analgesic effect, respectively. In two phase 2b studies it led to a significant reduction in painful neuropathy scores and small nerve fibre regeneration in the cornea and skin in individuals with diabetic painful neuropathy [259] and sarcoid neuropathy [260].

Tanezumab

Tanezumab is the first fully humanized monoclonal antibody that binds circulating and tissue nerve growth factor (NGF), preventing it from binding to tropomyosin receptor kinase A and p75 and reducing the expression of pain-related transmitters, receptors, and ion channels. However, in 2010 an FDA hold was placed on anti-NGF mAb clinical studies, because of reports of serious joint-related adverse events and concerns of sympathetic nerve damage. Therefore, to date there is only one report from a prematurely terminated clinical trial reporting after eight weeks. Individuals with diabetic painful neuropathy were randomized to subcutaneous tanezumab 20 mg administered on day 1 and week 8 ($n = 38$) or placebo ($n = 35$). There was a significant reduction in the average pain score and significantly higher percentages of tanezumab-treated individuals had $\geq 30\%$, $\geq 50\%$, and $\geq 70\%$ reductions in average pain

scores at week 4 and week 8, with no change in the neuropathy impairment score and quantitative sensory testing, though there was a non-significant reduction in IENFD [261]. In 2017 the FDA granted fast-track status for tanezumab as a non-opioid pain medication, particularly for hip and knee osteoarthritis, and trials are also being currently undertaken for neuropathic pain.

Vitamin D

Vitamin D deficiency is highly prevalent in people with diabetes and is a risk factor for diabetic sensorimotor polyneuropathy [262, 263]. A meta-analysis in people with type 2 diabetes ($n = 1484$) confirmed a highly significant correlation between serum vitamin D3 levels and the risk of diabetic neuropathy [264]. We have shown that vitamin D deficiency is particularly associated with painful diabetic neuropathy and the odds ratio in favour of painful diabetic neuropathy was 9.8 (95% CI 2.2 to 76.4) for vitamin D deficiency ($<20\text{ }\mu\text{g/l}$) and 4.4 (95% CI 1.1 to 19.8) for vitamin D insufficiency ($<30\text{ }\mu\text{g/l}$) [265]. In an open-label prospective study, a single intramuscular dose of 600 000 IU of vitamin D3 provided significant pain relief in a cohort of individuals with painful diabetic neuropathy [266].

Diabetic autonomic neuropathy

Cardiac autonomic neuropathy

Cardiac autonomic neuropathy is the impairment of cardiovascular autonomic control in people with diabetes after the exclusion of other causes [267]. Abnormal cardiovascular autonomic reflex tests have been reported in up to 7% of individuals at diagnosis of type 1 diabetes and type 2 diabetes [268–270], with an increase in prevalence to 30% (DCCT/EDIC) after 14 years of type 1 diabetes [148, 271] and in other studies to 70% after 15 years [272].

Cardiac autonomic neuropathy is an independent risk factor for mortality in people with diabetes [267, 273]. A meta-analysis of 12 studies ($n = 1468$) showed that individuals with cardiac autonomic neuropathy have a 1.96-fold (95% CI 1.53 to 2.51) increased risk of silent myocardial ischaemia during exercise [108] and it is also associated with left ventricular dysfunction [274, 275]. Cardiac autonomic neuropathy extends cardiovascular risk stratification in people with and without cardiovascular disease and identifies individuals requiring more intensive monitoring during the perioperative period.

Diagnosis of cardiac autonomic neuropathy

The ADA recommends screening for cardiac autonomic neuropathy at diagnosis of type 2 diabetes and after five years for those with type 1 diabetes. Furthermore, individuals with microvascular complications and hypoglycaemia unawareness should be assessed for cardiac autonomic neuropathy [1, 276]. The diagnosis of cardiac autonomic neuropathy includes the documentation of symptoms and signs (Table 45.4), although there is a weak correlation between symptoms and autonomic deficits [272, 277]. Cardiac autonomic neuropathy may initially be asymptomatic, with the only sign being decreased heart rate variability with deep breathing, which can progress to a resting tachycardia ($>100\text{ bpm}$). In individuals with resting tachycardia and a history of suboptimal glucose management, where the diagnosis of cardiac autonomic neuropathy is very likely, the ADA position statement advises no additional testing [1]. It is important to exclude other causes such as idiopathic orthostatic hypotension, syncope, and postural orthostatic tachycardia syndrome [278].

Table 45.4 Clinical manifestations of diabetic autonomic neuropathy.

System	Manifestation
Cardiovascular system	Resting tachycardia, orthostatic hypotension Sudden death, malignant arrhythmia
Respiratory system	Reduced ventilatory drive to hypercapnia/hypoxaemia Sleep apnoea, respiratory arrest
Pupillary system	Pupillary reflex dysfunction, reduced dark adaptation
Gastrointestinal tract	Oesophageal motor dysfunction Diabetic gastroparesis (gastropathy) Gallbladder dysfunction Diabetic enteropathy (diarrhoea) Colonic hypomotility (constipation) Anorectal dysfunction (faecal incontinence)
Urogenital system	Diabetic cystopathy (neurogenic vesical dysfunction) Erectile dysfunction, female sexual dysfunction
Thermoregulation	Sudomotor dysfunction: distal hypohydrosis or anhidrosis, gustatory sweating Vasomotor dysfunction: vasodilatation, arteriovenous shunting, peripheral oedema
Neuroendocrine system	Hypoglycaemia-associated autonomic failure (HAAF) Defective counter-regulation, hypoglycaemia unawareness Reduced hormonal responses to orthostatic changes/exercise

Cardiovascular autonomic reflex testing

Cardiovascular autonomic reflex testing are the gold standard for diagnosing cardiac autonomic dysfunction. They are well standardized and easily performed with good sensitivity, specificity, and reproducibility, but are not widely available [279]. The diagnosis of cardiac autonomic neuropathy should be based on an abnormality in at least two of the following cardiac autonomic tests as per the Ewing criteria [267]:

- Parasympathetic function:
 - Heart rate response to deep breathing (excitation/inhibition [E/I] ratio).
 - Heart rate response to standing (30 second/15 second ratio).
 - Heart rate response to the Valsalva manoeuvre (Valsalva ratio).
- Sympathetic function:
 - Blood pressure response lying to standing.
 - Blood pressure response to a sustained handgrip.

A complete diagnostic work-up for cardiac autonomic neuropathy is presented in Table 45.5. Heart rate variability can be assessed by calculation of indices based on the R-R interval (time domain analysis) or by spectral analysis (frequency domain analysis) of an array of R-R intervals on an electrocardiogram (ECG). The Valsalva manoeuvre should not be performed in those with advanced diabetic retinopathy because of the potential risk of inducing retinal or vitreous haemorrhage.

The Toronto Neuropathy Study Group recommends that the diagnosis of cardiac autonomic neuropathy is based on at least one abnormality in heart rate response to deep breathing, standing, and the Valsalva manoeuvre, and blood pressure response to standing with the following staging [34]:

- Possible or early cardiac autonomic neuropathy defined by the presence of one abnormal cardiovagal test.
- Definite or confirmed cardiac autonomic neuropathy defined by at least two abnormal cardiovagal tests.

Part 7 Microvascular Complications in Diabetes

Table 45.5 Diabetic autonomic neuropathy of the cardiovascular, respiratory, neuroendocrine, sudomotor, vasomotor, and pupillomotor systems: clinical features, diagnostic work-up, and specific treatment.

Organ manifestations/clinical features	Diagnostic procedures	Treatment
Cardiovascular system		
Resting tachycardia and/or fixed heart rate	Basic diagnostic work-up	Cardiovascular autonomic neuropathy
Loss of circadian rhythm of blood pressure	HRV during deep breathing and after standing	In general, no specific treatment necessary (diagnosis and therapy of coronary heart disease and heart failure)
Increase in nocturnal systolic blood pressure	Postural change in blood pressure	
Orthostatic hypotension		
Exercise intolerance	Extended diagnostic work-up	Sinus tachycardia: cardioselective β -receptor blockers
Abnormal plasma catecholamines	Cardiac autonomic function tests	
Syncope and light-headedness, visual impairment, and fragility	Resting HRV (time and frequency domain)	Orthostatic hypotension
Intraoperative cardiovascular lability	E/I ratio during deep breathing; max/min 30:15 ratio	Liberal salt intake, physical training, compression stockings, avoidance of hypotensive drugs
Silent ischaemia and painless myocardial infarction	Valsalva ratio	Midodrine (α_1 -adrenergic agonist)
Diastolic dysfunction	Orthostatic test	Fludrocortisone
Arrhythmias	24 h HRV, syncope work-up	(9 α -fluorohydrocortisone)
Sudden cardiac death		
Respiratory system		
Central respiratory dysregulation with reduced respiratory drive in response to hypercapnia or hypoxia	Sleep laboratory, as applicable	CPAP therapy, as applicable
Sleep apnoea syndrome		
Respiratory arrest		
Neuroendocrine system		
Hypoglycaemia-associated autonomic dysfunction	Optimal blood glucose management	Avoidance of symptomatic and asymptomatic (often nocturnal) hypoglycaemia
Blunted or absent hormonal counter-regulation		Hypoglycaemia awareness training (blood glucose awareness training)
Hypoglycaemia unawareness		
Increased glucose threshold for hypoglycaemic symptoms		
Decreased catecholamine secretion when standing or on physical exertion		
Sudomotor and vasomotor systems		
Dyshidrosis, anhidrosis ('dry feet')	Sweat tests	Topical agents containing fat or urea
Gustatory sweating	Quantitative sudomotor axon reflex test	Avoidance of exposure to intense heat
	Thermoregulatory sweat test	Limiting intake of identified cause of sweating (dietary component)
	Silastic sweat imprint	Anticholinergic drugs, clonidine (low dose)
	Acetylcholine sweatspot test	Topical glycopyrrolate cream
	Neuropad: indicator plaster	Focal hyperhidrosis: Botulinum toxin
	Sudoscan: quantitative sudomotor test	
Pupillomotor system		
Myosis Defective pupillary reflexes Reduced dark adaptation	Clinical examination Infrared pupillometry (constriction rate, dilation rate, latency of pupillary light reflex)	Advise patient of impaired adaptation to dark and danger of night blindness Glaucoma (check intraocular pressure)

CPAP, continuous positive airway pressure; E/I, expiration/inspiration; HRV, heart rate variability.

Source: Modified from Ziegler et al. 2014 [49]. Reproduced with permission. © Georg Thieme Verlag KG.

- Severe or advanced cardiac autonomic neuropathy defined by orthostatic hypotension (asymptomatic or symptomatic), in addition to heart rate test abnormalities.

There is a circadian variation in the frequency of acute cardiovascular events, with an increased incidence in the hours of the early morning. It is therefore important to undertake 24-hour monitoring of heart rate and blood pressure when studying the neural control of the circulation [280].

Novel techniques for the diagnosis of cardiac autonomic neuropathy

CCM has been used to show that corneal nerve loss has a high diagnostic sensitivity and specificity for diabetic autonomic neuropathy [281] and sudomotor dysfunction [282]. Sudoscan

measures foot and hand electrochemical skin conductance as a marker of sympathetic sudomotor dysfunction [141] shows a sensitivity of 65% and specificity of 80% for cardiac autonomic neuropathy [141, 283]. LDI FLARE closely correlates with heart rate variability in people with type 1 diabetes [284].

Management of cardiac autonomic neuropathy

Established risk factors for cardiac autonomic neuropathy include persistent hyperglycaemia, diabetes duration, hypertension, obesity, hyperlipidaemia, and smoking [148, 151, 270–272, 285–287]. The Steno-2 trial showed that intensified multifactorial treatment to improve weight, blood pressure, glycaemia, and lipids in people with type 2 diabetes reduced the risk of cardiac autonomic neuropathy progression by 68% [288, 289]. In the DCCT, intensive

glycaemic management in people with type 1 diabetes reduced the development of cardiac autonomic neuropathy by 45% [148]. There are currently no FDA-approved disease-modifying treatments to reverse cardiac autonomic neuropathy. A small study had suggested favourable effects of alpha-lipoic acid on cardiac autonomic neuropathy [290]; however, triple antioxidant therapy (allopurinol 300 mg daily, alpha-lipoic acid 600 mg twice daily, and nicotinamide 750 mg twice daily) in individuals with mild to moderate cardiac autonomic neuropathy found no benefit [291].

Orthostatic hypotension

Orthostatic hypotension is defined by a reduction in blood pressure on standing of >20/10 mmHg (in those with blood pressure >150/90 mmHg a fall of >30/15 mmHg) without an appropriate increase in heart rate (<15 bpm) [292]. The symptoms of orthostatic hypotension include light-headedness, weakness, faintness, and syncope. Management includes a review of medication, fluid and salt repletion, and encouragement of physical activity and exercise to avoid deconditioning [293, 294]. Midodrine and droxidopa are approved by the FDA for the treatment of symptomatic neurogenic orthostatic hypotension [295]. Fludrocortisone is not FDA approved, but works principally through sodium retention; however, there are concerns over supine hypertension, hypokalaemia, congestive cardiac failure, and peripheral oedema [296].

Gastrointestinal dysfunction

Gastrointestinal symptoms occur frequently among people with diabetes and are associated with considerable morbidity [297]. Autonomic neuropathy of the gastrointestinal system may involve the oesophagus, stomach, gallbladder, pancreas, and small and large intestine. The clinical features, diagnostic work-up, and specific treatment of diabetic autonomic neuropathy involving the gastrointestinal tract are listed in Table 45.6.

Oesophageal dysfunction

The prevalence of oesophageal dysmotility in people with diabetes is as high as 63% [298]. The thoracic oesophagus and lower oesophageal sphincter are composed of smooth muscle fibres innervated by the autonomic nerves of the myenteric plexus. Autonomic neuropathy and structural remodelling of the oesophageal musculature in diabetes result in abnormal peristalsis, spontaneous contractions, and reduced lower oesophageal sphincter tone [299]. Symptoms including dysphagia, retrosternal discomfort, and heartburn are uncommon and an obstructive lesion should be ruled out via endoscopy [276]. Oesophageal motility disturbances are demonstrable using scintigraphic techniques. Manometric studies show diminished pharyngeal and oesophageal contractions and reduced lower sphincter tone. Prokinetic drugs can be tried empirically. Since people with reduced oesophageal motility may be at risk of delayed transit and hold-up of tablets, potentially leading to localized mucosal ulceration and delayed drug absorption, they should always drink after taking their medication.

Gallbladder dysfunction

Autonomic neuropathy may lead to an atonic gallbladder that dilates with bile retention leading to stone formation [276].

Gastroparesis

Diabetes is the most common cause of gastroparesis, a condition characterized by delayed gastric emptying in the absence of a mechanical obstruction [300]. Gastroparesis can manifest with a

variety of symptoms, including early satiety, nausea, vomiting, and anorexia. In more refractory cases it is associated with significant morbidity, impaired quality of life, anxiety, and depression having an impact on the individual's self-management of diabetes [301, 302].

Gastric emptying is determined by the physicochemical composition of food (carbohydrates leave the stomach most rapidly, proteins less so, and fats remain longest), its consistency (large chunks of meat remain in the stomach longer than small pieces), motor activity of the stomach, and the interaction of the stomach and duodenum, including involvement of gastrointestinal hormones. Gastric emptying is dependent on coordinated smooth muscle contraction regulated by the enteric neural plexus, and the intensity is controlled by efferent sympathetic and parasympathetic activity. Any abnormality of gastric electrical rhythm and transmission can lead to ineffective gastric propulsion [303, 304].

Diagnosis

The diagnosis of gastroparesis entails the exclusion of a mechanical obstruction, typically with an oesophagogastroduodenoscopy or barium meal. The gold standard for diagnosis of gastroparesis is gastric-emptying scintigraphy. This involves an overnight fast followed by a standard low-fat radiolabelled meal, ingested within 10 minutes. Imaging is performed at baseline and after one, two, and four hours in the standing position. Gastric delay is defined by >60% retention at two hours or >10% retention at four hours. A gastric-emptying breath test and SmartPill™ (Medtronic, Watford, UK) are alternative methods to establish gastric delay. The SmartPill enables ambulatory assessment of individuals, is radiation free, and may also provide additional physiological information [305].

Management

The general principles of management are to restore nutritional and hydration status, alleviate symptoms, and stabilize glucose levels [306]. Dietetic input should be sought early, with multiple small meals low in fat and fibre being preferred to fewer large ones [307–309]. Assisted nutrition should be considered when oral nutrition is not possible or inadequate and the enteral route is preferable to parenteral nutrition, due to the lower risk of complications such as line infection and thrombosis [309]. Optimization of insulin treatment with the use of basal insulin and omission or delay in the prandial injection can be useful. In an open-labelled pilot study of 42 individuals with gastroparesis (both type 1 diabetes and type 2 diabetes), there were improved glycaemic levels, less hypoglycaemia, and an improved gastroparesis symptom score with the use of sensor-augmented pump or pump and continuous glucose monitoring [310].

Metoclopramide is the only FDA-approved drug for the treatment of gastroparesis. However, concerns regarding potentially irreversible tardive dyskinesia have led to an FDA warning restricting its use to no longer than three months and recommendations to use the lowest effective dose for the shortest possible time. Domperidone is licensed only for treating nausea and vomiting and should be used at the lowest effective dose for the shortest possible duration, not exceeding one week. Erythromycin is a macrolide antibiotic that is an agonist of the motilin receptors leading to increased antral contraction [311]. The intravenous route is favoured in acutely hospitalized individuals, though tachyphylaxis may occur with this drug, usually after four weeks of use [312].

Mechanical options for intervention include transpyloric stenting, gastric electrical stimulation, and gastric per-oral endoscopic myotomy, and in severe intractable gastroparesis laparoscopic pyloroplasty or gastrectomy [306].

Table 45.6 Diabetic autonomic neuropathy of the gastrointestinal tract: clinical features, diagnostic work-up, and specific treatment.

Organ manifestations/clinical features	Diagnostic procedures	Treatment
All gastrointestinal manifestations	Basic diagnostic work-up History Exclusion of structural and infectious diseases	
Dysphagia and reflux disease	Extended diagnostic work-up Stage 1 Oesophagogastroduodenoscopy Other relevant imaging Stage 2 Oesophageal manometry 24 h pH monitoring	Dysphagia Prokinetic agents in individual cases Reflux Proton pump inhibitors
Diabetic gastroparesis	Stage 1 Oesophagogastroduodenoscopy Abdominal sonography Other imaging, as applicable Laboratory tests Stage 2 Gastric-emptying scintigraphy $[^{13}\text{C}]$ Octanoic acid breath test	Gastroparesis Dietary change: frequent, small, low-fibre, low-fat meals Adjust insulin injection to meal interval Prokinetic agents: metoclopramide, domperidone Erythromycin (off-label) For severe refractory symptoms Gastric electrical stimulation (gastric pacemaker) Jejunal feeding tube Parenteral nutrition
Diabetic cholecystopathy	Laboratory tests Abdominal sonography	
Diabetic diarrhoea (enteropathy) and exocrine pancreatic insufficiency	Stage 1 Endoscopy Abdominal sonography Laboratory tests, including examination of stool for pathogenic organisms Other imaging, as applicable Stage 2 Lactose, fructose, sorbitol hydrogen breath test Glucose hydrogen breath test Faecal elastase-1, as applicable Lactulose hydrogen breath test, as applicable $\text{D}-\text{Xylose}$ absorption test, as applicable	Diarrhoea Bulking agents Loperamide Cholestyramine Clonidine Octreotide Bacterial overgrowth of the small intestine Broad-spectrum antibiotics (e.g. ciprofloxacin, metronidazole, and doxycycline one after the other, each for 10 d) Severe exocrine pancreatic insufficiency Pancreatic enzymes
Diabetic constipation (colonic hypomotility)	Stage 1 Digital rectal examination Ileocolonoscopy Laboratory tests Abdominal sonography, as applicable Other imaging, as applicable Stage 2 Magnetic resonancing imaging (MRI) defecography Anorectal manometry Hinton test Neurological examination	Constipation Sufficient fluids, fibre, and physical activity Gelling agents (pectins, psyllium preparations) Fibre-rich foods, e.g. wheat bran, linseed Laxatives, e.g. sodium picosulfate, bisacodyl, macrogol, lactulose/lactitol Depending on tolerance and efficacy Biofeedback for rectal emptying disorder Prucalopride (licensed only in women)
Diabetic faecal incontinence	Stage 1 Digital rectal examination Rectal endosonography MRI defecography Stage 2 Anorectal manometry Neurological examination, as applicable	Faecal incontinence Anti-diarrhoeal medications Pelvic floor gymnastics Biofeedback Sacral nerve stimulation in refractory cases

Diabetic diarrhoea

Diabetic diarrhoea is a troublesome gastrointestinal complication characterized by intermittent, brown, watery, painless, and voluminous stool, particularly at night. Other causes of diarrhoea must be excluded, especially concomitant metformin use and pancreatic

exocrine insufficiency. Diarrhoea has been reported by up to 20% of people with diabetes [313]. Steatorrhoea is also common and may occur in as many as 75% of people with diabetic diarrhoea. Typically, diabetic diarrhoea occurs in long-standing and suboptimally managed type 1 diabetes and is more common in men than

in women. The pathogenesis is complex and autonomic neuropathy, bacterial overgrowth, and pancreatic exocrine insufficiency may all contribute [314]. If bacterial overgrowth is present, then broad-spectrum antibiotics should be the first step in management with courses of 1–2 weeks every month. Other pharmacological therapies include somatostatin analogues (octreotide) and selective serotonin 5-hydroxy tryptamine type 3 (HT3) receptor antagonists (ramosetron) [314, 315].

Colonic dysfunction

Constipation may affect ~60% of people with type 2 diabetes and is a common gastrointestinal complaint, although it may also be attributed to ageing [313]. Increased oxidative stress and apoptosis with loss of enteric neurons contribute to the motility disturbances [316]. The diagnostic assessment includes a digital rectal examination, proctosigmoidoscopy, and/or colonoscopy. Megacolon or megasigmoid may be found occasionally. Symptoms do not correlate with radiographic changes, which may be absent despite significant symptoms. The colonic segmental transit time can be examined using radiopaque markers to distinguish between diffuse colonic hypomotility and rectosigmoid dysfunction [317].

An increase in dietary fibre may reduce the intestinal transit time. However, it may also lead to increased gas production and the quantity of fibre should be increased gradually to avoid excessive flatulence and bloating, which may already be present in people with diabetes. Lactulose decreases pH and increases osmotic activity to stimulate colonic propulsive activity. Chronic laxative use, particularly with the anthraquinone group (senna, cascara, aloes), may aggravate existing autonomic neuropathy. More severe constipation or obstipation unresponsive to conventional management may benefit from a trial of drugs that stimulate the colonic smooth muscle, including bethanechol (cholinergic agonist) or pyridostigmine (cholinesterase inhibitor) [317].

Urogenital system

Bladder dysfunction

Bladder dysfunction may occur in up to 50% of individuals with diabetes [278] and presents with a spectrum of symptoms ranging from bladder overactivity to impaired bladder contractility and urinary retention [318]. The *temporal theory of diabetic bladder dysfunction* proposes that hyperglycaemia-induced polyuria causes compensatory bladder hypertrophy and associated myogenic and neurogenic alterations [319]. Diabetic cystopathy begins with an increased initiating threshold for the micturition reflex, followed by decreased detrusor activity and incomplete bladder emptying [320]. People with mild autonomic neuropathy initially report reduced urinary frequency; however, as autonomic efferent fibres become damaged, the frequency of urination declines and dribbling and overflow incontinence ensue. It is important to exclude other conditions such as urinary tract infection, and therefore urinalysis and culture and examination for benign prostatic hypertrophy are important, especially in older men. In women, it is important to include a complete urogynaecological examination to rule out pelvic organ prolapse, as well as an assessment of the integrity of pelvic floor muscle.

Urodynamic evaluation should be performed to differentiate between people with diabetic cystopathy and other causes of bladder outflow obstruction. Cystometry usually shows the presence of residual urine and reduced sensation of bladder filling. A study of 194 women with type 2 diabetes showed that they had significantly

higher nocturia scores, weaker urinary streams, reduced voided volumes, and an increased residual urine volume of >100 ml in 13.9% compared to 1.8% of women without diabetes [321]. Over time the progressive increase in post-void residual volume can lead to chronic urinary tract infection and irreversible bladder fibrosis, with hydronephrosis and renal impairment. The clinical features, diagnostic work-up, and specific treatment of diabetic autonomic neuropathy of the urogenital system are shown in Table 45.7.

Management

Therapies include lifestyle modification such as weight reduction, amount and timing of fluid intake, and pelvic floor muscle training. Individuals should be educated to void every third hour during the daytime to compensate for the lack of first desire to void. Repetitive voiding by double or triple voiding techniques may replace deficient detrusor contraction and enable the person to discharge almost all of the bladder volume. Crede's manual compression to apply suprapubic pressure or the Valsalva manoeuvre can also be useful in facilitating micturition [322]. However, in people with impaired or absent detrusor muscle activity, intermittent self-catheterization is the primary therapy [323].

Anti-cholinergic drugs may benefit those with detrusor overactivity; however, there is a limited role for pharmacotherapy in the treatment of detrusor areflexia. Antimuscarinic medication includes oxybutynin 5–30 mg three times a day and tolterodine 2–8 mg twice a day for detrusor hyperreflexia and parasympathomimetic medication to reduce detrusor contractility [1]. Surgical options for individuals with refractory symptoms include vesical neck resection, though this carries a risk of retrograde ejaculation in men and cystourethrocele in women [324]. Selective pudendal nerve block may be used to reduce bladder outlet resistance and sacral neuromodulation.

Erectile dysfunction

Sexual function in men and women with diabetes is discussed in greater detail in Chapter 54 and so will only be covered in brief here. Erectile dysfunction is defined by the persistent or recurrent inability to achieve and maintain penile erection of sufficient rigidity to permit satisfactory sexual activity for at least three months [325]. It occurs in ~50% of men with diabetes and is more severe and less responsive to treatment compared to men without diabetes [326]. Risk factors include persistent hyperglycaemia, metabolic syndrome, hypertension, dyslipidaemia, lower estimated glomerular filtration rate (eGFR), and higher albumin-to-creatinine ratio.

Cholinergic and non-cholinergic non-adrenergic neurotransmitters mediate erectile function by relaxing the smooth muscle of the corpus cavernosum. A principal neural mediator is NO, which activates guanylyl cyclase to form intracellular guanosine monophosphate, a potent second messenger for smooth muscle relaxation. *In vivo* studies of isolated corpus cavernosum tissue from men with diabetes have shown functional impairment in autonomic and endothelium-dependent relaxation of corpus cavernosum smooth muscle [327, 328]. Small nerve fibre damage detected using CCM is more closely associated with erectile dysfunction than testosterone levels in men with type 1 diabetes [329], type 2 diabetes [330], and obesity [331].

The aim of initial management is to encourage smoking and alcohol cessation, reduce weight and metabolic syndrome [332], and treat with statins [333]. Treatment with testosterone is recommended in individuals with low testosterone levels (<8 nmol/l; 231 ng/dl) and reduced libido, but is contraindicated in men with prostate or breast cancer or severe heart failure [334].

Table 45.7 Diabetic autonomic neuropathy of the urogenital system: clinical features, diagnostic work-up, and specific treatment.

Organ manifestations/ clinical features	Diagnostic procedures	Treatment
Diabetic cystopathy (bladder-emptying dysfunction)	Basic diagnostic work-up Micturition diary over 48 h Extended diagnostic work-up International Prostate Symptom Score (IPSS) Uroflowmetry Residual urine measurement Digital rectal examination for men Urodynamic testing	Behavioural changes Electrical stimulation Biofeedback Anticholinergics α -Receptor blockers Antibiotic therapy Bladder neck incision Self-catheterization Suprapubic cystostomy
Erectile dysfunction	Basic diagnostic work-up Stage 1 Sexual history, International Index of Erectile Function questionnaire (IIEF-5) Total (free) testosterone, prolactin, FSH, LH Stage 2 (optional) Test with a PDE-5 inhibitor (sildenafil, vardenafil, tadalafil) Extended diagnostic work-up Stage 3 (only if surgical therapy is planned/indicated) Intracavernosal injection test Doppler/duplex sonography Cavernosometry/cavernosography Nocturnal tumescence measurement	Erectile dysfunction Avoidance of medication leading to (antihypertensives, antidepressants) Stage 1 PDE-5 inhibitors (sildenafil, tadalafil, vardenafil) Stage 2 Erection aid system (vacuum pump) Corpus cavernosum auto-injection therapy Stage 3 Corpus cavernosum implant Hypogonadism Testosterone substitution

FSH, follicular stimulating hormone; LH, luteinizing hormone; PDE-5: phosphodiesterase type 5.

Source: Modified from Ziegler et al. 2014 [49]. Reproduced with permission. © Georg Thieme Verlag KG.

The first-line oral medication is 5-phosphodiesterase (PDE-5) inhibitors. In a meta-analysis of starting dosages of PDE-5 inhibitors, sildenafil 50 mg had the greatest efficacy, but also had the highest rate of overall adverse events. Tadalafil 10 mg had intermediate efficacy, but had the lowest overall rate of all adverse events. Vardenafil 10 mg had similar overall adverse events to sildenafil 50 mg, but a markedly lower global efficacy [335]. Men with diabetes are less likely to respond to PDE-5 inhibitors, with a ~50% non-responder rate [336]. The lack of response may reflect a more severe neurogenic component in these individuals [329]. In a recent study the assessment of nocturnal penile tumescence and rigidity, which reflects predominantly neurogenic abnormalities, had an area under the curve (AUC) of 0.860 in differentiating sildenafil responders from non-responders [337]. Additional modalities such as low-intensity extracorporeal shock-wave therapy show promise [338–341], but require larger and better-designed clinical trials.

Female sexual dysfunction

Sexual dysfunction is more common in women with diabetes and almost one in two women with diabetic neuropathy reported sexual dysfunction [342]. Reduced sexual arousal, decreased lubrication,

and painful intercourse are the most common symptoms of sexual dysfunction in women with diabetes. They are attributed to psychological factors more so than in men [343] and are also associated with depression [344, 345].

Gustatory sweating

Gustatory sweating refers to facial diaphoresis, often accompanied by flushing, that follows the ingestion of food or drink. It occurs particularly in individuals with diabetic nephropathy or neuropathy [346] and in one study 69% of individuals with nephropathy and 36% with neuropathy reported gustatory sweating, compared to less than 5% in people with diabetes without complications [347].

A double-blind placebo-controlled trial using a 0.5% glycopyrrolate cream applied to affected areas on alternate days showed a reduction in both the severity and frequency of diabetic gustatory sweating [346]. However, this agent is limited to those who do not experience scalp sweating, as it cannot be applied beyond the hairline. Intracutaneous injection of botulinum toxin type A in the affected facial skin area resulted in a cessation of sweating within four days and lasted for 24 weeks [348].

³ German Diabetes Centre (DDZ), Institute for Clinical Diabetology, Leibniz Centre for Diabetes Research at Heinrich Heine University, Düsseldorf, Germany

Key points

- Diabetes accounts for 75–90% of excess coronary artery disease risk seen in people with diabetes and enhances the effects of other cardiovascular risk factors.
- A range of haemodynamic and metabolic factors contribute to macrovascular disease in diabetes.
- There is clear *in vitro* and *in vivo* evidence that glucose exerts direct and indirect toxic effects on the vasculature.
- The accumulation of advanced glycation end-products (AGEs) exerts pro-oxidant, pro-inflammatory, and pro-fibrotic effects on the vasculature via receptor-independent and receptor-dependent effects. Furthermore, the AGE receptor (RAGE) is pivotally involved in the pathogenesis of diabetes-accelerated atherosclerosis. The pro-inflammatory signalling of RAGE is mediated through the angiotensin II receptor type 1 (AT₁).
- Specific insulin resistance pathways appear to contribute to atherogenesis in diabetes.
- The components of the classic renin–angiotensin–aldosterone system (RAAS) and in particular more recently discovered components such as angiotensin-converting enzyme 2 appear to contribute to macrovascular

disease in diabetes. Inhibitors of RAAS have consistently demonstrated reduced endothelial dysfunction and atherosclerosis in animal models via suppression of inflammation, fibrosis, and oxidative stress.

- Other vasoactive components such as endothelin and urotensin II are also likely to contribute to macrovascular complications in diabetes and interact with the RAAS. Furthermore, the role of novel tumour necrosis factor (TNF)-related ligands, such as TNF-related apoptosis-inducing ligand and osteoprotegerin, and the complement system in atherosclerosis are currently under evaluation.
- Treatments that reduce oxidative stress, including nicotinamide adenine dinucleotide phosphate (NADPH) oxidase inhibitors and inhibitors that attenuate inflammation, have been shown to be anti-atherosclerotic in experimental and clinical studies, although this effect is not uniform. Inflammasome activation plays an important role in diabetes-associated atherosclerosis.
- A multifactorial approach treating conventional cardiovascular risk factors in addition to diabetes-specific risk factors is currently viewed as the optimal strategy to reduce the burden of cardiovascular disease in diabetes.

Epidemiology of diabetic macrovascular complications

Macrovascular complications develop in people with type 1 diabetes [1, 2] and type 2 diabetes [3, 4]. This is of particular concern as the increasing prevalence of diabetes now also affects adolescents and younger adults, thus promoting the earlier development of long-term cardiovascular complications. Even after adjusting for concomitant risk factors, such as hypertension and hyperlipidaemia, there remains an excess risk for cardiovascular disease (CVD) in people with diabetes [5, 6]. Indeed, diabetes itself accounts for 75–90% of the excess coronary artery disease risk and enhances the effects of other cardiovascular risk factors. Death from stroke and from myocardial infarction are leading causes of mortality in type 1 diabetes and type 2 diabetes [2, 7].

A range of haemodynamic and metabolic factors have been considered responsible for the development and progression of macrovascular disease in diabetes (Figure 46.1) [8]. In terms of haemodynamic factors, the hormonal cascade known as the renin–angiotensin–aldosterone system (RAAS) plays a pivotal role in diabetes-associated atherosclerosis; however, other vasoactive hormone systems, such as the endothelin [9] and urotensin systems [10, 11], have also been implicated in diabetes-related macrovascular disease. Furthermore, oxidative stress and a decrease in antioxidant defence have emerged as critical factors driving many atherogenic processes in diabetes [12], in addition to a host of immune-inflammatory responses involving factors such as tumour necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) [13] and the complement system [14]. More recently, activation of the inflammasome has also been shown to contribute to CVD in diabetes.

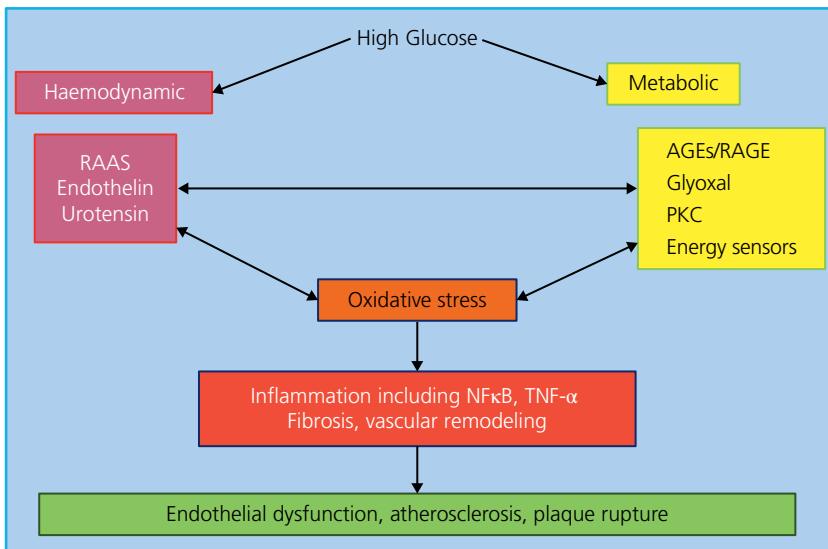

Figure 46.1 Haemodynamic and metabolic mediators contribute to the pathogenesis of diabetes vascular complications. Haemodynamic factors include the renin–angiotensin–aldosterone system (RAAS) and other vasoactive factors. Metabolic factors include glucose and glucose metabolites such as the formation of advanced glycation end-products (AGEs) including glyoxal, their interaction with the receptor RAGE, as well as energy sensors. Both pathways interact with each other and lead to oxidative stress and inflammation, thus promoting endothelial dysfunction and atherosclerosis. NF κ B, nuclear transcription factor κ B; PKC, protein kinase C; TNF- α , tumour necrosis factor α .

Pathogenesis of diabetic macrovascular disease

Chronic exposure of the vascular endothelium to hyperglycaemia induces an inflammatory response involving the adhesion and transmigration of monocytes through the vascular wall into the subendothelial space [15]. Furthermore, accelerated generation and vascular deposition of advanced glycation end-products (AGEs) in addition to interactions with the AGE receptor (RAGE) in diabetes initiate oxidative reactions that promote the oxidation of low-density lipoprotein (LDL) cholesterol (oxLDL) [16], which enhances the pro-inflammatory properties of the endothelium [17]. Monocytes differentiate into macrophages, which, via uptake of lipids, transform into foam cells and accumulate in the vascular wall. The early atherosclerotic process results in the formation of fatty streak lesions, which over time develop into more advanced lesions, characterized by infiltration with vascular smooth muscle cells (VSMCs), formation of a necrotic core, and further lipid accumulation [15]. In humans, these lesions can demonstrate features of instability and plaque rupture, including intraplaque haemorrhages in addition to heightened thrombogenicity.

Role of hyperglycaemia

A pivotal role for glycaemia and duration of diabetes exposure has been well established for microvascular complications in the UK Prospective Diabetes Study (UKPDS) study [18, 19]; however, the data was not as convincing for macrovascular disease. The importance of hyperglycaemia for macrovascular injury was subsequently extensively investigated in a series of studies. It was suggested that glycated haemoglobin (HbA_1c) acts as an independent and continuous risk factor for macrovascular disease [20–23]. For an increase in HbA_1c from 5.5% (37 mmol/mol) to 9.5% (80 mmol/mol), there is a 10-fold increase in microvascular disease endpoints, while the risk for macrovascular disease endpoints increases only twofold.

Clinical trials and hyperglycaemia

Clinical trials such as the Action to Control Cardiovascular Risk in Diabetes trial (ACCORD) [24], Action in Diabetes and Vascular disease: PreterAx and DiamicroN-MR Controlled Evaluation (ADVANCE) trial [25], and the Veterans Affairs Diabetes Trial

(VADT) [26] explored the effect of tight glycaemic management on cardiovascular endpoints in people with type 2 diabetes. As observed in the initial reports of the Diabetes Control and Complications Trial (DCCT) in people with type 1 diabetes and in the UKPDS trial in people with type 2 diabetes, tight blood glucose management had little effect on macrovascular outcomes. This was further emphasized by subsequent studies including the ADVANCE [25] and ACCORD trials [24]. Both studies demonstrate no significant cardiovascular benefit, with the ACCORD study even suggesting possibly deleterious cardiovascular outcomes in association with tight glucose management.

One possible explanation for the lack of a positive effect of tight glycaemic management on cardiovascular outcomes may be the short duration of these trials (<5 years). Indeed, as best seen in the longer follow-up of the Steno-2 study [27] and a long-term follow-up of the UKPDS [28], the benefits of prior intensified cardiovascular risk management including aggressive glucose management may not appear for up to 10 years after initiation of the studies. Thus, in view of the relative lack of an impact on CVD with intensive glucose management, other risk factor modification strategies need to be emphasized. The recent publication of the ADVANCE-ON trial did not show a benefit of the initially intensive glucose-lowering treatment arm in terms of cardiovascular outcomes after six years of follow-up, whereas the initially treated blood pressure arm continued to show cardiovascular protection [29].

Consistent with these findings, a recent meta-analysis of the major cardiovascular trials including ACCORD, ADVANCE, and VADT demonstrated only a modest beneficial effect in CVD. In contrast, the evaluation of novel anti-diabetes drugs, such as sodium–glucose cotransporter-2 (SGLT-2) inhibitors [30] and glucagon-like peptide 1 (GLP-1) receptor agonists [31], has reported cardiovascular benefits with decreased cardiovascular and all-cause mortality in most trials, and this has had a significant impact on the understanding of glucose management and its association with cardiovascular outcomes.

The evidence for other anti-diabetes agents, such as dipeptidyl peptidase 4 (DPP-4) inhibitors, is less convincing and most trials have not demonstrated superior protection with respect to macrovascular disease [32, 33].

Direct and indirect glycotoxicity

Hyperglycaemia has direct and indirect toxic effects on vascular cells. Increased glucose levels enter the polyol pathway at an increased flux rate, leading to heightened formation of diacylglycerol. In addition, an increased flux of glucose into the hexosamine pathway may contribute to glucose-mediated vascular injury in diabetes. To investigate specifically hyperglycaemia-mediated atherosclerosis, aldose reductase transgenic mice have been studied [34]. These mice demonstrated increased glucose delivery via the polyol pathway and also showed early atherosclerosis, but did not develop advanced vascular lesions. It has been suggested that the formation of reactive dicarbonyls is a more reliable marker of glucose toxicity than the conventional measurements of fasting glucose or HbA_{1c} [35], although this is yet to be proven.

In Vitro studies

Cell culture experiments provide clear evidence that hyperglycaemia induces a range of pro-atherogenic effects [36]. Glucose directly activates monocytes-macrophages *in vitro*, initiating increased expression of cytokines such as interleukin 1β (IL-1β) and IL-6 [36]. Furthermore, this leads to protein kinase C (PKC) and nuclear factor κB (NFκB) activation, resulting in increased production of reactive oxygen species (ROS). Auto-oxidation of glucose can also lead to the formation of ROS and can mediate oxLDL. Scavenger receptors on activated macrophages can mediate the uptake of modified lipids such as the pro-atherogenic oxLDL. The formation of AGEs in the hyperglycaemic milieu can lead to the formation of modified albumin, which inhibits scavenger receptor class B type 1-mediated efflux of cholesterol to high-density lipoprotein (HDL). Therefore, prolonged hyperglycaemia can indirectly lead to a range of secondary changes, including increased ROS formation via activation of nicotinamide adenine dinucleotide phosphate (NADPH) oxidases, changes in lipid profile, cellular lipid accumulation, and foam cell formation, in addition to AGE-mediated modification of proteins leading to altered cellular structure and function.

Animal models

The study of atherosclerosis in diabetes has long been hampered by the lack of an appropriate animal model. Our group and others have developed a murine model of diabetes-associated macrovascular disease, the ApoE knockout (KO) mouse, rendered diabetic by multiple low doses of streptozotocin injections. This model is considered by the National Institutes of Health/Juvenile Diabetes Research Foundation (NIH/JDRF) co-sponsored Animal Models for Diabetes Complications Consortium (AMDCC) to be an appropriate model to study macrovascular disease in diabetes [37].

To address the separate roles of hyperglycaemia and dyslipidaemia in diabetes-associated atherosclerosis, mice deficient in the LDL receptor were bred with transgenic mice expressing a viral protein under control of the insulin promoter [38]. When infected with the virus, T cells mediate destruction of pancreatic β cells that express the viral protein, thus closely mimicking the autoimmune response in human type 1 diabetes. In these animals, atherosclerosis development was accelerated even on a normal diet, suggesting that hyperglycaemia was driving atherosclerosis in these mice [38, 39]. When the animals were placed on a high-fat diet, a further acceleration of atherosclerosis occurred, suggesting that glucose and lipids may act through synergistic mechanisms to accelerate atherosclerosis. Furthermore, plaque disruption and intraplaque

haemorrhages, features of plaque instability and potential plaque rupture, were observed in this model [38].

There has been a lack of an appropriate animal model demonstrating features of plaque instability and rupture in diabetes. More recently Chen et al. have developed such a model using a tandem stenosis approach in the carotid artery. This model showed characteristic changes associated with plaque rupture, albeit not in the diabetic context [40].

Metabolic memory

The concept of *glycaemic memory* describes the deferred effects of prior glycaemic status on the subsequent development of diabetic complications. Chronic hyperglycaemia during the earlier stages of diabetes can precipitate or accelerate the development of complications later in the course of diabetes even when glycaemic levels are subsequently improved. Three studies have provided evidence for such a metabolic imprint, the DCCT/Epidemiology of Diabetes Interventions and Complications (EDIC) trial in type 1 diabetes [2] and the Steno-2 trial [27] and UKPDS in type 2 diabetes [28]. These studies have shown that hyperglycaemia was associated with an increased subsequent burden of complications. Another study in people with type 2 diabetes, VADT, compared intensive with standard glucose management (HbA_{1c} 6.9% vs 8.4%, 52 mmol/mol vs 68 mmol/mol), but did not demonstrate significant cardiovascular protection after the participants had been exposed to hyperglycaemia for long periods (12–15 years) [26].

The concept of *metabolic memory* raises two important issues. First, hyperglycaemia may expose people with diabetes to its harmful effects years before type 2 diabetes is diagnosed. Indeed, 25% of people show complications at the time of diagnosis of type 2 diabetes. Therefore, it has been postulated that early diagnosis and strict glycaemic management may be pivotal to reduce the induction of this metabolic memory with subsequent development of long-term diabetes-related vascular complications. Second, glycaemic oscillations including peaks and troughs, which are not reflected in the HbA_{1c} levels [41, 42], may have a key role in mediating growth factor and cytokine expression in addition to inducing epigenetic changes [43]. Epigenetic mechanisms control the gene expression changes through enzyme-mediated epigenetic alterations, namely histone modification, DNA methylation, and non-protein coding RNAs, and are highly dynamic and respond to environmental stimuli such as hyperglycaemia.

There are many cellular and molecular processes that may contribute to the mechanisms underlying metabolic memory, with most of them relating to glycotoxicity. These pathways include the formation of AGEs, glycation of DNA, and increased flux of glucose metabolism, leading to increased oxidative damage, overproduction of PKC-β, and mitochondrial stress. Transient hyperglycaemia induces long-lasting activation of epigenetic changes in the promoter region of the NFκB subunit p65 in aortic endothelial cells both *in vitro* and *in vivo*. These hyperglycaemia-induced epigenetic changes were prevented by reducing mitochondrial superoxide production or superoxide-induced generation of α-oxoaldehydes such as methylglyoxal (Figure 46.2) [43]. These studies suggest that transient hyperglycaemia causes persistent atherogenic effects during subsequent normoglycaemia by inducing long-lasting changes in chromatin remodelling, and highlight a critical role for ROS in epigenetic modulation of glucose-responsive pathways. Specifically, hyperglycaemia results in recruitment of the mobilization of the histone methyl transferase Set7 to the nucleus, with increased H3K4 mono-methylation of the proximal promoter region of the

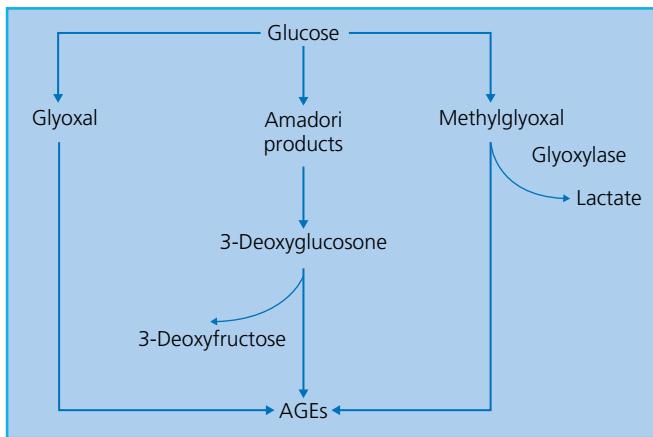

Figure 46.2 The formation of advanced glycation end-products (AGEs) can involve early glucose metabolites such as glyoxal and methylglyoxal, highly reactive dicarbonyls, and key precursors of AGEs.

NFKB subunit p65 gene. This process leads to increased expression of pro-atherogenic pathways including monocyte chemotactic protein 1 (MCP-1) and vascular cell adhesion molecule 1 (VCAM-1) [43]. Subsequent studies in mice that were initially diabetic but returned spontaneously to normoglycaemia have also demonstrated persistent upregulation of pro-inflammatory genes such as p65 and MCP-1 as a result of prior hyperglycaemia. Novel Set7 networks encompassing immune-inflammatoy pathways [44], including antioxidant molecules such as heme oxygenase 1 by H3K4m1-dependent and H3K4m1-independent pathways, have been implicated in the development of macrovascular disease in diabetes [45]. Recent studies by Paneni et al. validated Set7 as an epigenetic regulator of vascular cell inflammation in people with diabetes, which was associated with an increase in the oxidative stress marker 8-isoPGF₂α [46] and vascular dysfunction in individuals with diabetes. Furthermore, more detailed epigenetic studies revealed that changes in histone modifications as a result of prior hyperglycaemia also included changes in H3K9 methylation of the p65 promoter, in addition to effects on various histone methyl transferases and interestingly also demethylases such as LSD-1 [47]. In addition, H3K9 hyperacetylation of several genes including *HMOX1*, *HMOX1*, *IL-8*, *Cox2*, *TNFα*, and *MMP10* has been detected in vascular and immune cells in people with diabetes [48, 49].

An earlier study demonstrated that the gene repressive mark, H3K9me3, plays an important role in VSMC inflammation in diabetes. This study identified downregulation of the H3K9me3-writing enzyme, Suv39h1, and reduced levels of H3K9me3 on inflammatory genes responsible for VSMC-mediated inflammation in diabetic *db/db* mice [50]. Furthermore, dimethylation of H3K9 is associated with vascular complications of diabetes. In a rat model of diabetes, reduced levels of H3K9me2 correlated with the elevated expression of histone demethylase KDM3a in VSMCs [51].

BETs (bromodomain and extraterminal-containing protein family) specifically recognize acetylated lysine residues on histone tails and facilitate binding of transcription factors and the transcriptional machinery including RNA polymerase II [52]. The use of specific BET inhibitors like JQ-1 attenuates atherosclerosis and intimal hyperplasia in experimental models [52]. Importantly, the BET inhibitor apabetalone (RVX-208) prevents hyperglycaemia-induced upregulation of IL-1β, IL-6, and TNF-α in human endothelial cells and in aortic plaques in *ApoE*^{-/-} mice [53]. Furthermore,

analysis of non-randomized studies showed that treatment with apabetalone was associated with fewer cardiovascular events compared to placebo [54]. The recent phase III BETonMACE trial, designed to investigate the impact of apabetalone on cardiovascular outcomes in 2425 individuals with diabetes after an acute coronary syndrome, did not meet the primary cardiovascular endpoint of cardiovascular death, non-fatal myocardial infarction, or stroke [55]. However, the drug showed a highly favourable profile on secondary endpoints, namely heart failure.

Insulin resistance

Insulin resistance occurs in type 2 diabetes and in people with impaired glucose tolerance, and has been associated with increased cardiovascular risk [56–58]. There is now increasing evidence that insulin resistance promotes atherosclerosis as an independent risk factor [59–61]. Furthermore, insulin resistance is often associated with a proatherogenic lipid profile that includes a high very low-density lipoprotein (VLDL) component, a low HDL, and small dense LDL.

In vitro studies have shown that insulin exerts both pro- and anti-atherogenic effects [62, 63], which has led to the hypothesis of pathway-specific insulin resistance (Figure 46.3). It has been suggested that insulin resistance towards glucose transport also affects resistance to the anti-proliferative effects of insulin, whereas the signalling pathways leading to cellular proliferation remain intact (Figure 46.3). Insulin signalling via phosphatidylinositol-3-kinase (PI3K) has been associated with antiproliferative and antithrombotic effects, with decreased adhesion molecule expression such as MCP-1, VCAM-1, and intercellular adhesion molecule 1 (ICAM-1). Furthermore, nitric oxide (NO) production is mediated via the PI3K signal transduction pathway and therefore is impaired in insulin resistance. NO reduces oxLDL and proliferation of VSMCs. In contrast, effects on VSMC proliferation and migration are mediated via the Ras/Raf/MEKK/MAPK signal transduction pathway, which is further stimulated in the context of hyperinsulinaemia, suggesting that pathway-specific insulin resistance contributes to the proatherogenic effects of insulin. IL-6 decreases insulin-stimulated NO production from endothelial cells via decreased activity of insulin signalling mediated by enhanced TNF-α production [64]. Paradoxically, IL-6 increases insulin-stimulated glucose uptake into skeletal muscle and adipose tissue via enhanced insulin signalling, yet IL-6 and insulin have not been linked to increased TNF-α expression in skeletal muscle [64].

Advanced glycation end-product formation

AGE formation originates from early glycation products, the Schiff bases, which form the more stable Amadori products such as 1-amino-1-deoxyfructose derivatives. The Amadori products undergo further enzymatic modifications resulting in several reactive intermediates such as 3-deoxyglucosone and methylglyoxal (Figure 46.2). Methylglyoxal reacts with amino, sulphydryl, and guanidine functional groups in proteins, causing browning, denaturation, and redox-active diamine cross-linking between lysine residues of the target amino acids. Methylglyoxal also generates hydroimidazolones, N^e -(carboxyethyl)lysine, a homologue of carboxymethyllysine (CML) and methylglyoxal-lysine dimer [65, 66]. The AGE-based cross-links are resistant to enzymatic degradation and therefore very stable [67]. The rate of AGE formation is dependent on multiple factors, including the ambient concentrations of various sugars including glucose, the extent of oxidative stress, and the duration of exposure to these various stimuli [68, 69].

More recently, research has been focused not only on AGE modifications on cellular and short-lived extracellular proteins, lipids, and DNA, but also on the impact of key intermediates including the highly reactive dicarbonylmethylglyoxal [35, 70]. Methylglyoxal is 20 000 times more reactive with proteins than glucose itself. Methylglyoxal formation may correlate better with glucose fluctuations observed in diabetes and may explain why post-prandial glucose concentrations are independent risk factors for CVD [71]. Impaired glucose metabolism and type 2 diabetes correlate with higher plasma methylglyoxal (MGO) levels. Furthermore, MGO-derived AGEs are associated with increased risk of cardiovascular events in people with type 2 diabetes [72]. In the experimental setting, oral administration of methylglyoxal to non-diabetic animals leads to accelerated atherosclerosis similar to that observed in diabetic animals in association with upregulation of vascular inflammatory markers [70].

The detoxifying enzyme glyoxalase-1 (GLO-1), which reduces methylglyoxal accumulation, may play a key role in diabetes-related vascular disease [72]. It is downregulated in diabetes and other states of inflammation, hypoxia, and ageing. Genomic studies have shown GLO-1 as a molecular mechanism in the development of CVD [73, 74].

Direct effects of vascular advanced glycation end-product accumulation

AGEs directly influence endothelial function [75] in addition to enhancing the evolution of macrovascular disease [76, 77]. AGEs mediate their effects both directly and via receptor-mediated mechanisms. AGE accumulation in the vascular wall is associated with changes in the structural integrity of proteins, disturbance of their cellular function, and degradation of these proteins [36]. AGEs accumulate on many proteins, including collagen, albumin, and apolipoproteins. Furthermore, the cross-linking of AGEs with matrix molecules can disrupt matrix–matrix and matrix–cell interactions. AGE cross-linking to collagens decreases vascular elasticity and reduces vascular compliance, resulting in increased vascular stiffness [78, 79]. In addition, AGEs can quench NO [75, 80] and generate ROS by stimulating NADPH oxidase activity [81].

Advanced glycation end-product-binding proteins

The receptor-mediated effects of AGEs occur via binding to proteins such as RAGE [82], AGE-R1 (p60), AGE-R2 (p90), and AGE-R3 (galectin-3), the ezrin–radixin–moesin (ERM) family of proteins [83], macrophage scavenger receptor ScR-11, and

CD-36 [84]. The exact roles of AGE-R1, -R2, and -R3 have not been fully elucidated. Finally, the interaction between AGEs and several macrophage scavenger receptors, such as CD36 [84], has been postulated to promote atherosclerosis with studies using CD36 KO mice, supporting the view that CD36 promotes atherosclerosis [85].

Receptor for advanced glycation end-products

RAGE is a multiligand signal transduction receptor of the immunoglobulin superfamily of cell surface molecules that acts as a pattern recognition receptor [82]. In addition to binding ligands that actively participate in inflammation and immune responses, RAGE serves as an endothelial adhesion receptor for leucocyte integrins and promotes leucocyte recruitment and extravasation of infiltrating cells. Of direct relevance to diabetes-related macrovascular complications, RAGE is found on endothelial cells and monocytes–macrophages [77, 86, 87], and has been implicated in inflammatory lesions in many disorders [88].

Downstream effects of advanced glycation end-product receptor activation

Engagement of RAGE leads to activation of the proinflammatory transcription factor NF κ B (Figure 46.4) [89]. AGE binding to RAGE activates various signalling pathways, including NADPH oxidase [81], MAPKs, p21 ras [81], extracellular signal-regulated kinases (ERKs) [90, 91], and PKC, causing activation and translocation of NF κ B [89]. Furthermore, expression of RAGE itself can be induced by NF κ B [91]. RAGE expression within tissues is markedly enhanced in response to metabolic disturbances such as diabetes, dyslipidaemia, uraemia, and ageing, possibly because of accumulation of AGEs in these conditions [86, 88]. In plaques from diabetic ApoE KO mice, upregulation of connective tissue growth factor (CTGF) is AGE dependent [76] and may be mediated via RAGE. Intracellular accumulation of AGEs may also promote phenotypic conversion of VSMCs into foam cells within atherosclerotic plaques [92].

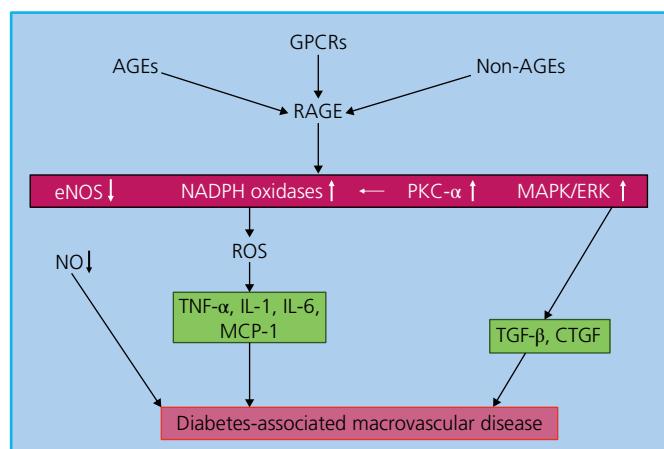

Figure 46.4 Activation of AGE receptor (RAGE) contributes to diabetes-associated macrovascular disease via increased production of reactive oxygen species (ROS), decrease in nitric oxide (NO) availability, and activation of the nuclear transcription factor κ B (NF κ B) and tumour necrosis factor α (TNF- α), in addition to activation of pro-fibrotic growth factors such as transforming growth factor β (TGF- β) and connective tissue growth factor (CTGF) associated with vascular remodelling. eNOS, endothelial nitric oxide synthase; ERK, extracellular signal-regulated kinase; GPCRs, G-protein-coupled receptors; MAPK, mitogen-activated protein kinase; MCP, monocyte chemoattractant protein; NADPH, nicotinamide adenine dinucleotide phosphate; PKC, protein kinase C.

A link between the inflammatory signalling through the angiotensin II receptor type 1 (AT_1) and RAGE has recently been proposed. Indeed, the transactivation of RAGE mediates angiotensin II-induced inflammation and atherogenesis. When RAGE was deleted or inhibited, the adverse pro-inflammatory events triggered by the AT_1 receptor were prevented. Treatment with the mutant RAGE peptide S391A-RAGE362–404 inhibited transactivation of RAGE and attenuated Ang II-dependent inflammation and atherogenesis [93].

Transient intermittent hyperglycaemia accelerates atherosclerosis and increases myelopoiesis involving enhanced glucose uptake via GLUT1 as well as glycolysis in neutrophils. This event promotes the production of S100A8/A9 by neutrophils, which is also a RAGE ligand. The studies emphasize the importance of fluctuating glucose levels in the development of atherosclerosis that are not adequately captured by HbA_{1c} [94].

Studies reducing vascular advanced glycation end-product accumulation

Several pharmacological interventions have been used to reduce the accumulation of AGEs via decreasing the total AGE load or via chemical modification of existing AGEs into inactive forms [95, 96]. Aminoguanidine is a potent inhibitor of the formation of AGEs, scavenges reactive dicarbonyl AGE precursors [95, 96], and decreases oxidative damage to mitochondrial proteins [97]. In experimental and clinical diabetes, aminoguanidine treatment reduces microvascular [98] and more recently macrovascular complications in a model of accelerated atherosclerosis, the diabetic ApoE KO mouse [76].

Another potential agent that inhibits AGE accumulation is ALT-711 or alagebrium [99]. Based initially on a range of *in vitro* studies, this thiazolium compound and its original prototype, phenylthiazolium bromide [100], have been shown to cleave preformed AGEs, hence one of the postulated mechanisms of ALT-711 is as an AGE cross-link breaker [99].

The removal of established cross-links in rats with diabetes by ALT-711 is associated with reversal of the diabetes-induced increase in large artery stiffness, increased collagen solubility, and reduced vascular and cardiac AGE accumulation [79, 101–103]. In addition, alagebrium prevents the progression of nephropathy [104, 105], possibly via direct inhibition of PKC- α phosphorylation [106], thus reducing renal expression of vascular endothelial growth factor (VEGF). Treatment with ALT-711 in diabetic ApoE KO mice was associated with a significant reduction in atherosclerosis [76]. This anti-atherosclerotic effect was associated with reduced vascular AGE accumulation and RAGE expression. Alagebrium treatment was also associated with less inflammation and reduced expression of pro-fibrotic growth factors, in particular CTGF [107, 108]. In the clinical setting, ALT-711 reduces pulse pressure and improves vascular compliance in people with systolic hypertension [79].

Soluble advanced glycation end-product receptor

There are three major splice variants of RAGE [109]. First, the full-length RAGE receptor; second, the N-terminal variant that does not contain the AGE-binding domain; and third, a C-terminal splice variant, soluble RAGE (sRAGE), which does not contain the trans-membrane and effector domains. It remains controversial whether the effects of sRAGE are primarily as a decoy to ligands such as AGEs or whether sRAGE acts as a competitive antagonist to the full-length biologically active RAGE [109, 110].

Soluble advanced glycation end-product receptor and diabetes-associated atherosclerosis

sRAGE has been identified as having therapeutic value in a model of diabetes-associated atherosclerosis, the streptozotocin diabetic ApoE KO mouse [111, 112]. In the original study, Park et al. [112] reported that diabetic ApoE KO mice treated with sRAGE showed a dose-dependent suppression of atherosclerosis and reduced plaque complexity. These beneficial effects were independent of effects on glucose or lipid levels. Furthermore, AGE levels in these diabetic mice were suppressed in a dose-dependent manner by sRAGE to levels similar to those seen in non-diabetic mice. Furthermore, the effect of RAGE blockade with sRAGE was investigated in established atherosclerosis [111]. Administration of sRAGE decreased the expression of RAGE, in addition to reducing the number of infiltrating inflammatory cells and gene expression for transforming growth factor β (TGF- β), fibronectin, and type IV collagen in both the aorta and the kidney in association with a reduced plaque area. Therefore, it was concluded by these investigators that RAGE activation contributes not only to lesion formation, but also to the progression of atherosclerosis.

sRAGE treatment is also effective in reducing vascular complications in other models of atherosclerosis and diabetes. Atherosclerosis in the LDL receptor $^{-/-}$ mouse made diabetic by streptozotocin injection [113] was significantly attenuated by sRAGE treatment. ApoE KO mice bred onto a db/db background, a model of type 2 diabetes and deficient leptin receptor signalling, showed increased atherosclerosis that was significantly attenuated by daily sRAGE treatment [114].

To understand better the specific role of RAGE in the genesis of vascular lesions, mice selectively deficient in RAGE/ApoE (RAGE $^{-/-}$ /ApoE $^{-/-}$) have been created [115]. These mice completely lack not only tissue-bound full-length RAGE, but also sRAGE. As had been predicted by the pharmacological intervention studies directed towards the RAGE ligands and AGEs, RAGE KO mice bred onto an ApoE $^{-/-}$ background showed a marked reduction in plaque area in the presence and absence of diabetes [105, 106]. RAGE deletion has been investigated in streptozotocin diabetic RAGE/ApoE KO mice and showed a significant reduction in atherosclerotic plaque area compared with diabetic ApoE KO mice expressing RAGE. These vascular changes seen in the streptozotocin diabetic double RAGE/ApoE KO mice were associated with reduced inflammation, less accumulation of RAGE ligands such as S100/CML, decreased infiltration by macrophages and T lymphocytes, and a reduction in expression of pro-fibrotic and pro-inflammatory growth factors and cytokines [115, 116].

These promising results with RAGE antagonism have encouraged the development of RAGE-neutralizing compounds for clinical use. The RAGE-modulating agent TTP488 is currently being considered in phase II clinical trials in people with Alzheimer disease, with some positive results [117]. Another compound, TTP4000, is currently in phase I clinical trials. The recent findings about the transactivation of RAGE with glucocorticoid (GRC) receptors may hold promise for novel approaches to block the pro-atherosclerotic action of RAGE [93].

Interaction with the renin–angiotensin–aldosterone system

Because diabetes-related complications appear to be multifactorial in origin and involve interactions between haemodynamic pathways such as the RAAS and metabolic pathways such as hyperglycaemia and the formation of AGEs, there has been

increasing investigation of the potential links between these various pathways (Figure 46.1) [118]. There is evidence that AGE accumulation can induce an upregulation of certain components of the RAAS, although these studies have been performed predominantly in the renal context [119]. Furthermore, angiotensin-converting enzyme (ACE) inhibition appears to confer its end-organ protective effect partly via a reduction in AGEs and an increase in sRAGE [120]. Therefore, the status of the RAAS could represent a key modulator in AGE-induced diseases. More recently, other therapeutic interventions shown to be anti-atherosclerotic have been reported to exert part of their vasculo-protective effect via inhibition of the AGE/RAGE pathway. These include angiotensin II receptor blockers (ARBs), peroxisome proliferator-activated receptor α (PPAR- α), and PPAR- γ agonists and statins [121–123].

It is now considered that the pro-inflammatory signalling of the AT₁ receptor is at least in part mediated by the transactivation of the cytosolic tail of RAGE, the receptor for AGEs, thus linking metabolic and haemodynamic pathways directly via two distinct receptors.

Role of vasoactive hormones in diabetes-related atherosclerosis

Classic renin–angiotensin–aldosterone system

Renin was described more than 100 years ago by Tigerstedt and Bergman [124]. Nevertheless, our understanding of the RAAS is still not complete and has grown increasingly complex over the last decade. The classic pathway is now very well characterized (Figure 46.5). The generation of angiotensin (AT) I and II is not restricted to the systemic circulation and also takes place in vascular and other tissues (Figure 46.5) [125].

Novel aspects of the renin–angiotensin–aldosterone system: ACE2

In 2000, a further enzyme associated with the generation of angiotensin peptides was identified; ACE2 is a carboxypeptidase with sequence similarity to ACE [126]. ACE2 does not generate angiotensin II but increases the formation of AT-(1–7) (Figure 46.6). This heptapeptide causes vasodilatation and has growth-inhibitory effects [127]. Further research, including into specific inhibitors, is needed to elucidate the many functions of ACE2 inside and outside the RAAS.

Angiotensin receptors

The effects of all angiotensin peptides are mediated through specific cell surface receptors (Figures 46.5 and 46.6). The AT₁ receptor mediates most of the effects usually associated with angiotensin II. The role of the AT₂ receptor subtype remains controversial, but it appears to antagonize certain effects of angiotensin II mediated via the AT₁ receptor [128]. Its role in the macrovasculature remains controversial [129].

Role of the renin–angiotensin–aldosterone system in macrovascular disease

Local RAAS activation has an important role in the pathogenesis of diabetes-induced endothelial dysfunction and atherosclerosis [130–132]. As a result, there is a strong rationale for blockade of the RAAS to prevent cardiovascular events in individuals with diabetes. In addition, several clinical trials [133–138] have suggested that blockade of the RAAS may protect against the development of type 2 diabetes.

Renin–angiotensin–aldosterone system and regenerative endothelial cell repair

The RAAS has a role in affecting the number of regenerative endothelial progenitor cells in individuals with diabetes. An increased concentration of circulating endothelial progenitor cells,

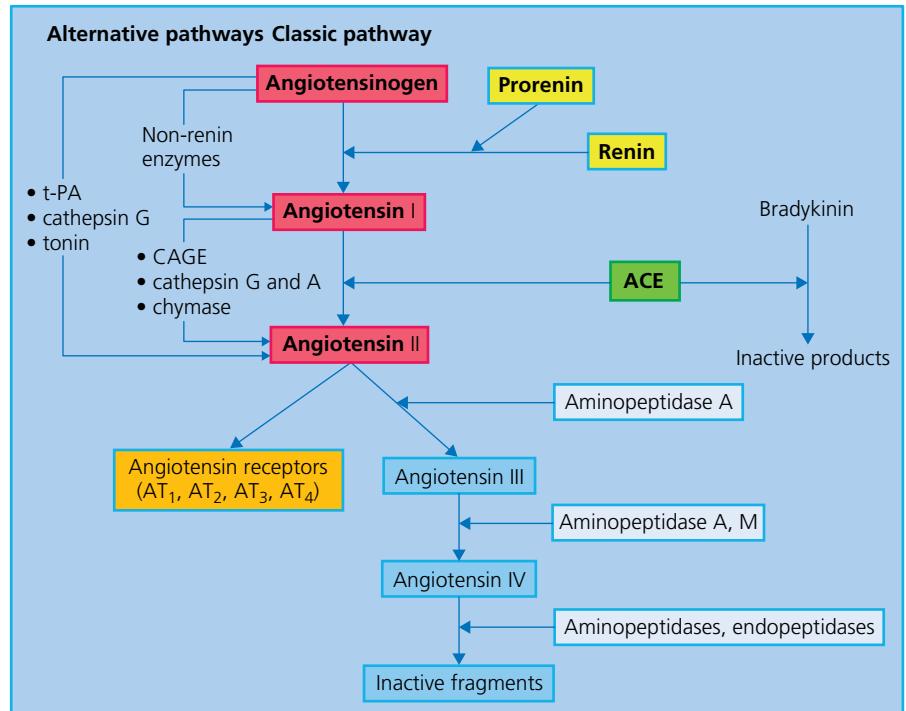

Figure 46.5 Overview of the enzymatic cascade of the renin–angiotensin–aldosterone system (RAAS): classic and alternative pathways. In the classic pathway, renin cleaves the decapeptide angiotensin I (AT I) from angiotensinogen. AT I is then converted to angiotensin II (AT II), which acts through several receptor subtypes, AT₁ and AT₂ receptors being the more relevant in the vasculature. CAGE, chymostatin-sensitive angiotensin II-generated enzyme; t-PA, tissue plasminogen activator.

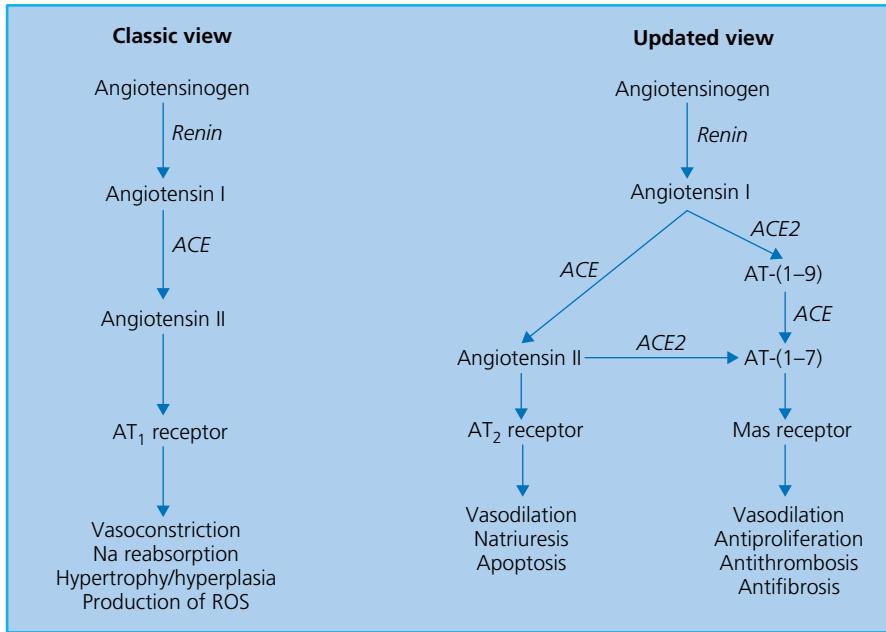

Figure 46.6 New aspects of the renin–angiotensin–aldosterone system (RAAS) components and its interactions. The classic RAAS illustrates the main pathway for angiotensin II (AT II) generation from angiotensin I (AT I) via ACE, with effects being mediated via the AT₁ receptor. The updated view illustrates the new components of the RAAS in which ACE2 has a role in degrading AT I to AT-(1–9) and AT II to the vasodilator AT-(1–7), which acts through the Mas receptor.

which are believed to maintain the integrity of the vascular endothelium, has been associated with a favourable cardiovascular outcome in people with coronary artery disease [139]. A study in individuals with type 2 diabetes [140] suggested that treatment with olmesartan, an ARB, increases the number of regenerative endothelial progenitor cells, which could contribute to the beneficial cardiovascular effects seen with AT₁ receptor blockade.

Role of AT-(1–7) and ACE2 in endothelial dysfunction

It has been hypothesized that disruption of the ACE–ACE2 balance may result in abnormal blood pressure, with increased ACE2 expression protecting against hypertension, and ACE2 deficiency causing hypertension (Figure 46.6) [139, 141]. AT II produces endothelial dysfunction through different pathways, such as increasing oxidative stress and exerting proliferative and pro-thrombotic activities [142], while AT-(1–7), which is generated by the enzyme ACE2, promotes the release of NO and prostaglandins [143, 144] and potentiates bradykinin effects in different experimental models [143, 145]. AT-(1–7) also inhibits growth of VSMCs [146], platelet aggregation and thrombosis [147], inflammation, fibrosis [148], and oxidative stress [149], which in turn might lead to restoration of endothelial function. It appears that AT-(1–7) can antagonize AT II effects, not only by the stimulation of other vasodilators but also through AT₁ receptor inhibition. In this regard, Kostenis et al. reported that the Mas receptor, which is increasingly considered to be the major receptor conferring the biological effects of AT-(1–7), seems to act as a physiological antagonist of the AT₁ receptor, thus counteracting many of the actions of AT II at the endothelial level [150].

Renin–angiotensin–aldosterone system activation and atherosclerosis

Clinical and experimental evidence clearly indicates that activation of the RAAS is central to almost all these pro-atherosclerotic pathways (Figure 46.7) [132, 151]. Diet et al. [131] observed increased ACE protein accumulation within the atherosclerotic

plaque in human coronary arteries, suggesting that ACE may contribute to increased production of local AT II, which may participate in the pathophysiology of artery disease. There is also evidence that AT II and the AT₁ receptor are overexpressed in atherosclerotic plaques [130, 152–154]. Blockade of the RAAS with an ACE inhibitor or an AT₁ receptor antagonist prevents atherosclerosis by mechanisms involving inhibition of pro-inflammatory molecules such as VCAM-1 and MCP-1 and pro-sclerotic and pro-proliferative cytokines such as CTGF and platelet-derived growth factor [130, 154].

Production of pro-inflammatory cytokines, such as IL-1 β , TNF- α , and IL-6, have a major role in the pathogenesis of atherosclerosis [155]. IL-6, ACE, and AT₁ receptors have been detected in stable and unstable atherosclerotic plaques [153, 156]. AT II stimulates the redox-sensitive nuclear transcription factor, NF κ B, which could serve as a unifying signalling system for inflammatory stimuli in atherogenesis through enhanced expression of adhesion molecules ICAM-1 and VCAM-1, E-selectin, MCP-1, and IL-8. Both ACE inhibitors and AT₁ receptor blockers decrease the expression of several adhesion molecules, thus confirming that the chronic inflammatory response associated with atherosclerosis appears to be modulated by AT II at every level and can be targeted therapeutically by RAAS inhibition [132, 157, 158].

The sustained pro-inflammatory state seems to play an important part in the transformation of a stable atherosclerotic plaque into a vulnerable plaque prone to rupture. Plaque rupture has been connected with activation of matrix metalloproteinases in the fibrous cap of the atherosclerotic lesion [159], and AT II is implicated in matrix metalloproteinase activation, both through direct action and through induction of pro-inflammatory cytokines such as IL-6.

ACE2 and diabetes-accelerated atherosclerosis

Although studies on the expression and activity of ACE2 in atherosclerosis are limited, there is increasing evidence that such more recently identified components of the RAAS may be involved in the development and progression of atherosclerosis. Zulli et al. [160]

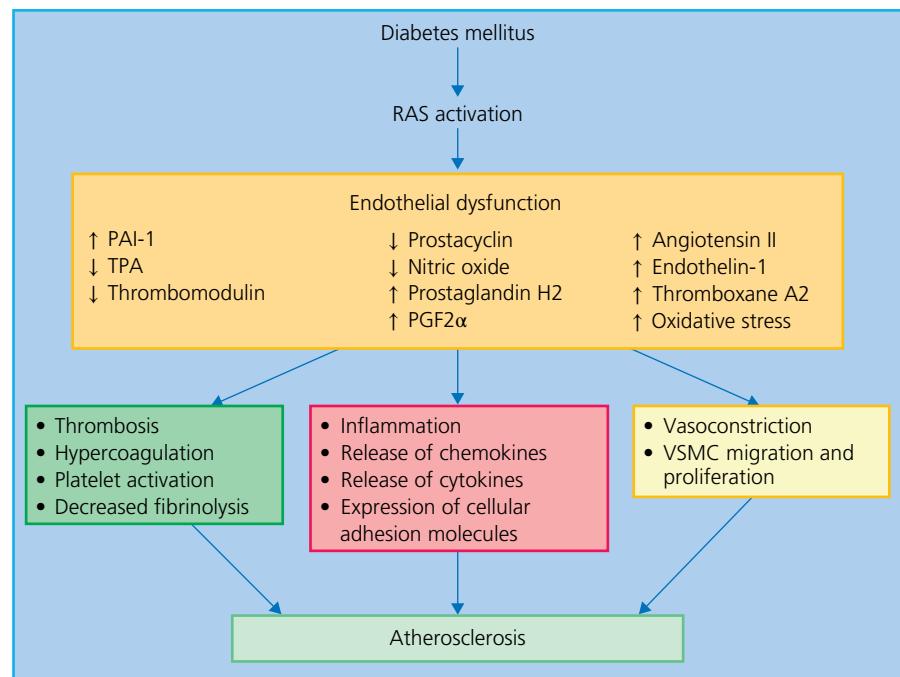

Figure 46.7 Effects of diabetes-induced renin–angiotensin–aldosterone system (RAAS) activation on mechanisms associated with endothelial dysfunction and atherosclerosis. In diabetes, activation of RAAS induces endothelial dysfunction that is characterized by vasoconstriction, inflammation, cellular growth, and thrombosis. By losing its protective properties, dysfunctional endothelium is a major promoter of atherogenesis and, consequently, cardiovascular events. PAI-1, plasminogen activator inhibitor-1; TPA, tissue plasminogen activator; VSMC, vascular smooth muscle cell.

have shown very high expression of ACE2 in endothelial cells, macrophages, and α -smooth muscle cells within atherosclerotic plaques in a rabbit model of atherosclerosis. It is unclear whether this increase in ACE2 is in response to injury in an attempt to protect the vessel by increasing levels of AT-(1–7).

In the human context, there is significant activation of the cardiac RAAS after coronary artery occlusion, and RAAS blockade reduces remodelling and improves survival in humans after myocardial infarction. Cardiac ACE2 expression and activity are also increased with experimental myocardial infarction [161]. Studies using ACE2 KO mice crossed with the atherosclerosis-prone ApoE^{−/−} mouse have shown that ACE2 KO mice develop a similar degree of atherosclerosis to diabetic ApoE^{−/−} mice, with a concomitant activation of inflammatory markers [162]. The induction of streptozotocin diabetes in ACE2/ApoE KO mice was not associated with a further increase in plaque area, suggesting that the down-regulation of ACE2 in diabetes plays a key role in the development of atherosclerosis [163]. All these observations suggest that an imbalance in the RAAS plays a central role in the pathogenesis of atherosclerosis, and that the preservation and augmentation of ACE2 expression and activity represent a potential therapeutic target for the prevention of CVD in diabetes.

Renin–angiotensin–aldosterone system and oxidative stress

Local production of ROS has a pivotal role in atherosclerosis, specifically in the diabetic milieu. Increased vascular superoxide production is seen in aortas from diabetic atherosclerotic ApoE KO mice [121]. These changes were mediated by increased NAD(P)H oxidase (Nox) activity in the aorta with increased expression of various Nox subunits including p47phox, gp91phox, and rac-1 [121]. Increased local vascular ROS generation in diabetes is further supported by the demonstration of increased nitrotyrosine staining in these diabetic plaques [164–166]. Interventions that reduce vascular superoxide production such as

PPAR- α and PPAR- γ agonists have been associated with reduced plaque formation, further emphasizing the link between vascular oxidative stress and atherosclerosis [121, 167]. Furthermore, the deletion of antioxidant enzymes such as glutathione peroxidase, specifically the Gpx1 isoform in the vascular wall, results in an increase in plaque area particularly in the diabetic context via increases in inflammatory mediators including adhesion molecules and chemokines [168]. Treatment of Gpx1-deficient mice with the Gpx1 analogue, ebselen, reduced oxidative stress variables and atherosclerosis in diabetic Gpx1/ApoE KO mice [169]. Furthermore, in the Gpx1/Apo E double KO mice, there was associated upregulation of RAGE, further linking vascular RAGE expression to increased oxidative stress and accelerated atherosclerosis in settings such as diabetes [168].

Therapeutic implications

Renin–angiotensin–aldosterone system inhibition and cardiovascular protection

Pharmacological therapy that interrupts the RAAS may afford special benefits in reducing CVD in people with diabetes [135, 170, 171]. In a *post hoc* subgroup analysis of the Captopril Prevention Project (CAPP) study, participants with diabetes treated with captopril fared significantly better than those treated with conventional therapy (β -blockers and diuretics) in terms of primary endpoint and also for myocardial infarction, all cardiac events, and total mortality [171]. These relative beneficial effects of ACE inhibitor therapy were particularly striking in those at highest risk, specifically those with the highest median fasting glucose or those with more elevated blood pressure. This is in contrast to the UKPDS [172], in which there were comparable cardiovascular benefits for people with type 2 diabetes who were randomized to captopril or atenolol, perhaps reflecting a lower CVD risk in the individuals with newly diagnosed diabetes in the UKPDS.

In MICRO-HOPE, a substudy of the Hypertensive Old People in Edinburgh (HOPE) study [173] that included 3577 individuals who had diabetes and one other CVD risk factor, there was a risk reduction of 25% for combined cardiovascular events, 37% for cardiovascular mortality, 22% for myocardial infarction, and 33% for stroke. In the Fosinopril versus Amlodipine Cardiovascular Events Trial (FACET) study, the incidence of cardiovascular events was less in participants with type 2 diabetes and hypertension treated with fosinopril than the amlodipine-treated group [174]. The European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease (EUROPA) [175] showed that ACE inhibition reduced cardiovascular mortality and morbidity in participants with established coronary artery disease without left ventricular dysfunction. The data from these trials were pooled with those of the Quinapril Ischemic Event Trial (QUIET) [176] study in a meta-analysis that included 31 555 participants [177]. This analysis showed that, compared with placebo, ACE inhibitor therapy produced a significant 14% reduction in all-cause mortality and myocardial infarction, a 23% reduction in stroke, and a 7% statistically significant reduction in revascularization procedures. The ADVANCE study [25, 178] showed that the administration of the ACE inhibitor perindopril and the diuretic indapamide in high-risk people with type 2 diabetes induced a reduction in macrovascular outcome compared with placebo.

Reports of trials with ARBs indicate that these agents have cardiovascular protection effects in individuals with type 2 diabetes similar to those observed with ACE inhibitors. In the Losartan Intervention for Endpoint reduction in hypertension (LIFE) study [135], treatment with losartan in people with type 2 diabetes and left ventricular hypertrophy resulted in a significant reduction in death from CVD and all-cause mortality. An analysis of the large Reduction of Endpoints in NIDDM with Angiotensin II Antagonist Losartan (RENAAL) study showed that treatment with losartan in participants with type 2 diabetes, nephropathy, and left ventricular hypertrophy reduced the cardiovascular risk to levels similar to those observed in individuals without left ventricular hypertrophy [179]. The Ongoing Telmisartan Alone and in combination with Ramipril Global Endpoint Trial (ONTARGET) [180] showed that the ARB telmisartan provides a benefit similar to that of a proven ACE inhibitor such as ramipril in high-risk people with CVD or those with diabetes and end-organ damage. This is a population similar to that examined previously in the HOPE study. Furthermore, in the ONTARGET study, the combination of ramipril with telmisartan, despite the further lowering of blood pressure, did not reduce the risk of cardiovascular events compared with an ACE inhibitor alone, but was associated with additional adverse effects including hypotension and renal dysfunction. Hence an ACE inhibitor, or possibly an ARB, is an initial antihypertensive agent of choice in people with diabetes because these agents have the capacity to prevent or delay the development of diabetic macrovascular complications, thus significantly reducing cardiovascular mortality and morbidity.

Endothelin system

Endothelin (ET) was first discovered in 1988 by Yanagisawa et al. [181] and is one of the most potent vasoconstrictors. There are three distinct ET genes that encode different mature endothelin sequences, designated ET-1, ET-2, and ET-3. Big ET-1 is converted into mature 21 amino acid ET-1 by ET-converting enzyme. ET-1 is

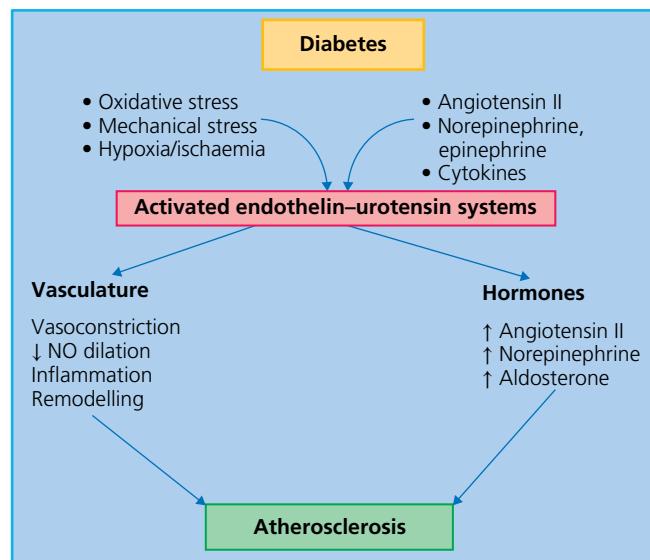

Figure 46.8 Proposed mechanisms of the endothelin and urotensin systems on atherosclerosis in diabetes. In diabetes, activation of the endothelin system induces vasoconstriction, vascular smooth muscle cell proliferation, wall thickening, inflammation, and tissue remodelling, thus leading to the development and progression of atherosclerosis.

predominantly present in endothelial cells. In 1990, the ET_A and ET_B receptor subtypes [182] were cloned. ET_A receptors are found in VSMCs and mediate vasoconstriction and cell proliferation (Figure 46.8). ET_B receptors are found in endothelial cells (ET_{B1}), where they mediate vasodilation via the release of NO, and on smooth muscle cells, where they may elicit vessel contraction and cell proliferation (Figure 46.8).

Role of endothelin in diabetes-related macrovascular complications

Plasma concentrations of ET-1 are increased in people with type 2 diabetes complicated with atherosclerosis compared with those without diabetes with atherosclerosis and healthy individuals [183]. Kalogeropoulou et al. [184] demonstrated increased ET-1 levels in people with diabetes and carotid atherosclerosis. ET stimulates the production and release of inflammatory cytokines from monocytes [185] and enhances the uptake of LDL cholesterol by these cells, promoting a phenotypic change into foam cells [186]. Cytokines released from monocytes-macrophages, in turn, stimulate ET-1 production, providing positive feedback for further cytokine production [187].

In several animal models, both ET_A receptor-selective and non-selective ET_A/ET_B receptor blockade inhibits the development of atherosclerotic lesions, suggesting that elevated vascular ET-1 tissue levels promote endothelial dysfunction and vascular structural alterations via the activation of ET_A receptors [186, 188]. Treatment with an ET_A receptor antagonist decreased the atherosclerotic lesion area in the aorta in ApoE knock-out mice [9, 189]. Similar results have been reported with a non-selective ET_A/ET_B receptor blocker in rabbits. The role of the ET_B receptor in atherosclerosis remains controversial at this stage, although it has been shown to have anti-atherosclerotic effects via stimulation of NO production [190].

Finally, some of the beneficial effects of ACE inhibitors in term of cardiovascular protection may be mediated at least in part by endothelin inhibition. Captopril inhibits endothelin release from

cultured human endothelial cells and decreases 24-hour urinary ET-1 excretion [191]. Furthermore, ET_A receptor antagonism appears to be beneficial in the treatment of diabetic nephropathy, but there are currently no data to support a protective effect on macrovascular disease in people with diabetes. More recently, endothelin receptor antagonists have been trialled in type 2 diabetes-related nephropathy. A study using avosentan had to be terminated prematurely owing to off-target effects leading to fluid retention, heart failure, and cardiovascular mortality [192]. It is possible that the antidiuretic effect mediated by activation of the ET_B receptor is responsible for this effect. Newer and more ET_A receptor-selective endothelin blockers, such as atrasentan, have been evaluated and have demonstrated a reduction in residual albuminuria in people with type 2 diabetes [193]. If these renoprotective effects will also translate into cardiovascular protection, as suggested in pre-clinical studies, they will need to be evaluated in long-term studies with predefined cardiovascular endpoints.

A recent study using endothelium-specific expression of ET-1 in diabetic ApoE^{-/-} mice suggested that the pro-atherosclerotic effect of endothelin involves the pro-oxidant NADPH-oxidase Nox1 [194]. These studies are consistent with previous studies suggesting that Nox1 plays a pivotal role in diabetes-associated atherosclerosis [166] and that novel Nox inhibitors as well as ET blockers could provide vasculoprotection in diabetes [195].

Urotensin II

Several reports have revealed the powerful vasoconstrictile effect of urotensin II (UT II) consistent with a potential importance of this peptide in cardiovascular physiology and diseases (Figure 46.8) [196]. A specific UT II receptor was identified in 1999 [197]. Elevated circulating concentrations of UT II have been detected in people with various cardiovascular states including heart failure, hypertension [198], carotid atherosclerosis, pre-eclampsia and eclampsia, renal dysfunction, and diabetes mellitus [199]. In addition, upregulation of the urotensin receptor system has been found in individuals with congestive heart failure and pulmonary hypertension [200].

Role of urotensin II in atherosclerosis

Expression of UT II is upregulated in endothelial, myointimal, and medial smooth muscle cells of atherosclerotic human coronary arteries. Boussette et al. [10] demonstrated that UT II expression is increased in both atherosclerotic carotid arteries and aortas. Plasma UT II level is correlated positively with carotid atherosclerosis in people with essential hypertension [201]. In ApoE KO mice, urotensin expression was significantly higher than in wild-type control mice [202]. Chronic infusion of UT II enhances atherosclerotic lesions in the aorta of ApoE knockout mice by increasing ROS production and acyl-CoA-cholesterol acyl transferase 1 expression. UT II expression in endothelial cells and VSMCs is increased following balloon injury in rat carotid arteries [203]. Furthermore, treatment with a UT II receptor blocker was associated with a 60% reduction in intimal lesion development.

UT II is linked to the activation of the redox-sensitive enzyme NADPH oxidase in the vascular wall and increased expression of inflammatory cytokines (Figure 46.8). In human peripheral blood mononuclear cells, inflammatory stimuli including IL-1 β and TNF- α strongly enhance urotensin receptor mRNA and protein expression [204]. Of direct relevance to atherosclerosis, UT II has been

shown, predominantly in *in vitro* studies, to enhance LDL cholesterol and ROS production via NADPH oxidase and to promote monocyte recruitment.

Oxidative stress

Excessive production of ROS, in conjunction with dysfunctional antioxidant defence systems, shifts the redox state of the cellular environment in favour of oxidant species, a state termed *oxidative stress*. Clinically, people with diabetes exhibit increased expression of various markers of oxidative stress [205, 206] and reduced antioxidant capacity [207, 208]. Despite a strong theoretical basis, clinical trials of antioxidant treatments for the lowering of CVD burden have produced disappointing results [137, 209].

Role of reactive oxygen species in diabetes-accelerated atherosclerosis

Reactive ROS and its products can directly damage vascular endothelial cells leading to apoptosis [210], autophagy [211], and DNA damage [212, 213]. Aberrant activation of redox-sensitive signalling molecules including protein kinases and transcription factors also plays a central part in diabetes-mediated vascular pathology [214]. Increased ROS production is associated with the induction of inflammatory gene expression, which occurs via upregulation of redox-sensitive inflammatory gene master regulator NF κ B [215].

Nicotinamide adenine dinucleotide phosphate oxidase production of reactive oxygen species

Several enzymatic and non-enzymatic sources contribute to pathological increases in ROS generation in the diseased vasculature, including Nox, nitric oxide synthetase (NOS), myeloperoxidase (MPO), and xanthine oxidase (XO) [216]. However, the Nox enzymes are widely recognized as the major ROS producers in the vasculature [217] and also represent viable pharmacological targets for the treatment of diabetes-associated vascular disease [218].

The Nox isoforms Nox1, Nox2, Nox4, and Nox5 are differentially expressed in vascular cells, and play unique roles in physiology and disease [217, 219]. Several groups, including our own, have demonstrated increased gene and protein expression of Nox1 and Nox4 in hyperglycaemic conditions associated with increased atherosclerosis [164–166, 220–223]. Important roles for Nox1-derived superoxide have been described for AGE-mediated VSMC activation [224] and diabetes-associated endothelial dysfunction [225]. Recent evidence has identified a central role for Nox1 in accelerating atherosclerosis in the aorta of diabetic mice [166]. Controversy surrounds the role of Nox4 in vascular disease. Nox4 is constitutively expressed and produces predominantly hydrogen peroxide [165, 217, 226]. Its role in vascular disease appears to be dependent on the disease and experimental model under investigation. More recently, a vasculo-protective role for Nox4 has been demonstrated in a model of long-term diabetes-associated atherosclerosis [165]. Studies focusing on endothelial cell function following ischaemia and AT II stimulation have shown protective effects of Nox4 [227–229]. In contrast, Nox4-derived ROS promotes cardiac hypertrophy [230] and cardiovascular ageing [231].

Nox5 is a calcium-dependent Nox isoform expressed in human endothelial and vascular smooth muscle cells [232] and also monocytes and macrophages [233]. The exact function of vascular Nox5 is not known, but it affects endothelial nitric oxide synthase (eNOS) [234] and VSMC proliferation [235]. In macrophages, Nox5 expression and activity were induced by treatment with the

pro-inflammatory cytokine interferon- γ (IFN- γ) [233], suggesting a link between Nox5 and inflammation [236]. However, the lack of Nox5 in mice and rats has hindered investigations, and this has resulted in the generation of humanized Nox5 transgenic mouse models of vascular disease [236, 237]. Nox5 is involved in uncoupling of endothelial NO synthase and is associated with age-related hypertension [238]. Furthermore, Nox5 was associated with a phenotypic switch of VSMCs and promoted extracellular vesicle-mediated vascular calcification [239].

Inflammation and immune responses

There is an altered immune response in diabetes-associated macrovascular disease [115, 223, 240]. In diabetes, elevated ROS upregulates the expression of pro-inflammatory genes that lead to foam cell formation [241]. Emerging links between Nox-derived ROS and innate-adaptive immune cell responses have provided insight into the potential immunomodulatory role of Nox in diabetes-associated atherosclerosis. Induction of Nox4 in human monocytes and macrophages is required for oxLDL-stimulated ROS production and cytotoxicity [242]. Gray et al. also identified an important role for Nox1-derived ROS in monocyte adhesion and macrophage accumulation in the lesions of diabetic ApoE^{-/-} mice [166]. More recently, we described an immunomodulatory role of Nox1- and Nox4-derived ROS in diabetes-associated atherosclerosis in the aortic sinus of ApoE^{-/-} mice [164]. In humans, T cells isolated from atherosclerotic plaques recognize and respond to oxLDL [243, 244].

Activation of the inflammasome in diabetes accelerates atherosclerosis development. Indeed, the recent Canakinumab Anti-Inflammatory Thrombosis Outcome Study (CANTOS) trial has provided proof of concept that canakinumab, an IL-1Ra inhibitor, reduced cardiovascular events in individuals with myocardial infarction [244]. This study included a high proportion of individuals with diabetes. Furthermore, NLRP3-inflammasome inhibitors such as MCC950 have shown attenuation of plaque formation and inflammation in the experimental setting [245].

Tumour necrosis factor-related apoptosis-inducing ligand and osteoprotegerin

TRAIL is a member of the TNF ligand family [246] and is expressed across all cell types of the vasculature, including macrophages of atherosclerotic plaques [247]. Both the membrane-bound and soluble forms of TRAIL rapidly induce apoptosis in multiple transformed cell lines and tumour cells, but not in normal cells [246, 248].

Osteoprotegerin is a member of the TNF receptor superfamily [249] that is produced by various tissues, including the cardiovascular system. Osteoprotegerin has two known TNF family ligands: receptor activator of NF κ B ligand (RANKL) [250] and TRAIL [251]. Increasing experimental evidence suggests that both TRAIL and osteoprotegerin are involved in vascular pathophysiology.

The potential role of soluble recombinant (sr)TRAIL in the pathogenesis and/or treatment of diabetes-induced atherosclerosis has been investigated *in vivo* in streptozotocin diabetic ApoE^{-/-} mice [252]. Repeated intraperitoneal injections of srTRAIL significantly attenuated plaque development and contributed to the stabilization of atherosclerotic lesions by selectively decreasing the number of infiltrating macrophages and increasing the VSMCs within the atherosclerotic plaques [252]. Diabetic rats treated with srTRAIL also had improved endothelial function and suppressed

ROS generation [253]. Knockdown of Nox4 in VSMCs significantly reduced TRAIL-induced activity of the NF κ B reporter gene and ICAM expression [254]. The potential clinical relevance of these results was corroborated by animal-based studies, which identified that TRAIL can be regulated by insulin levels and may be involved in regulating vascular tone [255], and two studies showing significantly lower srTRAIL serum levels in people with acute coronary syndrome compared with those with stable angina or normal coronary arteries [256, 257]. Furthermore, individuals with untreated diabetes had lower concentrations of circulating TRAIL than healthy people in association with reduced flow-mediated endothelium-dependent arterial dilatation. Diabetes treatment resulted in an increase in TRAIL concentrations and an improvement in flow-mediated endothelium-dependent arterial dilatation, but concentrations were still lower than in those without diabetes [253].

Osteoprotegerin-deficient mice demonstrated calcifications of the aorta and renal arteries [258], suggesting that osteoprotegerin might have a role in protecting against vascular calcification. Interestingly, a study in older women found a significant correlation between elevated osteoprotegerin serum levels and cardiovascular mortality [259]. The potential links between osteoprotegerin and vascular disease in humans have been further supported by the detection of a single-nucleotide polymorphism in the promoter region of the human gene for osteoprotegerin related to vascular morphology and function [256]. Several independent studies have reported elevated serum and/or plasma osteoprotegerin levels in people with diabetes, and in particular in people with diabetes and vascular complications [260–263]. Although some authors have proposed that the increase in osteoprotegerin levels may represent a defence mechanism against other factors that promote vascular pathologies, other studies support a pro-atherosclerotic role for osteoprotegerin in the vasculature [223, 264, 265].

Complement activation

The complement cascade is an important part of the body's innate immune system, activated via one of three pathways; the classical pathway, the lectin pathway, and the alternative pathway, which converge into a common terminal pathway (Figure 46.9). In addition, homeostasis is another important function of the complement system based on its ability to distinguish between healthy host cells and host cells presenting with damage-associated molecular patterns, for instance necrotic or apoptotic [266]. It is therefore intriguing that the complement system is being linked with diabetes complications and in particular the lectin pathway of complement activation, which is activated by pattern-recognition molecules recognizing specific molecular patterns of carbohydrates and acetylated moieties [267].

It is hypothesized that diabetes causes complement auto-reactivity as a result of hyperglycaemia-induced alterations in the carbohydrate patterns decorating host cells, as well as by glycation-induced dysfunction of complement regulatory proteins that normally protect healthy host cells from complement attack, such as CD59 [268, 269]. Mannan-binding lectin (MBL) is the best studied pattern-recognition molecule of the lectin pathway and accumulates in various organs of diabetic animals, including the heart and the kidneys [270–272]. In a 12-year observational study, individuals with type 1 diabetes and high circulating MBL levels at baseline had an increased risk of dying during follow-up compared with those with lower MBL levels [273]. This indicates a genetic predisposition depending on the MBL2 genotype as the circulating MBL

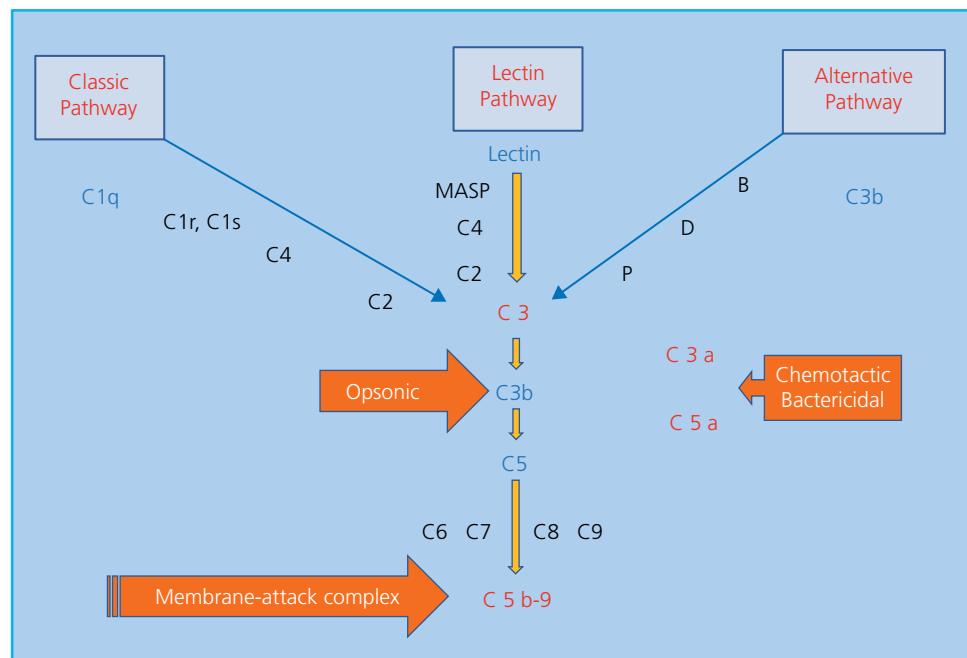

Figure 46.9 Schematic representation of the complement system. The complement cascade is activated by one of the three pathways: classic, lectin, or alternative. Activation leads to formation of the membrane-attack complex and also formation of opsonic, chemotactic, and bactericidal factors.

concentration varies many-fold between people as a result of polymorphisms of the *MBL2* gene and its promotor, whereas the within-person variation is much smaller [274, 275]. Accordingly, people with *MBL2* genotypes expressing high circulating MBL levels had an increased risk of dying during follow-up compared to those with *MBL2* genotypes expressing lower MBL levels, which indicates a causal role of MBL in the risk of mortality in type 1 diabetes [273]. Likewise, among individuals with type 2 diabetes followed for 15 years, those with high baseline MBL concentrations had a greater risk of dying than individuals with lower MBL levels [276]. However, in a recent study of more than 7000 individuals with type 2 diabetes followed for five years, a more detailed analysis was possible [277]. In this study, a U-shaped association between MBL and cardiovascular events was found, as both the lowest as well as the higher MBL levels were associated with an increased risk compared with the intermediate MBL concentrations [277]. In addition to these reports, numerous studies point to a critical role of MBL in diabetic kidney disease. In brief, high MBL levels represent an increased risk of kidney disease in both type 1 diabetes [278–281] and type 2 diabetes [282]. These observational data are supported by evidence of a causal role of MBL in the development of diabetic kidney disease in animal studies [270–272, 283]. Similarly, inhibition of complement factor C5 results in the attenuation of renal injury in diabetic rats [284]. In addition, clinical studies, aiming to inhibit further downstream in the complement cascade using the C5 inhibitor pexelizumab, initially showed reductions in mortality following acute myocardial infarction, as well as in mortality or myocardial infarction after coronary artery bypass graft surgery [285]. However, these beneficial clinical effects were not confirmed in a later and larger study [286].

The mechanisms linking the complement system with diabetes complications remain to be elucidated. However, an interesting concept is based on the membrane-attack complex, which is formed by the common terminal complement pathway. These complexes form pores penetrating target membranes and normally cause osmotic lysis of invading pathogens. However, sublytic membrane-attack

complexes can form on mammalian cells, causing them to release growth factors, MCP-1, and IL-1 and to mediate inflammation, which is known to contribute to the development of diabetes complications [287]. Furthermore, complement activation causes NLRP3 inflammasome activation, which likewise induces inflammation via IL-1 β and IL-18 [288, 289]. C5a receptor blockade attenuates inflammation and renal injury in a model of diabetes [290]. However, further studies are needed to determine if manipulation of the complement system represents a promising target in the treatment and prevention of diabetes-associated macrovascular disease.

Interventions to reduce diabetes-associated macrovascular complications

A range of interventions have been proposed for reducing the macrovascular complications of diabetes, including lifestyle modification, weight reduction, dietary changes, and regular exercise.

Glucose management

Optimal glucose management is pivotal for the prevention and treatment of microvascular complications of diabetes; however, based on clinical trials [19, 25, 28], the evidence for beneficial effects on macrovascular outcomes is less clear. Nevertheless, it has been suggested to aim for HbA_{1c}<7% (53 mmol/mol), but to be more cautious in those with underlying and pre-existing CVD. Since 2008, cardiovascular outcome trials have been required by regulators for licensing new glucose-lowering agents. These trials have shown that GLP-1 receptor agonists and SGLT-2 inhibitors reduce the risk of cardiovascular death, myocardial infarction, and stroke [291]. For example, in the Empagliflozin Cardiovascular Outcome Event Trial (EMPA-REG) study, the SGLT-2 inhibitor empagliflozin reduced cardiovascular and total mortality [292], with an associated benefit on renal endpoints including end-stage renal failure, doubling of serum creatinine, and albuminuria [293].

Table 46.1 Comparison of glucagon-like peptide 1 (GLP-1) receptor agonists and sodium–glucose cotransporter 2 (SGLT-2) inhibitors and their effect on cardiovascular events and cardiovascular death.

Drug type	Study name	Drug name	MACE Hazards ratio (95% CI)	Cardiovascular death – Hazard ratio (95% CI)
GLP-1 receptor agonist	ELIXA	Lixisenatide	1.02 (0.89 to 1.17)	0.89 (0.78 to 1.22)
	LEADER	Liraglutide	0.87 (0.78 to 0.97)	0.78 (0.66 to 0.93)
	SUSTAIN-6	Semaglutide	0.74 (0.58 to 0.95)	0.98 (0.65 to 1.48)
	EXSCEL	Exenatide once weekly	0.91 (0.83 to 1.00)	0.88 (0.76 to 1.02)
	Harmony	Albiglutide	0.78 (0.68 to 0.90)	0.93 (0.73 to 1.19)
	REWIND	Dulaglutide	0.88 (0.79 to 0.99)	0.91 (0.78 to 1.06)
	PIONEER 6	Oral semaglutide	0.79 (0.57 to 1.11)	0.49 (0.27 to 0.92)
	EMPA-REG	Empagliflozin	0.86 (0.74 to 0.99)	0.62 (0.49 to 0.77)
	CANVAS	Canagliflozin	0.86 (0.75 to 0.97)	0.87 (0.72 to 1.06)
	DECLARE-TIMI	Dapagliflozin	0.93 (0.84 to 1.03)	0.98 (0.82 to 1.17)
SGLT-2 inhibitor	CREDENCE	Canagliflozin	0.83 (0.68 to 1.02)	0.78 (0.61 to 1.0)
	Vertis CV	Ertugliflozin	0.97 (0.85 to 1.11)	0.92 (0.77 to 1.11)

CI, confidence interval; MACE, major adverse cardiovascular events.

The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) study, which evaluated the effects of the GLP-1 receptor agonist liraglutide, also showed clear benefits on cardiovascular and renal disease [294]. These positive findings emphasize the importance of these novel drugs on cardiovascular outcomes in people with type 2 diabetes. However, despite the clear evidence of reduction in overall and cardiovascular mortality, renoprotection, and reduction in heart failure, the evidence for a direct atheroprotective effect with these new agents is less clear.

A recent meta-analysis evaluating the effect of SGLT-2 inhibitors on macrovascular complications has shown that these drugs significantly reduced the risk of major adverse cardiovascular events (MACE) as well as cardiovascular death, compared to placebo [30, 291] (Table 46.1). Specifically, the SGLT-2 inhibitor empagliflozin showed the largest reduction in MACE [292] and was the only SGLT-2 inhibitor that showed a reduction in the risk of cardiovascular death. Canagliflozin [295, 296] and empagliflozin [292] also demonstrated a reduction in MACE, while dapagliflozin [297] and ertugliflozin [298] did not demonstrate such an effect.

GLP-1 receptor agonists have also been assessed for their role in reducing macrovascular complications in diabetes in several clinical trials [31] (Table 46.1). A recent meta-analysis demonstrated a significant reduction in MACE by 12%, cardiovascular death by 11%, stroke by 11%, myocardial infarction by 9%, all-cause death by 12%, heart failure by 9%, and kidney disease by 12%, without significant heterogeneity across the studies, suggesting a class effect for cardiovascular and renal outcomes [31].

Liraglutide (LEADER [294]), semaglutide (Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes, SUSTAIN-6 [299]), albiglutide (Harmony Outcomes [300]), and dulaglutide (Researching Cardiovascular Events with a Weekly Incretin in Diabetes, REWIND [301]) significantly reduced the risk for the primary composite cardiovascular endpoint, which included death from cardiovascular cause, non-fatal myocardial infarction, and non-fatal stroke. In comparison, lixisenatide (Evaluation of Lixisenatide in Acute Coronary Syndrome, ELIXA [302]), exenatide once weekly (Exenatide Study of Cardiovascular Event Lowering, EXSCEL [303]), and oral semaglutide (Peptide Innovation for Early

Diabetes Treatment, PIONEER 6 [304]) were not found to reduce cardiovascular events. Furthermore, liraglutide significantly reduced the risk of death from cardiovascular causes and semaglutide (non-oral) reduced the risk of non-fatal stroke compared to placebo.

The Dapagliflozin and Prevention of Adverse Outcomes in Heart Failure (DAPA-HF) [305] and Empagliflozin Outcome Trial in Patients with Chronic Heart Failure and Reduced Ejection Fraction (EMPEROR-Reduced) [306] trials have shown the efficacy and safety of SGLT-2 inhibitors in improving cardiovascular mortality and morbidity in individuals with heart failure and reduced ejection fraction (HFrEF) with and without diabetes. These drugs have become a key part of heart failure therapy and are effective in reducing cardiovascular death or hospitalization for heart failure, regardless of the presence or absence of diabetes.

While these studies indicate that both SGLT-2 inhibitors and GLP-1 receptor agonists may reduce the risk of macrovascular complications in diabetes in high-risk individuals, it appears that some agents are better than others. It remains unclear whether the vasculoprotective effects of these drugs are also seen in individuals with early atherosclerotic disease or in terms of primary prevention. Furthermore, the glucose-independent mechanisms of these cardiovascular benefits of SGLT-2 inhibitors or GLP-1 receptor agonists have not been clearly delineated as yet. Current clinical trials will evaluate the effects of dual SGLT-2 inhibition and GLP-1 receptor agonism to assess potential synergistic or additive macrovascular protection in diabetes and in CVD without diabetes [30, 31].

These medications have now been implemented into guidelines [307], suggesting GLP-1 receptor agonists or SGLT-2 inhibitors as the preferred therapy after metformin in people with type 2 diabetes and established CVD.

Hypertension

Epidemiological studies have shown that the risk of cardiovascular events and mortality starts at blood pressure values as low as 115/75 mmHg for the general population and doubles for every increase of 20 mmHg in systolic and 10 mmHg in diastolic blood pressure (Chapter 47). The question of what systolic or diastolic blood pressure level should be targeted has not been completely

answered by currently available outcome trials. Based on studies such as the Hypertension Optimal Treatment (HOT) study [308], UKPDS [172], and the Appropriate Blood Pressure Control in type 2 Diabetes (ABCD) trial [309], a maximum systolic BP of 130–135 mmHg should be the goal for people with diabetes.

The ADVANCE trial [25] evaluated the effect of a fixed dose of perindopril and indapamide on macrovascular and microvascular outcomes in participants with type 2 diabetes. The treatment group showed a mean reduction in systolic and diastolic blood pressure of 5.6 and 2.2 mmHg, respectively, which was associated with an 18% reduction in cardiovascular deaths and a 14% reduction in coronary events in comparison with the control group. No lower limit for blood pressure reduction appears to exist at which benefits related to cardiovascular outcomes are not observed, with a similar pattern reported subsequently for renal disease [310]. The later ACCORD trial tested the effects of lowering blood pressure below 140/90 mmHg on cardiovascular outcomes [178]. Specifically, it aimed to evaluate if a blood pressure reduction to 120 mmHg systolic would further reduce the cardiovascular event rate. In the ADVANCE-ON trial, after six years of follow-up, benefits on cardiovascular outcomes were still present among those originally assigned to blood pressure-lowering therapy, but there was no evidence that glucose lowering had long-term benefits with respect to mortality or macrovascular events [29].

Choice of antihypertensive treatment

Experimental studies have clearly demonstrated a reduction in atherosclerosis with RAAS inhibitors, with a possible superiority of ACE inhibitors compared with ARBs in type 2 diabetes; however, there are no conclusive studies in people with diabetes to show clear superiority of one class of antihypertensive drugs over another. The majority of the beneficial effects on cardiovascular events appear to be related to the antihypertensive actions of these agents. The ONTARGET study was the first to evaluate the effect of combined RAAS blockade in comparison with full-dose ramipril and telmisartan alone [180]. There was no superiority of the ACE inhibitor over the ARB in terms of cardiovascular events, and dual blockade did not confer greater cardiovascular protection and indeed was associated with more adverse events; however, only 30% of all participants in this study had diabetes, and no specific subgroup analysis has been reported so far. Therefore, this study cannot conclusively answer the question of the superiority of different blockers of the RAAS and combination RAAS blockade on microvascular and macrovascular outcomes in diabetes.

Plasma aldosterone levels correlate with the progression of atherosclerosis as assessed in the carotid plaque area [311]. Mineralocorticoid receptor antagonists have been evaluated with respect to cardiovascular outcomes. The Randomized Aldactone Evaluation Study (RALES) study initially showed a beneficial effect of the non-specific aldosterone antagonist spironolactone on mortality [312], but in the more recent Eplerenone Post-AMI Heart Failure Efficacy and Survival Study (EPHESUS) trial [311] a 15% relative risk reduction in all-cause mortality and a 13% relative risk reduction in cardiovascular mortality/complications compared with participants on current standard therapy was demonstrated [313]. Although there is experimental evidence for eplerenone attenuating endothelial dysfunction [311] and early lesion size in experimental models of atherosclerosis [314], the evidence for a direct vasculoprotective effect of these newer agents is awaited, particularly in the context of diabetes.

Inhibitors of neutral endopeptidase (NEP) were associated with unwanted off-target effects, including angioedema [315, 316]. However, more recently the first-in-class combined ARB combined with a neprilysin inhibitor (ARNi) was evaluated for heart failure in the Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial [317]. Simultaneous inhibition of neprilysin enhanced the NEP system and blockade of the AT₁ receptor with valsartan reduced cardiovascular death and heart failure by 20% and all-cause mortality by 16%. This new class of drugs is a potential effective treatment for heart failure, but the effects in CVD and atherosclerosis need to be further elucidated.

Renal denervation

Initial encouraging results attenuating the overactivity of the sympathetic nervous system in hypertension using renal denervation demonstrated substantial and sustained reductions in blood pressure in people with resistant hypertension [318, 319]. Furthermore, additional beneficial effects were observed, including reductions in serum glucose, insulin, and C-peptide levels three months after denervation [320].

Surprisingly, a randomized clinical trial including a sham control arm (Renal Denervation in Patients with Uncontrolled Hypertension, Symplicity HTN3) did not find superiority of renal denervation compared with the sham control [321]. Many reasons for the failure of this trial have been discussed, including ineffective denervation, inexperience of the operators, and suboptimal medication taking [322]. More recently data from the robustly designed randomized sham-controlled proof-of-concept trials of renal denervation (SPYRAL HTN OFF-MED and SPYRAL HTN ON-MED) involving the next-generation Symplicity Spyral radiofrequency renal denervation system have shown beneficial effects on blood pressure reduction in the renal denervation-treated arm compared to placebo (24 h ambulatory blood pressure –7 vs –3.9 mmHg). It needs to be seen if these blood pressure reductions and associated haemodynamic, hormonal, and metabolic effects will translate into additional or superior vasculoprotection in diabetes [323, 324].

Dyslipidaemia

The lipid profile is usually altered in the diabetic milieu and further altered in the context of liver or renal disease. Dyslipidaemia further accelerates atherosclerosis development and progression (Chapter 48). At any given level of cholesterol, a person with diabetes has a two- to threefold increased cardiovascular risk over a person without diabetes.

Current guidelines based on numerous studies particularly with statins (e.g. Heart Protective Study, HPS [325], Collaborative Atorvastatin Diabetes Study, CARDS [326]) suggest reducing LDL levels <2.5 mmol/l, with some more recent evidence suggesting enhanced benefits if LDL is lowered to <2 mmol/l, triglycerides to <1 mmol/l, and HDL to >1 mmol/l according to pre-existing CVD and risk [327]. This area of research will significantly change with the recent advent of monoclonal antibodies against proprotein convertase subtilisin kexin 9 (PCSK9). These drugs are powerful agents that lower LDL levels by >60%. Furthermore, there have been early reports about beneficial effects on cardiovascular events [328, 329]. Whether there are anti-atherosclerotic effects of these drugs beyond cholesterol lowering, as has been postulated for statins, and efficacy in diabetes needs to be shown in future trials.

Hypercoagulability

Diabetes is associated with pro-thrombotic changes and enhanced coagulability, thus increasing cardiovascular risk [330, 331]. Although not studied in detail, agents such as aspirin may be useful in people with diabetes, with increasing evidence that higher doses of these agents are often required in individuals with diabetes to confer cardiovascular benefits. Other drugs to consider in diabetes are clopidogrel and other agents such as abciximab [332], which has been reported to be particularly effective in people with diabetes.

Novel therapies

Several approaches have been used to intervene in diabetes-associated complications, including aldose reductase inhibitors and PKC isoform inhibitors, in particular PKC β , but most of the evidence for a potential role for these agents has been obtained in the context of microvascular complications. Furthermore, inhibitors of glucose-induced ROS formation, such as benfotiamine, have been investigated in clinical trials with variable results. AGE inhibitors and RAGE antagonism have also been employed, mainly in the context of diabetic nephropathy. The cross-link breaker alagebrium reduces arterial stiffness in people with hypertension and improves

left ventricular function. Direct antagonists of RAGE and human chimeric sRAGE are currently being investigated in early clinical trials, but so far not with respect to macrovascular disease.

Multifactorial approaches

The Steno-2 study, using a multifactorial approach addressing lipids, blood pressure, and hyperglycaemia, demonstrated significant improvements on cardiovascular outcomes [28]. Thus, a synergistic multifactorial approach addressing glycaemic management in the context of additional strategies to reduce concomitant cardiovascular risk factors remains the best approach being currently considered. In terms of glucose lowering, the novel anti-diabetes drugs SGLT-2 inhibitors and GLP-1 receptor agonists have shown cardiovascular benefits and have been included in the new guidelines as preferred anti-diabetes treatments, in particular in individuals with underlying heart failure or CVD. Furthermore, strategies directed towards a reduction in activation of vasoactive systems such as the RAAS, the endothelin and urothelin systems, the AGE/RAGE axis, novel proteins such as TRAIL, and the complement system, in addition to oxidative stress and inflammation, may represent additional promising approaches to prevent and minimize macrovascular disease in diabetes.

Hypertension and Diabetes

Peter M. Nilsson

Lund University, Skåne University Hospital, Malmö, Sweden

Key points

- Hypertension in diabetes is a prevalent and treatable risk factor for cardiovascular complications, nephropathy, and retinopathy.
- Evaluation of hypertension by the use of ambulatory blood pressure monitoring should be offered to all people with type 1 diabetes and type 2 diabetes.
- Most antihypertensive drugs can be used for treatment, but blockers of the renin–angiotensin–aldosterone system (RAAS) may confer special clinical benefits for target organ protection.
- Drug combination therapy is needed for most people to achieve reasonable blood pressure control, even as initial treatment.
- Encouragement of home blood pressure measurements will make it possible to achieve better blood pressure management while also supporting the involvement and empowerment of the person with diabetes.
- According to European guidelines, the blood pressure goal for people with type 2 diabetes is $<130/80$ mmHg for those younger than 65 years and within a systolic range of 130–140 mmHg for older individuals.

Hypertension often accompanies both type 1 diabetes and type 2 diabetes. The association between the two conditions has long been recognized. In 1923, the Swedish physician Eskil Kylin described a syndrome of diabetes, hypertension, and hyperuricaemia [1], which are now regarded as aspects of the broader ‘metabolic syndrome’ that has been linked to insulin resistance [2, 3]. The relationship between diabetes and hypertension is complex. Both are common and so are likely to be associated by chance, but in some instances they may have a common cause, even programmed in early life; moreover, hypertension can develop as a consequence of diabetic nephropathy, and some drugs used to treat hypertension can induce diabetes in susceptible individuals, at least at higher dosages.

Hypertension is important because, like diabetes, it is a major cardiovascular risk factor and one that synergizes with the deleterious effects of diabetes. It is also a risk factor for microvascular complications, namely nephropathy and retinopathy. The management of hypertension in diabetes has been widely debated, and there is still a need to agree on treatment targets and strategies. According to European guidelines, the current blood pressure goal for therapy is $<130/80$ mmHg for those younger than 65 years and within a systolic range 130–140 mmHg for older individuals [4]. During the last 25 years, several well-constructed trials have added considerably to the evidence base [5–8], demonstrating convincingly the benefits of lowering blood pressure, but also highlighting how difficult this can be to achieve in practice.

Size of the problem

Hypertension is widely defined according to the World Health Organization/International Society of Hypertension (WHO/ISH) criteria (Table 47.1). People with diabetes are, however, still at risk of macrovascular and microvascular complications at blood pressure levels below these thresholds, and the treatment target range is therefore lower than 130/80 mmHg for those younger than 65 years (but not lower than 120/70 mmHg) and between a systolic range of 130–140 mmHg for older individuals according to European Guidelines [4].

Overall, hypertension (according to the WHO criteria $>140/90$ mmHg) is up to twice as common in people with diabetes as in the general population [9]. In white Europeans, 10–30% of people with type 1 diabetes and 60–80% of those with newly diagnosed type 2 diabetes have hypertension [10]. There are racial and ethnic differences in the prevalence of hypertension, which presumably are at least partly genetically determined. For example, hypertension (and macrovascular disease) is less frequent among the Pima and Mexican Americans [11]. Impaired glucose tolerance is also associated with hypertension (20–40% of cases), perhaps reflecting the common origins of these aspects of the metabolic syndrome [12].

The true prevalence of hypertension is increasing in the population with diabetes (especially type 2 diabetes) after allowing for the greater number of cases identified through improved screening and

Table 47.1 Criteria for hypertension and related tissue damage, defined by the World Health Organization (WHO) and the International Society for Hypertension 1999 [41].

Category	Systolic (mmHg)	Diastolic (mmHg)
WHO criteria for the general population ^a		
Optimal	<120	<80
Normal	<130	<85
High normal	130–139	85–89
Grade 1 hypertension (mild)	140–159	90–99
Subgroup: borderline	140–149	90–94
Grade 2 hypertension (moderate)	160–179	100–109
Grade 3 hypertension (severe)	≥180	≥110
Isolated systolic hypertension	≥140	<90
Subgroup: borderline	140–149	<90
Hypertension-related tissue damage (WHO criteria)		
Grade I: none		
Grade II: subclinical damage (e.g. retinopathy, proteinuria)		
Grade III: clinical damage (e.g. heart failure, ischaemia)		
Degree of proteinuria		
Microalbuminuria: 30–300 mg/24 h (20–200 mg/min)		
Macroalbuminuria: >300 mg/24 h (>300 mg/min)		

^aDesirable blood pressure limits in people with diabetes are suggested in Figure 47.5.

the lowering of thresholds for treatment of blood pressure [13]. The causes probably include the rising prevalence of obesity and improved survival of older people with diabetes.

Causes of hypertension in diabetes

Associations between hypertension and diabetes are listed in Table 47.2. Essential hypertension and isolated systolic hypertension are both common in people without diabetes, especially in older people. It is estimated that essential hypertension accounts for about 10% of cases in people with diabetes. Other important causes are the hypertension that coexists with insulin resistance, obesity, and impaired glucose tolerance in the metabolic syndrome, and hypertension secondary to diabetic nephropathy, as discussed in detail in what follows.

Hypertension in the metabolic syndrome

This syndrome comprises insulin resistance, impaired fasting glycaemia (including type 2 diabetes), a characteristic dyslipidaemia – hypertriglyceridaemia, low high-density lipoprotein (HDL) cholesterol, and somewhat raised low-density lipoprotein (LDL), with a clear excess of small, dense LDL particles – truncal obesity, procoagulant changes (raised plasminogen activator inhibitor 1 and fibrinogen levels), and hyperuricaemia [2, 14, 15]. As these abnormalities are all risk factors for atherosclerosis, the syndrome is associated with a marked tendency for early vascular ageing, leading to macrovascular disease, especially coronary heart disease (CHD) and stroke (Figure 47.1). As discussed in Chapter 17, insulin resistance has been proposed by Reaven [2], DeFronzo and Ferrannini [14], and others [15] to be a fundamental cause of hypertension and cardiovascular disease (CVD) in addition to type 2 diabetes. Insulin

Table 47.2 Associations between hypertension and diabetes.

Hypertension associated with type 2 diabetes (insulin resistance or metabolic syndrome)
Hypertension associated with nephropathy in type 1 diabetes
Coincidental hypertension in people with diabetes
Essential hypertension
Isolated systolic hypertension
Renal scarring (e.g. from recurrent pyelonephritis)
Diabetogenic anti-hypertensive drugs
Potassium-losing diuretics (chlortalidone, high-dose thiazides)
β-blockers (high dosages)
Combined diuretics and β-blockers (high dosages)
Drugs causing obesity, hypertension, and glucose intolerance
Glucocorticoids
Combined oral contraceptive pills
Antipsychotics
Endocrine disorders causing hypertension and glucose intolerance
Acromegaly
Cushing syndrome
Conn's syndrome
Phaeochromocytoma

resistance is partly genetically determined, while acquired factors such as obesity, physical inactivity, and perhaps malnutrition *in utero* and weight changes during early infancy may also contribute [16]. In support of the latter, family studies have revealed a correlation between the blood pressure of the mother and her offspring that appears to be non-hereditary in origin; early growth retardation may programme abnormal development of the vasculature and also the tissues that regulate glucose homeostasis. This could in turn be influenced by maternal genes for raised blood pressure that will not only programme the blood pressure of the offspring, but also may influence fetal growth retardation and a lower birth weight as a side phenomenon [17].

Insulin resistance is closely associated with high blood pressure in both humans and animals. Experimental induction of insulin resistance (e.g. feeding rats with fructose) is accompanied by a rise in blood pressure. More persuasively, an inverse relationship has been demonstrated in humans between blood pressure levels and insulin sensitivity [18] (Figure 47.2). Various mechanisms have been proposed to explain how insulin resistance and/or the accompanying hyperinsulinaemia could increase blood pressure (Figure 47.3). First, insulin is an endothelium-dependent vasodilator, releasing nitric oxide (NO) from the endothelium, which relaxes vascular smooth muscle [19]; blunting of this effect, caused by insensitivity to the action of insulin on the endothelium and also on metabolically important tissues, could contribute to the increased peripheral resistance that is the hallmark of hypertension in obesity and type 2 diabetes. Impaired endothelium-mediated vasodilation is associated with insulin-resistant states and may have a key role in the initiation and progression of atherosclerosis [20], further negatively influenced by smoking.

By contrast, insulin also has several actions that tend to raise blood pressure, and these are accentuated in insulin-resistant states, presumably because sensitivity to the effects of the raised insulin levels is preserved. Insulin acts on the distal renal tubule to retain Na⁺ ions and water [20, 21], an effect that still operates in people with insulin resistance [22], and so could contribute to

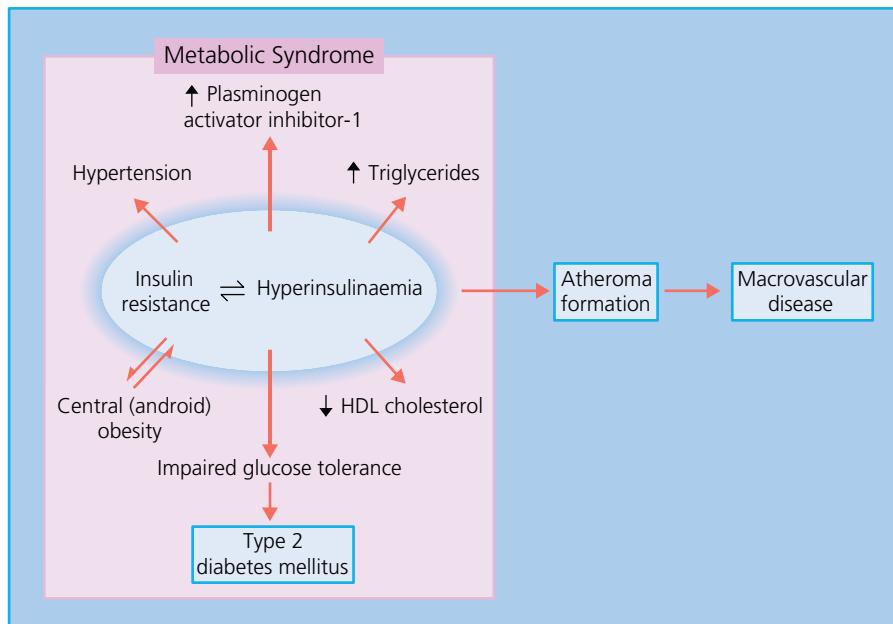

Figure 47.1 The metabolic syndrome. HDL, high-density lipoprotein.

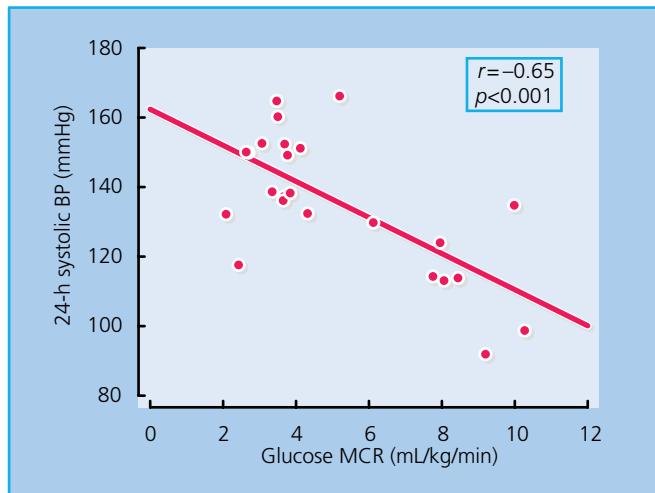

Figure 47.2 Hypertension is associated with insulin resistance. Insulin sensitivity, measured as the metabolic clearance rate (MCR) of glucose during an insulin clamp study, is inversely related to the mean 24 h systolic and ambulatory blood pressure (BP). Source: Pinkney et al. 1994 [18]. Reproduced with permission from Wolters Kluwer Health.

the rise in total body Na^+ content that occurs in obesity and type 2 diabetes [23]. Insulin also stimulates the cell membrane $\text{Na}^+–\text{K}^+$ ATPase, which would raise intracellular Na^+ concentrations in vascular smooth muscle and, by increasing systolic Ca^{2+} levels, would enhance contractility and increase peripheral resistance [22, 23]. Through its effects on the central nervous system (CNS), insulin may stimulate the sympathetic outflow. Theoretically, this could also increase blood pressure, although direct evidence in humans is lacking [22, 24]. Finally, insulin may stimulate the proliferation of vascular smooth muscle cells, which could lead to medial hypertrophy and increased peripheral resistance [22, 25].

Hypertension and diabetic nephropathy

This association is most obvious in young people with type 1 diabetes, in whom the presence of hypertension is strikingly related to renal damage and even minor degrees of proteinuria. Blood pressure begins to rise when the urinary albumin excretion (UAE) enters the microalbuminuric range ($>30 \text{ mg}/24\text{h}$) and is usually over the WHO threshold when UAE reaches the macroalbuminuric stage ($>300 \text{ mg}/24\text{h}$) [26]. The association may be partly genetically determined: people with diabetes and microalbuminuria commonly have parents with hypertension and may also inherit overactivity of the cell membrane $\text{Na}^+–\text{H}^+$ pump (indicated by increased $\text{Na}^+–\text{Li}^+$ counter-transport in red blood cells), which would tend to raise intracellular Na^+ concentrations and thus increase vascular smooth muscle tone [27].

The basic mechanisms of hypertension include decreased Na^+ excretion with Na^+ and water retention. Peripheral resistance is increased, to which raised intracellular Na^+ will contribute. The role of the renin–angiotensin–aldosterone system (RAAS) is uncertain, as both increased and decreased activity have been reported [28, 29]. These discrepancies may be explained by differences in diet, treatment, metabolic management, and the type and duration of diabetes. Na^+ retention and hypertension would be predicted to suppress the RAAS, whereas renin levels may be influenced by other complications of diabetes: renal tubular acidosis type 4 causes hyporeninaemic hypoaldosteronism and neuropathy can also lower plasma renin, while renin may be raised in retinopathy and advanced nephropathy. Individuals with microalbuminuria who are insulin resistant appear to be particularly susceptible to hypertension [30].

Impact of hypertension in diabetes

A large proportion of people with hypertension and diabetes show signs of cardiovascular aging and target-organ damage [10]. Hypertension, as an independent risk factor for atherosclerosis, synergizes with the effects of diabetes and significantly increases the development and progression of CHD and cerebrovascular and

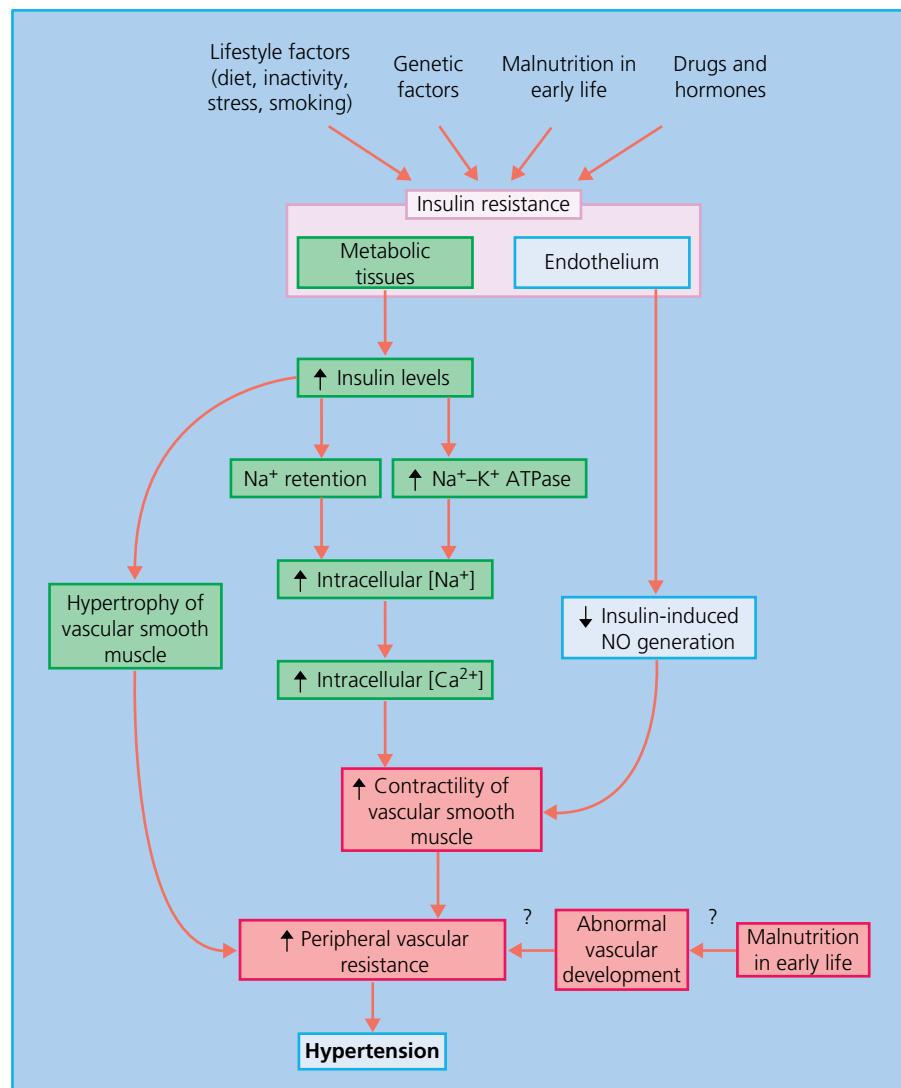

Figure 47.3 Possible mechanisms of hypertension in conditions of insulin resistance. NO, nitric oxide.

peripheral vascular disease. Overall, the effects of hypertension on deaths from CHD are increased two- to fivefold in people with diabetes, with the greatest relative increase occurring at the lowest blood pressure levels (Figure 47.4).

The deleterious effects of hypertension on left ventricular function are also accentuated by the presence of diabetes. These include impaired left ventricular relaxation [31] and increased left ventricular mass [32], the latter being an independent predictor of premature death from CHD.

Hypertension also predisposes to the development of certain microvascular complications, particularly nephropathy and end-stage renal disease, for which the risk is increased two- to threefold (Chapter 44). In addition, hypertension is also a risk factor for retinopathy, as has been confirmed by the beneficial effects of improved blood pressure management in people with type 2 diabetes reported by the UK Prospective Diabetes Study (UKPDS) [5].

In recent years, interest in arterial stiffness (arteriosclerosis) has increased, as this is a characteristic of people with the metabolic syndrome and type 2 diabetes [33]. Increased aortic pulse wave velocity (aPWV) is a marker of the arterial stiffness that is supposed to precede, but later also to interact with, atherosclerosis [34]. A threshold

of aPWV >10 m/s [35] is a marker of increased arterial stiffness that can also independently predict cardiovascular risk and total mortality [36]. At early stages, the degree of hyperglycaemia and dyslipidaemia also increases arterial stiffness in people with normoglycaemia or impaired glucose metabolism [37], resulting in early vascular ageing [38]. In fact, arterial stiffness is even a predictor of type 2 diabetes in a general middle-aged population [39].

Screening for hypertension in diabetes

As the two conditions are so commonly associated, people with diabetes must be regularly screened for hypertension and vice versa. People with hypertension, especially if they have obesity or are receiving treatment with potentially diabetogenic drugs, should be screened for diabetes at diagnosis and during follow-up. Should hyperglycaemia be detected, potentially diabetogenic antihypertensive drugs should be reduced or changed to others or used in combinations that do not further impair glucose tolerance; normoglycaemia can then often be restored when lifestyle improvements are also supported.

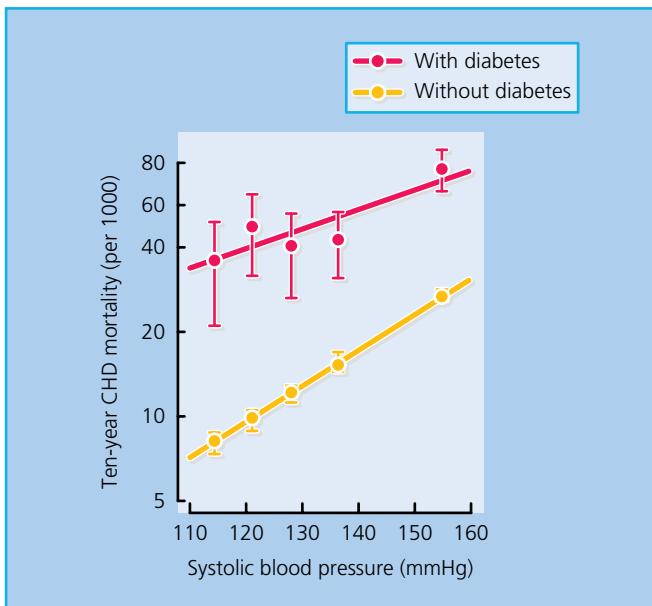

Figure 47.4 Synergistic effects of diabetes and hypertension on deaths from coronary heart disease (CHD). Data from 342 815 people without diabetes and 5163 people with diabetes aged 35–57 years, free from myocardial infarction at entry. Source: Reproduced with permission from O. Vaccaro, paper presented at the 26th Annual Meeting of the European Diabetes Epidemiology Group, Lund, 1991.

All people with diabetes should have their blood pressure checked at diagnosis and at least annually thereafter. This is especially important in those with other cardiovascular risk factors, such as nephropathy (which is associated with a substantial increase in the cardiovascular mortality rate), obesity, dyslipidaemia, smoking, or elevated glycated haemoglobin (HbA_{1c}), or with a positive family history of early-onset cardiovascular disease.

Measurement of blood pressure

Blood pressure should be measured with the individual in the supine or sitting position, with an accurate sphygmomanometer and a cuff of appropriate size (i.e. wider for people with obesity and an arm circumference of $>32\text{ cm}$). Systolic and diastolic blood pressure should be recorded, to the nearest 2 mmHg if using a manual sphygmomanometer, from phases I and V (i.e. appearance and final disappearance of the sounds of Korotkoff). Usual precautions

should be taken to ensure reliability and avoid ‘white coat’ stress effects, which can acutely raise blood pressure. Conditions should be quiet and relaxed, and at least two readings should be taken initially and then repeated at intervals over weeks or months to determine the person’s typical values and any trend towards change. Office blood pressure could be complemented by repeated home blood pressure recordings.

Blood pressure should also be checked with the individual in the upright position (one minute after standing), because there may be a significant postural fall ($>20\text{ mmHg}$ systolic) in people with autonomic neuropathy, older people, or those treated with vasodilators or diuretics. Marked postural hypotension, which can coexist with supine hypertension, may indicate the need to change or reduce antihypertensive medication, especially if symptoms are provoked.

Ambulatory blood pressure monitoring over 24 hours may be useful in some cases to exclude ‘white coat’ effects, and in people with early nephropathy who have nearly normal blood pressure during the day, but who may be at risk of hypertensive tissue damage because they do not have the physiological blood pressure dip during sleep. Masked hypertension (non-dipping at night) is also a common phenomenon in about 20–30% of all individuals with type 2 diabetes [40].

Diagnosis of hypertension in diabetes

The criteria issued in 1999 by the WHO and ISH define hypertension as an office blood pressure exceeding 140/90 mmHg (Korotkoff I–V) and borderline hypertension as being below these limits but above 130 mmHg systolic and/or 85 mmHg diastolic (Figure 47.5) [41]. Established hypertension is diagnosed when readings consistently exceed 140/90 mmHg over several weeks, or when the blood pressure is very high (diastolic blood pressure $>110\text{ mmHg}$), or when there are clinical signs of tissue organ damage from long-standing hypertension.

It is clear from numerous epidemiological studies that the WHO/ISH threshold is sometimes too high in people with diabetes because of their additional risk of both macrovascular and microvascular disease [42], and that there are definite benefits from treating people with microalbuminuria whose diastolic blood pressure is $<90\text{ mmHg}$. Various other expert bodies have suggested alternative, generally lower target levels (Figure 47.5). A consensus would be to aim for a blood pressure below 130/80 mmHg for those

Treatment strategies in people with diabetes

Recommendations	Class	Level
Antihypertensive drug treatment is recommended for people with diabetes when office BP is $\geq 140/90\text{ mmHg}$.	I	A
In people with diabetes receiving BP-lowering drugs it is recommended:		
• To target SBP to 130 mmHg and lower, if tolerated, but not lower than 120 mmHg.	I	A
• In older people (aged ≥ 65 years), to target to a SBP range of 130 to $<140\text{ mmHg}$.	I	A
• To target the DBP to $< 80\text{ mmHg}$, but not lower than 70 mmHg.	I	C
It is recommended to initiate treatment with a combination of an RAAS blocker with a CCB or thiazide/thiazide-like diuretic.	I	A
Simultaneous administration of two RAAS blockers, e.g. an ACE inhibitor and ARB, is not indicated.	III	A

younger than 65 years (but not lower than 120/70 mmHg) and within a systolic range of 130–140 mmHg for older people according to European [4, 43] and international guidelines [44, 45].

Investigation of hypertension in diabetes

Initial investigation of the person with diabetes and hypertension aims to exclude rare causes of secondary hypertension (Table 47.2), to assess the extent of tissue organ damage caused by hypertension and diabetes (Table 47.1), and to identify other potentially treatable risk factors for vascular disease. The major points in the medical history and examination are shown in Table 47.3:

- **Cardiac function.** A standard 12-lead electrocardiogram may show obvious ischaemia, arrhythmia, or left ventricular hypertrophy; the last is more accurately demonstrated by echocardiography, which will also reveal left ventricular dysfunction and decreased ejection fraction. Exercise testing or stress-echo testing and 24 h Holter monitoring may also be appropriate.
- **Renal function.** A fresh urine sample should be tested for microalbuminuria (Chapter 44) and another examined microscopically for red and white blood cells, casts, and other signs of renal disease. Microscopic haematuria can occasionally occur in people with type 1 diabetes (particularly children) in the apparent absence of significant renal dysfunction, but coexisting renal disease must always be excluded. Serum urea, creatinine, and electrolytes should be checked. If the serum creatinine concentration is raised, measurement of the glomerular filtration rate should be considered, ideally using a specific clearance method such as using chromium–ethylenediaminetetraacetic acid complex (Cr-EDTA), iohexol, or cystatin C. Further specialist investigations include an isotope renogram and other tests for renal artery stenosis (Figure 47.6). This complication of renal arterial atherosclerosis may affect up to 20% of older people with type 2 diabetes and, if bilateral, can lead to severe and sometimes permanent renal impairment if angiotensin-converting enzyme (ACE) inhibitors are given.
- **Lipid profile.** Fasting serum lipid concentrations should be checked. If total cholesterol or triglyceride levels are found to be elevated after repeated measurements, further investigation of lipoprotein subclasses – very low-density lipoprotein (VLDL), LDL, HDL, and also the apo-B-to-apo-A1 lipoprotein ratio – is recommended. Treatment for hyperlipidaemia should be considered if the total cholesterol is >4.0 mmol/l, the LDL cholesterol level is >2.5 mmol/l, or the LDL-to-HDL cholesterol ratio is >4, and with stricter targets according to European guidelines [43]. This is discussed in more detail in Chapters 48, 49, and 51.

Other forms of secondary hypertension may be indicated by clinical findings of endocrine or renal disease, significant hypokalaemia (plasma potassium <3.5 mmol/l without previous diuretic treatment), failure of hypertension to respond to standard treatment, or a sudden decline in glomerular filtration rate after starting treatment with ACE inhibitors (suggestive of renal artery stenosis).

Management of hypertension in diabetes

Strict blood pressure control is the primary goal of treatment. In recent years, target treatment levels have been lowered progressively to the current recommendation of a mean office blood

pressure below 130/80 mmHg for those younger than 65 years and within a systolic range of 130–140 mmHg for older individuals and for all people who can tolerate these levels without side effects, such as orthostatic reactions or compromising arterial circulation in critical vascular beds. Recent observations indicate that there may be subgroups of susceptible individuals who will not tolerate a dramatic reduction below 130 mmHg systolic blood pressure, and so caution should be exercised, especially when comorbidities are present. A blood pressure reduced below 120/70 mmHg may impair the coronary circulation in susceptible individuals.

Management begins with lifestyle modification, but few people respond to this alone, and most will require more than one antihypertensive drug, potentially as a single tablet fixed drug combination [4] from treatment initiation to manage blood pressure adequately, a fact that new guidelines emphasize [4, 43–45].

Non-pharmacological treatment

The treatment of hypertension in people with diabetes must be based on structured lifestyle intervention. This means weight reduction or weight stabilization in those with obesity, sodium restriction, diet modification, and regular physical exercise (moderate intensity, 40–60 minutes, 2–3 times weekly). Dietary saturated fat intake has been associated with impaired insulin sensitivity and should therefore be reduced [46]. Alcohol should be restricted to 2–3 units/d in men and 2 units/d in women, but omitted altogether if hypertension proves difficult to manage. It should be remembered that the Look AHEAD (Action for Health in Diabetes) study in the USA provided no evidence for benefits of weight loss *per se* as a strategy to lower cardiovascular risk and reduce mortality in individuals with obesity and type 2 diabetes of long duration, even though glucose and other risk factors may improve [47]. This underlies the rationale to aim for control of conventional cardiovascular risk factors in the first place, rather than weight loss itself, with drugs based on evidence and according to guidelines [4, 43–45].

Smoking causes an acute increase in blood pressure and greater variability overall [48]. Smoking cessation is especially important, as smoking not only accelerates the progression of atherosclerosis and vascular ageing, but also impairs insulin sensitivity [49] and worsens albuminuria [50]. Drug treatment with nicotine supplementation for 4–6 weeks (chewing gum or patches), bupropion, or varenicline (not available in Europe) may be useful.

When adopted in full, lifestyle modification can be effective for blood pressure control itself and is believed to benefit cardiovascular risk in general, even if the evidence is scanty. The measures mentioned can lower systolic and diastolic blood pressure by up to 11 and 8 mmHg, respectively [51], as much as many antihypertensive drugs, and sometimes enough to lessen the need for drug therapy. Weight reduction in those with obesity can similarly reduce blood pressure, but not cardiovascular events, according to the Look AHEAD study, which is why more research is needed [47]. It should be remembered that if target-organ damage is present, lifestyle advice is not enough and drug therapy should be considered.

Antihypertensive drug therapy

Numerous drugs are available to lower blood pressure, but some are better suited than others to the particular needs of people with diabetes because of their favourable or neutral effects on glucose metabolism and other factors. Most people with diabetes (at least two-thirds) will require combinations of antihypertensive drugs to

control blood pressure, with an average of around three different drugs in two large studies [5, 6]. Accordingly, the clinician must be able to use a wide variety of antihypertensive drugs and to choose combinations that exploit pharmacological synergy. Combination therapy usually means that lower dosages of individual drugs can be used, thus reducing the risk of adverse effects.

Diuretics

Diuretics are often effective antihypertensive agents for people with diabetes, in whom the total body sodium load is increased and the extracellular fluid volume expanded [52]; however, diuretics that increase urinary potassium and magnesium losses can worsen hyperglycaemia, as insulin secretion is impaired by potassium depletion, and insulin sensitivity in peripheral tissues may also be decreased [53]. The use of high-dose thiazide diuretics, equivalent to ≥ 5 mg/d bendroflumethiazide (bendrofluazide), increases the risk of people with hypertension developing diabetes by up to threefold; this does not seem to occur with low dosages (up to 2.5 mg/d bendroflumethiazide) [54]. Potassium depletion is particularly severe with high-dose chlortalidone (chlorthalidone), less so with furosemide (frusemide) and bendroflumethiazide, and apparently negligible with indapamide. This mechanism is irrelevant to those with C-peptide-negative type 1 diabetes who are totally dependent on exogenous insulin. Thiazides may also aggravate dyslipidaemia [55], although low dosages probably carry a small risk. Thiazides have also been associated with gout and erectile dysfunction and are therefore generally avoided in middle-aged men with diabetes and hyperuricaemia or erectile dysfunction; nevertheless, some evidence suggests that the risk of erectile failure may have been overstated. Diuretics may precipitate hyperosmolar hyperglycaemic syndrome and should be avoided or used at the lowest effective dose in people with a history of this complication.

Diuretics prevent CVD in older people with type 2 diabetes and systolic hypertension [56], but one observational study suggested that the use of diuretics increased cardiovascular mortality in those with hypertension and type 2 diabetes who remain hyperglycaemic in spite of treatment [57]. Overall, these drugs are effective and safe when used appropriately in people with diabetes.

Diuretics suitable for use in diabetic hypertension include furosemide, bendroflumethiazide (≤ 2.5 mg/d), hydrochlorothiazide, spironolactone, and indapamide. Low dosages should be used, sometimes in combination with potassium supplements or potassium-sparing drugs, such as amiloride. If ineffective, diuretics should be combined with another first-line drug (e.g. an ACE inhibitor or an angiotensin II receptor blocker [ARB]), rather than given at increased dosage. Spironolactone is best not combined with an ACE inhibitor, as this increases the risk of hyperkalaemia. Furosemide is useful in people with renal impairment (serum creatinine >150 μ mol/l) or oedema.

Serum urea, creatinine, and potassium should be checked when starting diuretic therapy and every 6–12 months thereafter, as dangerous disturbances in plasma potassium concentration can develop, especially in individuals with diabetes and renal impairment.

β -Adrenergic blocking agents

β -receptor blockers may significantly lower blood pressure in people with diabetes and hypertension, even though renin release (a major target for these drugs) is commonly reduced in diabetes

because of Na^+ and fluid retention. These drugs are often ineffective in Afro-Caribbean people, who commonly have low renin hypertension. Other mechanisms of action that reduce blood pressure include reductions in heart rate and cardiac output via interaction with β_1 - and β_2 -receptors in the myocardium and in the vessel wall.

Like diuretics, β -receptor blockers may aggravate both hyperglycaemia and dyslipidaemia [58]. These effects depend on both the dosage and the degree of selectivity of the individual drug. The hyperglycaemic effect is attributed to inhibition of β_2 -adrenergic-mediated insulin release and decreased insulin action in peripheral tissues; the long-term risk for a person without diabetes developing the disease may be increased sixfold [59], and even more if given together with thiazides. Some studies suggest that the hazards of both hyperglycaemia and hyperlipidaemia have been exaggerated and may be both dose dependent and secondary to weight gain [60]. The metabolic side effects of β -blockers can be reduced by using low dosages combined with other agents, particularly dihydropyridine calcium-channel antagonists, or by intensifying non-pharmacological efforts to decrease weight and improve physical activity.

β -blockers have other side effects relevant to diabetes. They may interfere with the counter-regulatory effects of catecholamines released during hypoglycaemia, thereby blunting manifestations such as tachycardia and tremor and delaying recovery from hypoglycaemia [61]. In clinical practice, however, this rarely presents a serious problem, especially when cardioselective β_1 -blockers are used. β -blockers may also aggravate erectile dysfunction and are generally contraindicated in second- or third-degree atrioventricular heart block, severe peripheral vascular disease, asthma, and chronic airway obstruction. Certain β -blockers such as metoprolol and carvedilol [62, 63] can be used favourably in cardiac failure in people with diabetes, as shown in the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) study, in which 25% of the participants had diabetes [62].

Atenolol is a commonly used drug, as it is cardioselective and water soluble, which reduces CNS side effects and renders its metabolism and dosage more predictable. It is mostly effective as a single daily dose, which probably encourages medication taking as prescribed. In the UKPDS, its effect was comparable to that of the ACE inhibitor captopril [64]; however, it should be kept in mind that the stroke-preventive effect of atenolol is 16% less than that of other antihypertensive drugs, based on data from meta-analyses. Metoprolol is an alternative, in moderate dosages. Both non-selective and selective β -blockers are effective in the secondary prevention of myocardial infarction after an initial event in people with diabetes [65]. Metoprolol or carvedilol may be indicated in those who also have heart failure [62, 63], and β -blockers in general are useful in individuals who suffer from angina or tachyarrhythmias.

Calcium-channel antagonists

These useful vasodilator agents do not generally worsen glycaemia when used at conventional dosages, although sporadic cases of hyperglycaemia have been reported after starting a calcium-channel antagonist of the dihydropyridine class [66]. This may be caused by inhibition of insulin secretion (a calcium-dependent process) in susceptible individuals, or a compensatory sympathetic nervous activation, which antagonizes both insulin secretion and action following vasodilatation.

Calcium-channel antagonists have a slight negative inotropic effect and are contraindicated in significant cardiac failure; they often cause mild ankle oedema, but this is caused by relaxation of the peripheral pre-capillary sphincters and raised capillary pressure rather than by right ventricular failure. Because of their potent vasodilator properties, these drugs can cause postural hypotension and can aggravate that brought about by autonomic neuropathy. Non-dihydropyridine calcium-channel antagonists (e.g. verapamil) reduce proteinuria in diabetic nephropathy, but this effect is not seen with dihydropyridine derivatives, such as nifedipine, amlodipine, felodipine, and isradipine [67].

Because of their other cardiac actions, these drugs are particularly indicated in people with hypertension who also have angina (e.g. sustained-release nifedipine and diltiazem) or supraventricular tachycardia (e.g. verapamil). Their vasodilator properties may also be beneficial in peripheral vascular disease. Calcium-channel antagonists are ideally combined with selective β_1 -blockers, but the specific combination of verapamil and β -blockers (especially together with digoxin) must be avoided because of the risk of conduction block and asystole. Overall, calcium-channel antagonists appear less or similarly cardioprotective, but better at preventing stroke, than either β -blockers or thiazide diuretics [68, 69].

Amlodipine given once daily is an evidence-based and convenient preparation for general use, and felodipine, isradipine, and sustained-release nifedipine are suitable alternatives.

Angiotensin-converting enzyme inhibitors

ACE inhibitors may be used in diabetes-related hypertension, even in cases where the general RAAS is not activated, as the drugs may interfere with local angiotensin action in specific target tissues. When used alone, however, these agents have a limited hypotensive action in many Afro-Caribbean people, who tend to have suppressed RAAS activity.

ACE inhibitors have no adverse metabolic effects and may even improve insulin sensitivity [70]; hypoglycaemia has rarely been reported [71]. These drugs are particularly beneficial in diabetic nephropathy by reducing albuminuria and possibly delaying progression of renal damage [72]. Their antiproteinuric effect may be caused specifically by relaxation of the efferent arterioles in the glomerulus, which are highly sensitive to vasoconstriction by angiotensin II, thus reducing the intraglomerular hypertension that is postulated to favour albumin filtration; however, the importance of this mechanism remains controversial [73]. ACE inhibitors are also indicated in cardiac failure, in combination with relatively low dosages of diuretics.

A dry cough is reported by 10–15% of people treated with ACE inhibitors (more commonly in women than in men), because these drugs also interfere with the breakdown of kinins in the bronchial epithelium. Changing to another ACE inhibitor or an ARB may avoid this problem. ACE inhibitors occasionally precipitate acute renal failure, particularly in older people and in individuals taking non-steroidal anti-inflammatory drugs (NSAIDs), or who have bilateral renal artery stenosis. Other side effects (rashes, neutropenia, taste disturbance) are unusual with the low dosages currently recommended, but become more prominent in renal failure. Because ACE inhibitors cause potassium retention, they should not generally be taken concurrently with potassium-sparing diuretics (spironolactone and amiloride) or potassium supplements. Serum creatinine and potassium levels should be monitored regularly,

especially in individuals with renal failure or type 4 renal tubular acidosis, in whom hyperkalaemia can rapidly reach dangerous levels. RAAS-blocking drugs should not be used in pregnant women, or fertile women without contraceptives, due to their teratogenic effects.

Ramipril, enalapril, lisinopril, and perindopril, given once daily for hypertension, are all well-established ACE inhibitors that are suitable for use in people with diabetes. The first dose of an ACE inhibitor should be small and taken just before bedtime to minimize postural hypotension, which may be marked in people receiving diuretics or on a strict sodium-restricted diet. The same problem may arise in those with autonomic neuropathy. ACE inhibitors are recommended in people with left ventricular dysfunction following myocardial infarction (Chapters 49 and 50). Ramipril has been shown to prevent cardiovascular morbidity and mortality in high-risk people with diabetes, with or without pre-existing ischaemic heart disease [74].

Angiotensin II type 1 receptor blockers

This class includes losartan, irbesartan, valsartan, candesartan, and telmisartan, which act on the AT₁ receptor to block it and thereby decrease blood pressure. They are metabolically neutral [75] and, unlike the ACE inhibitors, do not cause cough. They are effective antihypertensive drugs in people with diabetes [76] and slow the progression of nephropathy in those with diabetes and varying degrees of albuminuria (in the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan [RENAAL], Irbesartan Diabetic Nephropathy Trial [IDNT], and Irbesartan in Patients with Type 2 diabetes and Microalbuminuria [IRMA-2] studies) [77–79]. Losartan has also been shown in a subgroup of the Losartan Intervention For Endpoint reduction (LIFE) study to be better than atenolol in reducing both cardiovascular endpoints (by 25%) and total mortality (by 40%) in high-risk people with type 2 diabetes with hypertension and left ventricular hypertrophy [80]. Interestingly, the combination of an ACE inhibitor (lisinopril) with an AT₁ antagonist (candesartan) was more effective than either agent alone in lowering blood pressure and UAE in people with type 2 diabetes [81]; however, in the Ongoing Telmisartan Alone and in combination with Ramipril Global Endpoint Trial (ONTARGET) study, no extra benefits were recorded for the combination of telmisartan and ramipril on cardiovascular endpoints compared with monotherapy [82]. The combination of an ACE inhibitor and an AT₁ receptor blocker for treatment of hypertension is discouraged owing to the negative interaction and risk of adverse renal effects, as evident from the ONTARGET study [83].

Direct renin inhibitor

Another approach to block RAAS is via direct renin inhibition. In the Aliskiren Trial in Type 2 Diabetes Using Cardiorenal Endpoints (ALTITUDE) study, this strategy was not successful when the renin inhibitor aliskiren was combined with either an ACE inhibitor or an AT₁ receptor blocker versus placebo for cardiovascular and renal protection [84]. As a result, this combination is not recommended for people with type 2 diabetes, hypertension, and microalbuminuria in current European guidelines [4].

α1-adrenoceptor antagonists

α₁-blockers can lower blood pressure effectively and also improve dyslipidaemia and insulin sensitivity. Doxazosin is normally well tolerated, especially in combination therapy; side effects include

nasal congestion and postural hypotension. Doxazosin has been reported to be inferior to the diuretic chlortalidone in the prevention of stroke and heart failure [85].

Treatment strategies

In general, lifestyle modification should be tried initially for ~3 months. If moderate hypertension (systolic blood pressure >160 mmHg or diastolic blood pressure >100 mmHg) or signs of hypertensive tissue damage are present, then drug therapy should be started at the outset. Initially, monotherapy with one of the first-line drugs suggested should be used, or even as a fixed drug combination at initiation of treatment, the choice being influenced by other factors such as coexistence of angina, heart failure, or nephropathy. All drug treatment should be evidence based and cost-effective in the individual. A move to combination drug treatment is recommended for many people owing to the high prevalence of target-organ damage when early blood pressure control is mandatory [4, 43–45].

Hypertension in type 1 diabetes

ACE inhibitors are especially suitable if the individual has albuminuria or more advanced stages of diabetic nephropathy. Diuretics, β₁-selective blockers, and calcium-channel antagonists are equally valid alternatives with regard to blood pressure reduction.

If renal function is moderately impaired (serum creatinine values >150 μmol/l), thiazide diuretics become less effective, and furosemide or other loop diuretics should be used instead; however, in established end-stage renal disease (serum creatinine >500 μmol/l), furosemide may be toxic and dialysis must be started. In some people, hypoglycaemia may be masked by the use of β-blockers.

Hypertension in type 2 diabetes

Blood pressure control is generally more important than the choice of individual drugs. First-line agents, according to evidence from clinical studies, are ACE inhibitors, ARBs, low-dose thiazide diuretics (in older people), furosemide, and calcium-channel antagonists [4, 43–45].

Ramipril has evidence-based support for its use in individuals with type 2 diabetes because of their high cardiovascular risk [74]. β-blockers are second-line drugs for hypertension, but are indicated as secondary prevention (in combination with low-dose aspirin) for those who have had a myocardial infarction, provided that no serious contraindications are present. Low doses of thiazide diuretics are useful in older people with diabetes, as this class of drugs has proven efficacy in preventing stroke and all-cause mortality [8].

α₁-blockers may be used as part of combination therapy, especially in those with dyslipidaemia (high triglycerides and low HDL cholesterol levels) or prostatic hyperplasia. Indapamide is a well-tolerated non-thiazide diuretic and has no metabolic side effects. Spironolactone may also be of value, especially for older obese women with hypertension and hypervolaemia with a low renin profile, even though evidence from large-scale randomized studies is so far lacking.

Combination therapy

Combination therapy is needed in most people with diabetes (especially those with type 2 diabetes) to achieve satisfactory blood pressure management [4, 43–45]. It is often better to use

low-dose combinations than to increase dosages of single agents, as side effects are commonly dose dependent. Potassium-sparing agents (spironolactone and amiloride) should not be combined with an ACE inhibitor, because of the increased risk for hyperkalaemia.

Certain combinations of antihypertensive drugs have proved very safe and effective in low to moderate doses, such as ACE inhibitor plus diuretic, for example in the ADVANCE study with indapamide [86]; calcium-channel antagonists plus ACE inhibitor, for example in the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) study [87]; selective β_1 -blocker plus calcium-channel antagonist; or β_1 -blocker plus α_1 -blocker (less commonly used). In many high-risk individuals, a combination treatment could also be considered as initial therapy, especially when signs of target-organ damage are present.

Some studies have indicated a better diurnal blood pressure control if antihypertensive drugs can be taken at bedtime in persons with type 2 diabetes, especially in so-called non-dippers with elevated nighttime blood pressure [88].

Special considerations in ethnic groups

Hypertension in diabetes represents a serious medical problem in many ethnic groups, such as African Americans. In non-white European individuals, β -blockers and ACE inhibitors are often less effective at lowering blood pressure because the RAAS is already underactive. Diuretics and calcium-channel antagonists are typically drugs to be preferred, particularly in African Americans [89].

Outcome of treating hypertension in diabetes

It is well recognized that effective treatment of hypertension can slow the progression of diabetic nephropathy, lowering UAE and decreasing the rate of fall of the glomerular filtration rate [90]. The assumptions that improved blood pressure management would improve cardiovascular and other prognoses in type 2 diabetes have been confirmed by the UKPDS [5]. In this study, tighter blood pressure levels (averaging 144/82 mmHg) for over eighty years led to significant improvements in several outcomes, compared with less strict control that averaged 154/87 mmHg (Table 47.4). Interestingly, the most powerful effects were related to microvascular complications (retinopathy and nephropathy), although significant reductions were also seen in the risk of stroke (44%) and heart failure (56%). Myocardial infarction and peripheral vascular disease showed non-significant reductions (Table 47.4; Figures 47.7 and 47.8).

Overall, therefore, tight blood pressure management provides substantial benefits for people with hypertension and diabetes. Moreover, this treatment strategy seems to be cost-effective, at least according to the health economics analyses in the UKPDS [91]; however, it must be kept in mind that these benefits will not last if a continuous blood pressure reduction cannot be achieved long term, as shown by the 10-year follow-up of the UKPDS [92]. Antihypertensive treatment therefore has to be continued and not interrupted.

Table 47.4 Impact of stricter management of hypertension on diabetes complications, macrovascular disease, and diabetes-related deaths in type 2 diabetes.

Measure	Relative risk with tight control (mean, 95% confidence intervals)	p value
Diabetes-related deaths	0.76 (0.62 to 0.92)	0.19
All-cause mortality	0.82 (0.63 to 1.08)	0.17
Myocardial infarction	0.79 (0.59 to 1.07)	0.13
Stroke	0.56 (0.35 to 0.89)	0.013
Peripheral vascular disease	0.51 (0.19 to 1.37)	0.17
Microvascular disease	0.63 (0.44 to 0.89)	0.009

Source: Data from UKPDS 1998 [5].

Conclusions

The diagnosis, treatment, and follow-up of hypertension are of great importance for the person with diabetes [4, 43–45]. The treatment targets are demanding and require considerable effort from both people with diabetes and healthcare professionals, but the benefits are now undisputed. A modern approach to diabetes care aims at involving and motivating the individual at all stages of treatment for shared decision making and high quality of care [93]. This is also of importance for achieving long-term blood pressure control and a high degree of medication taking.

New antihypertensive drugs are being introduced [94], but fewer now than previously. They have to prove themselves with regard to both efficacy and tolerability. However, some anti-diabetes drugs appear to lower blood pressure in addition to blood glucose [95], but safety concerns are important. SGLT-2 inhibitors lower not only office blood pressure, but also 24 h ambulatory blood pressure, based on a combination of diuretic effects, weight loss, and other less well-understood mechanisms [96, 97].

In the future, the application of cardiovascular genomics may substantially change the approach to treating hypertension in diabetes [98], aiming at tailoring treatment according to the genotype of the individual (stratified or personalized medicine).

In the ACCORD blood pressure study [99], there was no significant difference in the primary composite outcome of cardiovascular events between participants randomized to achieve a systolic blood pressure goal below 120 mmHg versus below 140 mmHg, even though a reduction in stroke was noticed (secondary endpoint) in the intensive arm. This means that the optimal blood pressure goal for people with hypertension and type 2 diabetes is still not fully established. A recent meta-analysis concluded that among people with type 2 diabetes, blood pressure lowering was associated with improved mortality and other clinical outcomes among those with baseline blood pressure of 140 mmHg and greater, but increased in those with baseline blood pressure below 140 mmHg [100]. In younger people with shorter diabetes duration, fewer comorbidities, and higher estimated risk for stroke and renal events, the blood pressure goal could be at the lower range of 130–140/80–90 mmHg [100–102], and according to European guidelines lower than 130 in those younger than 65 years,

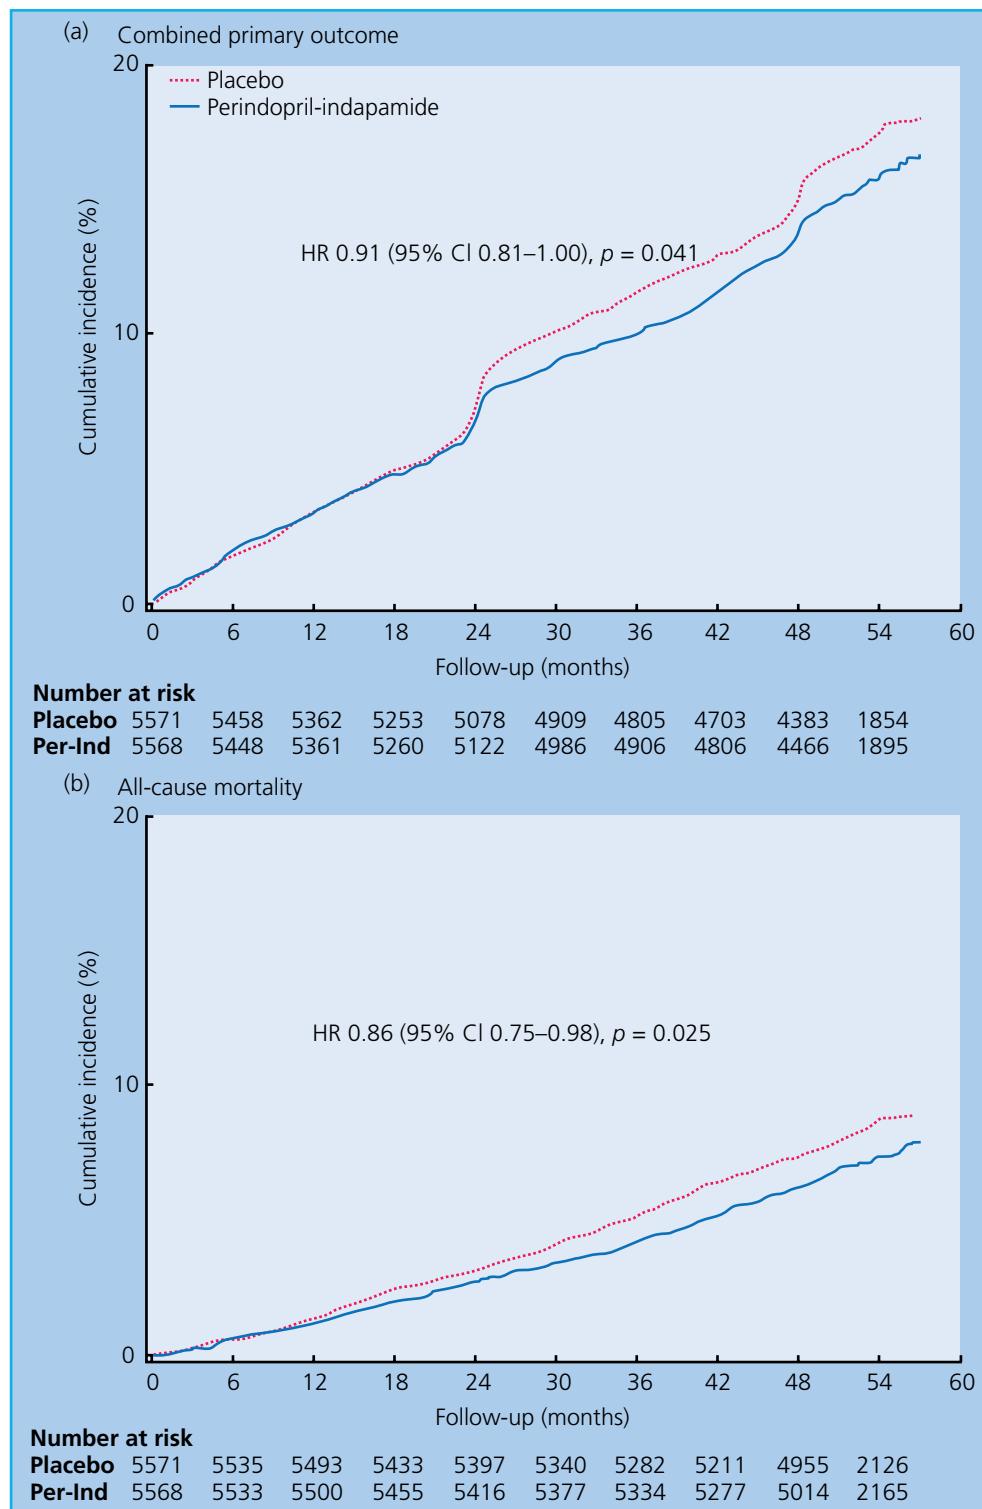

Figure 47.7 Kaplan–Meier curves for the (a) primary outcome and (b) all-cause mortality in the two study groups in the ADVANCE Trial [86]. The combined primary outcome was a composite of major macrovascular and microvascular events. Major macrovascular events were cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke. Major microvascular events were new or worsening nephropathy or retinopathy. CI, confidence interval; HR, hazard ratio.

but within the systolic blood pressure range of 130–140 mmHg for older people, if tolerated.

Finally, it takes a multifactorial approach to address and to treat all major cardiovascular risk factors, not only blood pressure,

to achieve lasting cardiovascular protection in persons with type 2 diabetes, as evidenced by the Steno-2 trial [103]. This strategy was also cost-effective [104] and should therefore be widely implemented.

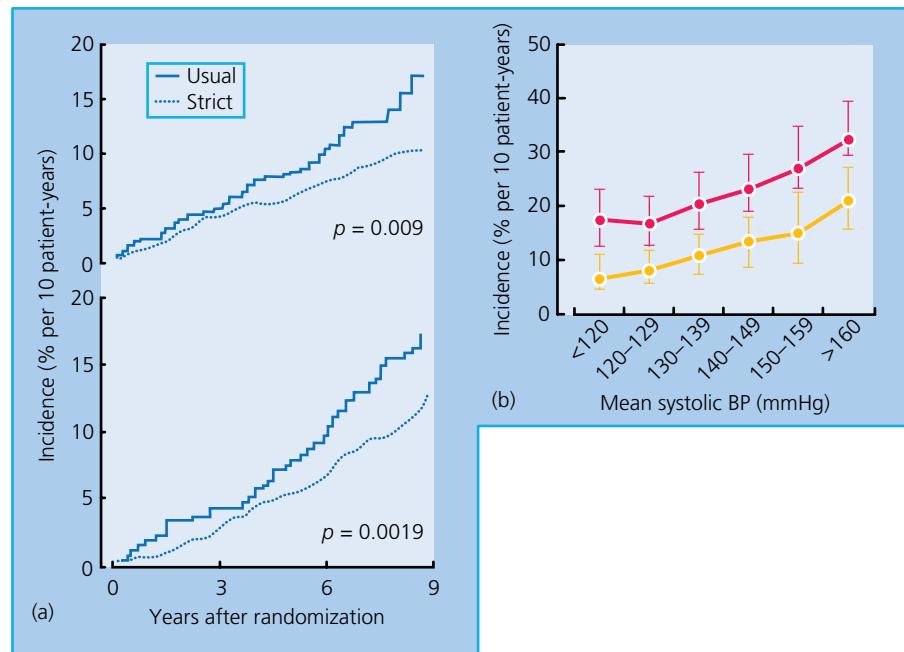

Figure 47.8 Treating hypertension improves the prognosis in type 2 diabetes. (a) Stricter blood pressure (BP) control (mean pressure 144/82 mmHg) significantly reduced the risks of both microvascular complications (top) and diabetes-related death (bottom), compared with less strict control (mean 154/82 mmHg). (b) Relationship between blood pressure and rates of microvascular disease and myocardial infarction. Lowering the blood pressure progressively reduced the risk of microvascular complications, but there was no significant effect on myocardial. The red line represents myocardial infarction and the yellow line represents microvascular complications. Source: UKPDS 1998 [5]. Reproduced with permission from BMJ Publishing Group Ltd.

Key points

- The greatest long-term risk in diabetes is cardiovascular disease, with macrovascular disease being the cause of 80% of mortality.
- Epidemiological studies have established that hyperglycaemia, nephropathy, and dyslipidaemia are risk factors for cardiovascular disease in type 1 diabetes.
- Low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, smoking, and hypertension are the principal risk factors in type 2 diabetes.
- In type 2 diabetes optimized glycaemic management has modest effects in reducing cardiovascular disease endpoints.

- The dyslipidaemia of type 2 diabetes is associated with elevated triglycerides, reduced HDL cholesterol, and small dense particles.
- Reduction of LDL cholesterol with statins has consistently shown cardiovascular event reductions of ~21% per 1 mmol/l LDL cholesterol.
- Monotherapy with fibrates led to a modest reduction in events in people with type 2 diabetes in the FIELD study.
- Trials now underway will allow the efficacy of combination lipid-lowering therapies in diabetes to be determined.
- Optimal management of all risk factors can reduce cardiovascular events and mortality in diabetes by 50%.

An association between diabetes and heart disease was described more than a century ago. In 1906, it was hypothesized that this association was due to atherosclerosis. The importance of diabetes as a cardiovascular disease (CVD) risk factor became established following the Framingham Study and this was subsequently confirmed by other landmark studies [1, 2]. The magnitude of diabetes as a CVD risk factor is substantial, with the increase in cardiovascular risk being two- to fourfold. Many guidelines regard diabetes as a coronary heart disease (CHD) risk equivalent [3, 4]. This concept is based originally on a Finnish cohort, which showed comparable risk of CHD outcomes such as myocardial infarction (MI) and CHD death, between individuals with type 2 diabetes for >10 years and people with established CHD [5]. This was still apparent after adjusting for known risk factors such as age, sex, hypertension, total cholesterol, and smoking. The Organization to Assess Strategies for Ischemic Syndromes (OASIS) study showed that people with diabetes and with no previous CVD have the same long-term morbidity and mortality as normoglycaemic individuals with established CVD after hospitalization for unstable coronary artery disease (CAD) [6]. However, there is wide variation in the rate of CHD in diabetes, which depends on the population studied, duration of diabetes, as well as existing risk factors (Figure 48.1) [7, 8]. This equivalence has not been confirmed by subsequent studies and it also seems less valid in older individuals, where those with existing CHD have a greater risk than people with diabetes without CHD [8–10]. People with type 1 diabetes are also at increased risk for CVD [11, 12]. Although people with type 1 diabetes mostly present at an earlier age, the rates of CVD are increased at all ages [13].

Concomitant CVD risk factors also differ according to the type of diabetes. Other markers of CVD risk in people with diabetes include diabetic retinopathy, autonomic neuropathy, erectile dysfunction, microalbuminuria, and proteinuria [14], with nephropathy being the most significant. In type 1 diabetes the risk of premature CVD is increased 7-fold for mortality and 12-fold for CVD events with sub-optimal risk factor management, and 1.3-fold for mortality and 1.8-fold for MI with optimal management [10].

In general, people with diabetes have a 2–4-fold increased CVD risk compared with people without diabetes [15, 16]. Most guidelines do not recommend formal CVD risk estimation in diabetes due to the significant risk these individuals already have and the tendency of risk calculation equations to underestimate risk in this group. Clinicians, however, may still opt to estimate the risk by employing various validated risk calculators, which include QRISK specific diabetes scores in the UK [17]. These predict risk with variable accuracy [18] and may depend on interpolated data [19]. As all methods of CVD risk estimation suffer from distinct limitations, so clinical judgement remains necessary to accurately risk stratify and select and titrate the appropriate treatment.

Cardiovascular disease risk factors in diabetes

Glucose

A risk continuum exists across a broad glucose concentration range, which incorporates individuals without diabetes, with the risk of CVD being lowest when the fasting blood glucose is between

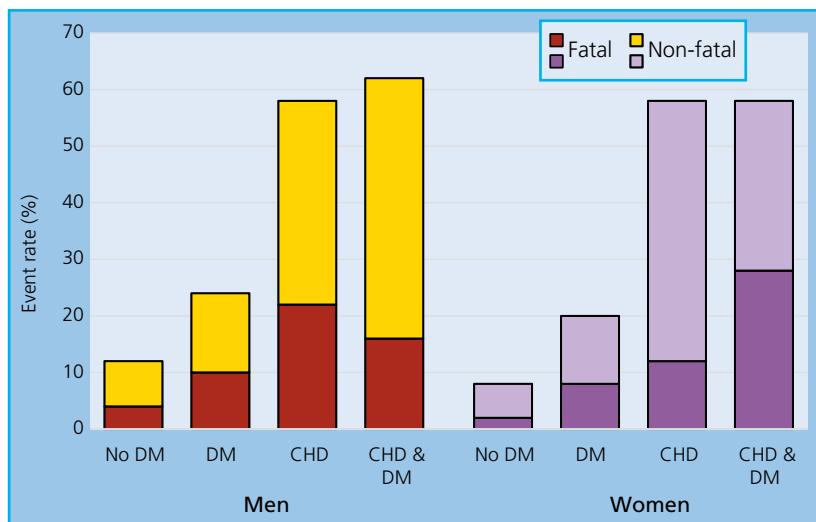

Figure 48.1 Lack of equivalence of cardiovascular risk in individuals with previous coronary heart disease (CHD) and those with diabetes (DM). Source: Data from Howard et al. 2006 [7].

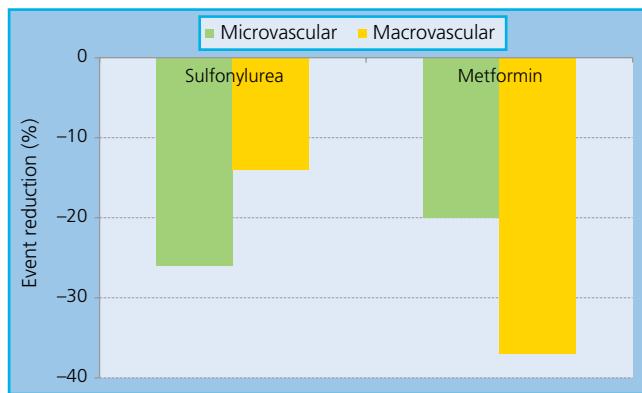

Figure 48.2 Results of the UK Prospective Diabetes Study for microvascular and macrovascular events at 10-year follow-up. Source: Data from Holman et al. 2008 [24].

4 and 4.9 mmol/l [20–22]. Epidemiological studies show a consistent association between blood glucose and atherosclerosis, but only recently have intervention studies shown an improvement in CVD outcomes by reducing glucose [16]. In the Epidemiology of Diabetes Interventions and Complications (EDIC) [23] follow-up from the Diabetes Control and Complications Trial (DCCT), glucose lowering in people with type 1 diabetes was associated with a long-term benefit with regard to CVD complications that became apparent only years after recruitment. In type 2 diabetes, 10 year follow-up data from the UK Prospective Diabetes Study (UKPDS) intensive glucose therapy showed long-term beneficial effects on macrovascular outcomes [24]. However, unlike the microvascular benefits, risk reductions for MI and death from any cause were observed only with extended post-trial follow-up (Figure 48.2). These results suggested that improved glucose management may result in a larger CVD risk reduction in persons with type 1 diabetes than among those with type 2 diabetes, which is consistent with the results of one meta-analysis (Figure 48.3).

Dyslipidaemia

The reasons for the excess risk for CVD in diabetes are numerous and varied and in part relate to the lipid abnormalities seen in diabetes [25–27]. Enhanced glycation of lipoproteins has direct effects

on lipoprotein metabolism, as these glycated lipoproteins are handled differently by lipoprotein receptors, particularly of the scavenger group, thus promoting atherogenesis [27, 28]. Enhanced glycation also amplifies the effects of oxidative stress on lipoproteins and this therefore implicates both type 1 diabetes and type 2 diabetes [29]. Diabetic dyslipidaemia refers to the atherogenic lipid abnormalities typically seen in persons with type 2 diabetes, characterized by elevated triglyceride (TG)-rich remnant lipoproteins (routinely measured as excess TG), small dense low-density lipoprotein particles (sdLDL) and low high-density lipoprotein (HDL) cholesterol concentrations [30, 31].

Several factors are likely to be responsible for diabetic dyslipidaemia, including:

- Insulin effects on liver apolipoprotein production.
- Downregulation of lipoprotein lipase (LPL) as opposed to hepatic lipase (HL).
- Increased cholesteryl ester transfer protein (CETP) activity.
- Peripheral actions of insulin on adipose and muscle [27].

Targeting dyslipidaemia has proven effective in preventing the macrovascular complications of diabetes. For many years the benefits of intervention on lipoproteins as CVD risk factors in diabetes were uncertain, as people with diabetes were excluded from trials of lipid-lowering therapies. No pre-specified data exist from early studies with bile acid sequestrants, fibrates, or nicotinic acid, but later studies with statins and fibrates have been performed in people with type 2 diabetes. Evidence has accumulated for LDL cholesterol being the prime risk factor for atherosclerosis [32], but more recently increased recognition of the role of TG-rich lipoproteins in CVD [33] has led to the suggestion that non-HDL cholesterol (difference of total and HDL cholesterol) might be a better guide to CVD risk, especially in diabetes [34].

Low-density lipoprotein cholesterol

LDL cholesterol is identified as the primary target of lipid-lowering therapy. Most laboratories report a calculated LDL cholesterol using the Friedewald equation, which tends to underestimate LDL cholesterol compared to direct assays or newer equations, especially if TGs are increased, as is often the case in people with diabetes [35]. Epidemiological studies show a strong association of cholesterol fractions including total cholesterol, LDL cholesterol, and non-HDL cholesterol (a measure of apolipoprotein B₁₀₀ containing particles

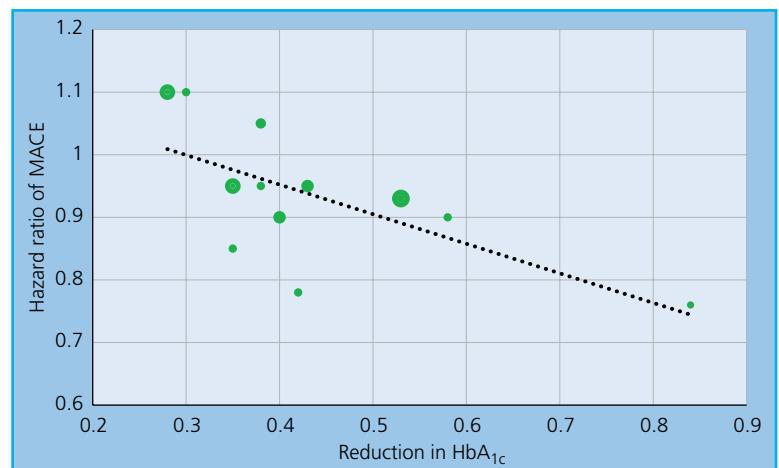

Figure 48.3 Meta-regression of improved glycated haemoglobin (HbA_{1c}) and cardiovascular events. MACE, major adverse cardiovascular events. Source: Data from Giugliano et al. 2019 [85].

including TG-rich lipoproteins) with CVD in people with and without diabetes [32, 34, 36]. Analysis of the UKPDS showed that LDL cholesterol was the strongest risk factor for CHD in the study population and HDL cholesterol was the second strongest [37]. In contrast, in type 1 diabetes the EDIC-DCCT collaboration shows stronger relationships for glycaemic and blood pressure management compared to lipids for CVD risk [38], but as participants age then LDL cholesterol becomes more significant [39].

Low-density lipoprotein subfractions

The LDL class comprises a heterogeneous population of particles with respect to lipid composition, charge, density, and particle size and shape [40]. The sizes of LDL particles fall between the large TG-enriched VLDL and the dense and small protein-rich HDL. In addition, these small dense LDL (sdLDL) particles are more atherogenic as they are more readily oxidized and glycated [30, 41]. Oxidized LDL delivers cholesterol to the atherosclerotic plaque in an unregulated way through uptake by the macrophage and is increased in diabetes [42]. New automated assays are now available for sdLDL [43] and may be more practical than magnetic resonance or gel assays, though some standardization is still required [44].

Large numbers of studies have confirmed the association of sdLDL with CVD [45]. However, no prospective studies have specifically examined whether altering particle size profiles results in benefits on CVD events, though analysis of the Veterans Affairs HDL Intervention Trial (VA-HIT) fibrate study does suggest some role for this mechanism [46]. Even with effective LDL cholesterol treatment, the residual risk of further CVD events remains high, emphasizing the importance of improving other abnormalities and other CVD risk factors commonly observed in these individuals [47, 48].

Triglycerides

The reason for the elevated TGs in diabetes is complex. However, it is also because of this derangement that it has been suggested that diabetes should not be called mellitus but rather 'lipidus' [49]. Defects in insulin action and hyperglycaemia can lead to changes in plasma lipoproteins in persons with diabetes. Alternatively, especially in the case of type 2 diabetes, the obesity/insulin-resistant metabolic disarray that is at the root of this form of diabetes could itself lead to lipid abnormalities exclusive of hyperglycaemia [27]. It

is this molecular interplay between lipid and carbohydrate metabolism that has led to what might be termed a 'lipocentric' view of the pathogenesis of insulin resistance and type 2 diabetes [50]. As fatty acids play such a central role in insulin sensitivity, obesity, and type 2 diabetes, it follows that the major disturbance in lipoprotein metabolism in diabetes is found in the TG-rich lipoproteins, stemming from abnormalities in chylomicron synthesis and clearance [51].

Triglycerides (also referred to as triacylglycerol) are formed from a single molecule of glycerol combined with three fatty acids and represent a heterogeneous group of molecules that, most frequently are measured collectively, as a 'family' of analytes [52]. As high serum TG levels are associated with abnormal lipoprotein metabolism, as well as with other cardiovascular risk factors including obesity, insulin resistance, diabetes, and low levels of HDL cholesterol, it is difficult to distinguish between cause and effect and to establish TGs as an independent CVD risk factor. However, meta-analyses show that elevated serum TG levels are associated with increased risk for atherosclerotic events in epidemiological cohort studies [33], but some familial causes of hypertriglyceridaemia have no apparent effect on atherosclerotic vascular disease [53].

The two main sources of plasma TGs are exogenous (i.e. from dietary fat) carried in chylomicrons (CM), and endogenous (from the liver) and carried in VLDL particles. In capillaries within fat and muscle tissue, these lipoproteins and chylomicrons are hydrolysed by LPL into free fatty acids. LPL is activated by apolipoprotein C-II (apoC-II), cleaving the TG core and releasing free fatty acids, which can be oxidized by muscle for energy or kept in adipose tissue for future use, and inhibited by the action of apoC-III [54]. In routine clinical practice hypertriglyceridaemia is the most frequent lipoprotein abnormality found in dysregulated diabetes. The mechanisms for these include increased absorption and production of TGs, allied with reduced catabolism of TG-rich particles caused by decreased activity of LPL. Increased adipose tissue lipolysis is a consequence of insulin resistance and/or insulin deficiency. The increased lipolysis results in increased fatty acid release from fat cells, with increase in fatty acid transport to the liver. Studies in tissue cultures, animal experiments [55], and in humans [56] suggest that fatty acids modulate liver apoB secretion. In parallel with increased liver TGs, production of apoB (the major protein component of VLDL and LDL) and hence the number of

particles are increased in type 2 diabetes. Microsomal triglyceride transfer protein (MTP) assembles the chylomicron in the intestine and the VLDL particle in the liver. MTP has been shown to be increased in the intestine of people with diabetes [57]. Cholesterol absorption also seems to be adversely influenced in people with diabetes. Levels of NPC1L1 protein, which plays a critical role in the absorption of cholesterol, are increased in diabetes. The ATP-binding cassette transporters ABC-G5 and ABC-G8 dimerize to form a functional complex necessary for efflux of dietary cholesterol and non-cholesterol sterols from the intestine and liver. These proteins have been shown to be reduced in diabetes in both liver and intestine. LPL is an insulin-dependent enzyme that is responsible for the conversion of lipoprotein TG into free fatty acids and has several other activities relating to lipid and carbohydrate metabolism [58]. Both in type 1 diabetes and type 2 diabetes, there is an associated reduced LPL activity, which is further suppressed by adipose-derived cytokines such as tumour necrosis factor alpha (TNF- α) and interleukin 6 (IL-6) [27].

Statins form the mainstay of lipid management based on their efficacy in lowering LDL cholesterol, but their effects on components of the atherogenic dyslipidaemia associated with type 2 diabetes are more modest, reducing TGs at most by 15–30% and raising HDL cholesterol typically by less than 10% [59]. Interventions usually affect both TGs and other lipid fractions and so it is difficult to distinguish between the individual benefits, but a residual benefit of 9% per 1 mmol/l reduction in TGs exists even after excluding the TG-reducing effects of omega-3 fatty acids [60].

High-density lipoprotein cholesterol

Like LDL, HDL also comprises a heterogeneous population of particles. The inverse relationship between HDL cholesterol levels and atherosclerotic CVD provides the epidemiological basis for the widely accepted hypothesis that HDL is atheroprotective [34]. HDL has several distinct but potentially overlapping atheroprotective functions [61, 62]. These include the well-known action on reverse cholesterol transport [63] as well as reductions in oxidative stress and innate immunity and inflammation [64]. More HDL-associated proteins are involved in immune and inflammatory functions than in lipid transport and metabolism, suggesting the fundamental role for HDL in innate immunity [65, 66]. There are several reasons that could account for the decrease in HDL cholesterol in diabetes [27]. The CETP-mediated exchange of VLDL TG for HDL cholesteryl esters is accelerated in the presence of hypertriglyceridaemia [67]. The TG in HDL is a substrate for plasma lipases, especially hepatic lipase that converts HDL to a smaller particle that is more rapidly cleared from the plasma. Precursors of advanced glycation end-products can also impair reverse cholesterol transport by HDL.

tion in CVD events with a Mediterranean diet enriched in nuts or olive oil compared with a control diet, but was likely underpowered for this subgroup [71]. Trials involving weight loss improve lipids by reducing hepatic steatosis (fatty liver) and allied secondary features such as the production of TG-rich lipoproteins. The Look AHEAD (Action for Health in Diabetes) study randomized 5145 obese people with type 2 diabetes to intensive lifestyle intervention or diabetes support and education for 9.6 years [72]. It showed no significant difference in CVD outcomes or safety despite improvements in surrogate and secondary outcomes such as glucose, lipids, blood pressure, sleep apnoea, liver fat, kidney disease, or retinopathy allied with a reduced need for diabetes medications.

Statins

Statins (2-hydroxy-methyl-glutaryl coenzyme A reductase inhibitors) work by inhibiting the rate-limiting step in cholesterol synthesis [67]. This results in intracellular depletion of cholesterol in hepatocytes that is sensed in the endoplasmic reticulum and results in cleavage of the sensor protein-releasing sterol receptor element-binding protein-2 (SREBP-2), which upregulates nuclear synthesis of cholesterol synthetic enzymes and the LDL receptor [67]. Increased LDL receptor expression causes a reduction in plasma cholesterol. Statins deliver a 20–50% reduction in LDL cholesterol, but 1% of people taking the drug develop myalgia with these agents. Even relatively modern studies discouraged recruitment or restricted entry to people with hypercholesterolaemia and reasonable levels of glycaemia (glycated haemoglobin [$\text{HbA}_{1\text{c}}$] <64 mmol/nmol; 8%), as in the Scandinavian Simvastatin Survival Study (4S), the first major statin trial [73]. The 4S included only 202 people with type 2 diabetes in 4444 participants. However, in this small group of participants, simvastatin therapy was associated with a 55% reduction in major CHD (fatal and non-fatal CHD; $p = 0.002$) compared with a 32% reduction in major CHD in people without diabetes [74]. The absolute benefit of cholesterol lowering in type 2 diabetes was greater than that in people with CHD but without diabetes, because persons with type 2 diabetes had a higher absolute risk of atherosclerotic events and CHD. This notion was later confirmed in studies that also recruited a subgroup of individuals with diabetes [75].

The Collaborative Atorvastatin Diabetes Study (CARDS) [76] and the Heart Protection Study (HPS) [77] included people with type 2 diabetes randomized in a double-blind, placebo-controlled design to atorvastatin 10 mg/d in CARDS and to simvastatin 40 mg/d in HPS. This produced, respectively, a 40% and 33% reduction in LDL cholesterol associated with a 37% and 31% reduction in combined CVD endpoints. While HPS was mostly a secondary prevention study recruiting people with established CVD, it included a pre-specified subgroup of 5963 individuals with diabetes (29% of the total study group) [77] of whom 600 persons had type 1 diabetes. The CARDS trial solely included individuals with type 2 diabetes and with more than one other risk factor (e.g. uncontrolled hypertension and/or microalbuminuria) but without prior overt CVD. The study was terminated two years early after showing early benefits. The data from trials and subgroups with diabetes were integrated in an individual patient-level meta-analysis of 18 686 individuals (type 1 diabetes 1466; type 2 diabetes 17 220), which showed that over 4.3 years of follow-up and 3247 major vascular events statin therapy reduced mortality by 9% per 1 mmol LDL cholesterol similar to the 13% per 1 mmol/l LDL cholesterol in the group without diabetes, driven by a 13% per 1 mmol/l LDL cholesterol reduction in CVD

Treatment options

Dietary treatments

Though many studies exist of different diets in people with diabetes, they typically only report short-term changes in lipids. Cardiovascular outcome studies are rarer and generally underpowered, but meta-analyses suggest a benefit for Mediterranean diets in populations at risk of CVD [68–70]. Recently, the Prevención con Dieta Mediterránea (PREDIMED) trial in 7447 people at high CVD risk, including 50% with type 2 diabetes, showed a 28–31% reduc-

death. Overall a 21% per 1 mmol/L LDL cholesterol reduction was seen in total vascular events, similar to the groups without diabetes in the studies [78].

Studies have investigated individuals with diabetes and nephropathy. In Die Deutsche Dialyse Diabetes (4D) study in persons with end-stage renal disease on dialysis with type 2 diabetes, aggressive LDL cholesterol reduction reduced events by a non-significant 8%, despite a 41% reduction in LDL cholesterol [79]. The Simvastatin Heart and Renal Protection (SHARP) study in 9270 individuals with chronic kidney disease (CKD stages 3–5), which included a subgroup with type 2 diabetes ($n = 2094$), simvastatin 20 mg, and added ezetimibe 10 mg, showed a similar 22% reduction in CVD events to 14% in the normoglycaemic group, with the greatest relative benefits with lower severity of CKD [80].

Cholesterol absorption and resorption inhibitors

Bile acid sequestrants are one of the oldest lipid-lowering therapies. They inhibit resorption-absorption of cholesterol in the terminal ileum. Data in people with diabetes are limited to their effects on lipids, where they reduce LDL cholesterol by 20% but tend to increase TGs, despite having a small effect on improving glucose levels. They have a poor side-effect profile with high rates of gastrointestinal disturbance. There are no CVD outcome studies with these drugs that have recruited any people with diabetes, so their effects on hard outcomes are unknown.

The cholesterol absorption inhibitor ezetimibe works by reducing the upper intestinal cholesterol absorption by inhibiting the function of Niemann-Pick C1-like protein 1 (NPC1L1) transporter to produce a 21% reduction in LDL cholesterol and, in contrast to bile acid sequestrants, has little effect on other lipid fractions. The Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) study compared the addition of ezetimibe with placebo in 18 144 individuals with acute coronary syndromes (ACS) optimized on statin therapy [81]. Statin optimization reduced LDL cholesterol from 2.4 to 1.8 mmol/l and ezetimibe delivered a further 0.4 mmol/l reduction. The 4933 persons with type 2 diabetes showed a greater 14% reduction in CVD events compared with 3% in the group without diabetes ($p = 0.02$). They had double the CVD event rate and thus half the number needed to treat (NNT) of 12, as opposed to 25 for CVD events including procedures in the overall study.

Proprotein convertase subtilisin kexin-9 inhibitors

Proprotein convertase subtilisin kexin-9 (PCSK9) inhibitors act to reduce LDL cholesterol by upregulating LDL receptor function and reduce LDL cholesterol by 57% [82]. The most recent trials in individuals with ACS have used PCSK9 inhibitors and required the presence of additional CVD risk factors, including type 2 diabetes. All individuals were optimized on statin therapy, but ezetimibe use was low (<5%). In the Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk (FOURIER) study, after 2–3 years CVD events were reduced by 16% after one year, rising to 25% after two years overall, in line with the 1 mmol/l reduction in LDL cholesterol after allowance was made for initiation effects in a secondary prevention population [83]. Effects in individuals with diabetes were similar to those without [84].

The accumulated evidence strongly supports the efficacy of LDL cholesterol-lowering therapies in reducing CVD, with the latest regression analyses suggesting benefits of 17% event reduction per 1 mmol/l LDL cholesterol reduction for all LDL cholesterol therapies, with no difference in results seen in individuals with diabetes (Figure 48.4) [86]. However, some therapies reducing TGs cause an increase in measured LDL cholesterol, mostly through enhanced conversion of very low-density lipoprotein (VLDL) to LDL particles, with the effects being proportional to baseline TGs. For instance, omega-3 fatty acids raise LDL cholesterol by 6% [87], while sodium-glucose cotransporter 2 (SGLT-2) inhibitors raise LDL cholesterol by 0.1 mmol/l (3%) and non-HDL cholesterol by 0.09 mmol/l (2%) [88]. The relevance of these secondary rises in LDL cholesterol is unclear, as these therapies show lipid-independent effects on rates of CVD.

Fibrates

The ‘fibrate’ class of lipid-lowering drugs is useful for lowering elevated TG or non-HDL cholesterol levels, as these agents, which act on peroxisomal proliferator-activating receptor alpha (PPAR- α), increase lipoprotein lipase activity, reduce apoC-III, and may increase HDL cholesterol or decrease fibrinogen [89]. VA-HIT evaluated the potential benefits of gemfibrozil in 2531 men who had suffered an acute MI. Individuals with relatively low LDL cholesterol (<3.6 mmol/l) and low HDL cholesterol (<1.0 mmol/l) were recruited. The primary CVD endpoint of fatal and non-fatal MI was reduced by 22% [90]. Similar effects were seen in the 25% of

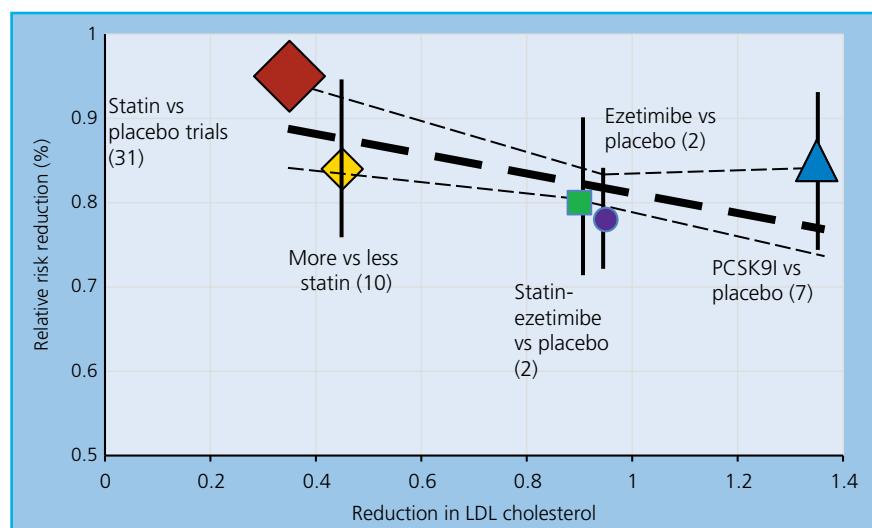

Figure 48.4 Meta-regression of effects of low-density lipoprotein (LDL) cholesterol-lowering therapies on cardiovascular event rates. PCSK9i, proprotein convertase subtilisin kexin-9 inhibitor. Source: Data from Wang et al. 2020 [86].

participants with type 2 diabetes. These outcomes were achieved despite relatively small changes in HDL cholesterol (8%) and no change in LDL cholesterol (0%). An exploration of the effect of gemfibrozil showed that the principal effect of the fibrate treatment was a 31% reduction in TGs, which reflects changes in particle sizes, but this effect was not related to CVD event reduction [91]. The subgroup of individuals with type 2 diabetes showed a relative risk reduction of 32% compared to 18% in the group without diabetes [92].

However, later fibrate trials showed less benefit. The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study randomized 9795 individuals with type 2 diabetes to fenofibrate (200 mg daily) or placebo who were not on statin treatment at the beginning of the study and participants were treated for five years [93]. A non-significant 11% reduction in the primary endpoint of CHD was found, but a reduction in the secondary endpoint of total CVD events was achieved ($p = 0.035$). The study was confounded by asymmetrical statin drop-in, with many more individuals with diabetes in the placebo arm being initiated on statin therapy during the trial (17%) than those in the fenofibrate arm (8%) [44]. As statin therapy is core to lipid management, the question arose as to whether fibrates added anything to statin therapy. *Post hoc* analyses suggested benefits in individuals with atherogenic lipid profiles (high TG, low HDL cholesterol).

The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study randomized 5518 individuals with type 2 diabetes and 37% with CVD to fenofibrate 200 mg on top of statin therapy [94]. There were no specific HDL cholesterol or TG recruitment criteria. After five years fibrate therapy delivered a 9% non-significant reduction in CVD events. The pre-specified dyslipidaemic subgroup ($n = 931$) showed a 29% reduction in CVD events compared to no change in the non-dyslipidaemic group ($p = 0.06$). The overall results led to fibrates being discouraged in use in combination therapy in the USA. As the role of fibrates added to statins in dyslipidaemic individuals with type 2 diabetes remains unclear, a further trial (Pemafibrate to Reduce cardiovascular OutcoMes by reducing triglycerides IN patiENTs with diabeTes, PROMINENT) is now underway using the selective PPAR modulator (SPARM) pemafibrate, which has similar lipid effects to fibrates [95]. Lipid-lowering fibre therapy in both the FIELD and ACCORD studies was associated with benefits on microvascular disease such as retinopathy and nephropathy [96].

It is difficult to compare fibrate trials as they seem to give heterogeneous results depending on the compound used. No fibrate trials

have shown a reduction in all-cause mortality, but meta-analyses suggest they may reduce non-fatal MI (Figure 48.5), although some of this can be explained by their predicted reduction in LDL cholesterol [97, 98]. However, this does not explain the effects seen with gemfibrozil, which does not reduce LDL cholesterol.

Niacin

Nicotinic acid (niacin) reduces hypertriglyceridaemia and LDL cholesterol and raises HDL cholesterol, so it has been referred to as the 'broad-spectrum' lipid drug [99]. Niacin was the first lipid-lowering agent to show a significant reduction in CVD events but not mortality. The Coronary Drug Project (CDP) randomized 3908 men with previous MI to either niacin or placebo and showed reduced CVD events but not mortality [100]. In the 15-year post-trial follow-up, niacin was associated with 11% lower mortality [101]. Unfortunately, niacin has been hampered by its side effects, particularly flushing (though amelioration strategies exist) [102] and hyperglycaemia. Niacin adversely affects glucose levels in a dose-related manner [103] and wider variations are seen in practice [104], but it was as effective at lowering CVD outcomes in individuals with hyperglycaemia as in persons with normoglycaemia in the CDP [105]. The Atherosclerosis Intervention in Metabolic syndrome with low HDL/high triglycerides: Impact on Global Health outcomes (AIM-HIGH) recruited 3414 individuals with CVD and low HDL cholesterol [106]. It used extended-release niacin on top of optimized statin therapy and showed no benefit on CVD events overall or in any subgroup. Similarly, the Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) recruited 25 673 individuals with CVD or at high risk of CVD, including 8299 persons with diabetes, but showed no benefits on CVD outcomes and an excess of infection or thrombocytopaenia with niacin therapy. As in AIM-HIGH, all participants were optimized on statin therapy, but HPS-THRIVE differed in lacking pre-specified lipid recruitment criteria (raised TG-to-HDL cholesterol atherogenic index) and in using extended-release niacin allied with laropiprant (an inhibitor of prostaglandin receptor D1, which reduces the flushing) [107]. These two trials have downgraded the usefulness of niacin in CVD.

Omega-3 fatty acids

Omega-3 fatty acids have complex actions, including effects on inflammation and a dose-dependent reduction in TGs mediated through the free fatty acid receptor 4 (FFAR-4) [108]. The efficacy

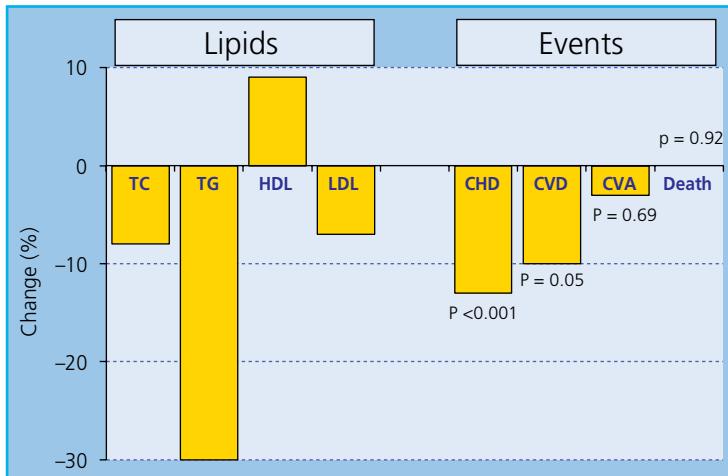

Figure 48.5 Fibrates: meta-analyses of effects on lipids and cardiovascular events. CHD, coronary heart disease; CVA, stroke–cerebrovascular accident; CVD, cardiovascular disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TC, total cholesterol; TG, triglycerides. Source: Data from Saha et al. 2007 [97] (10 studies, $n = 36\,489$) and Jun et al. 2010 [98] (18 studies, $n = 45\,058$).

of omega-3 fatty acids in reducing TGs was validated in the MARINE trial, which recruited individuals with significant hypertriglyceridaemia ($TG > 4.5 \text{ mmol/l}$) [109]. The role of omega-3 fatty acids in CVD and type 2 diabetes is complicated. Early trials of dietary supplementation and later pharmacological preparations (e.g. docosahexanoic acid [DHA]/eicosapentanoic acid [EPA]) showed benefits. Later, their effects were investigated in people with impaired glycaemia or type 2 diabetes in the Outcome Reduction with Initial Glargine Intervention (ORIGIN) study [110] and then in individuals with type 2 diabetes in the A Study of Cardiovascular Events iN Diabetes (ASCEND) trials [111] and showed no benefit. When data are meta-analysed, there is no benefit to omega-3 fatty acid therapy at a low dose ($< 1\text{ g}$) on CVD events (Figure 48.6) [112]. However, a trial in this meta-analysis that used higher doses of omega-3 fatty acids showed different results, suggesting that some heterogeneity was present. In the Japan EPA Lipid Intervention Study (JELIS), 18 645 individuals with CVD including 16% with type 2 diabetes were randomized to 2 g EPA on top of a fish-rich diet [113]. Added EPA therapy reduced CVD events by 19% in all participants and a similar 14% in the type 2 diabetes subgroup, independent of any effects of lipids. The effect of 4 g of an EPA derivative compared with mineral oil was investigated in 8179 individuals in the Reduction of Cardiovascular Events with Icosapent Ethyl Intervention Trial (REDUCE-IT) study [114] in individuals with CVD optimized on statin therapy and with $TG > 2.3 \text{ mmol/l}$ (later $> 1.7 \text{ mmol/l}$). Treatment was associated with a 25% CVD benefit independent of lipids in the overall study and 23% in the 4787 (58%) individuals with type 2 diabetes. The long-term outcomes study, the STatin Residual risk with Epanova iN hiGh cardiovascular risk patienTs with Hypertriglyceridemia (STRENGTH) trial, recruited 13 708 participants of whom 9170 had diabetes with an additional risk factor as well as dyslipidaemia with average $TG 2.7 \text{ mmol/l}$ and HDL cholesterol 0.93 mmol/l , and compared 2 g EPA-2 g DHA with corn oil [115]. EPA-DHA reduced TG by 19%, non-HDL cholesterol by 6%, and C-reactive protein by 14%, but raised LDL cholesterol by 2.3%. It had no effect in reducing CVD events. Furthermore, EPA therapy was associated with a 69% increase in new atrial fibrillation and gastrointestinal side effects. Some but not all high-dose studies with

EPA showed CVD benefits and so there may be a role for EPA in people with dyslipidaemia and optimal LDL cholesterol, but there is no role for low-dose therapies.

Other triglyceride-reducing agents

Anti-diabetes agents may also influence TG concentrations due to the peripheral actions of insulin on adipose and muscle or via their action on LPL. In poorly managed type 1 diabetes and even ketoacidosis, hypertriglyceridaemia and reduced HDL cholesterol are seen to occur, and these are most often corrected with insulin therapy. In type 2 diabetes, metformin [116], sulfonylureas [117], and acarbose [118] all show modest reductions in TG that correlate with HbA_{1c} [119, 120]. In general, thiazolidinediones have better overall effects on lipids compared to sulfonylureas or insulin [121]. However, pioglitazone and rosiglitazone have distinctly different effects on the lipid profile [89, 122]. Pioglitazone is associated with a reduction in TG, rosiglitazone with increased concentrations. In the PROspective pioglitAzone Clinical Trial In macroVascular Events (PROACTIVE) study, pioglitazone added to other anti-diabetes therapies in individuals with type 2 diabetes reduced CVD events by 11% in the main secondary endpoint [123].

Several other interventions exist that reduce TG secondary to their action in reducing weight [124]. Orlistat has been shown to prevent progression to diabetes in the XENical in the prevention of Diabetes in Obese Subjects (XENDOS) study [125]. Similar effects are seen with glucagon-like protein-1 (GLP-1) receptor agonists such as semaglutide, which can reduce body weight by up to 10 kg [126].

Agents to increase high-density lipoprotein cholesterol

As opposed to LDL cholesterol lowering, therapies for intervening in order to raise HDL cholesterol have proven to be not that simple. Some HDL therapies may reduce CVD without changing HDL cholesterol concentrations. A preliminary intravascular ultrasound study (IVUS) of a hyperfunctional form of apoA-1 (apoA-1_{Milano}) showed regression of coronary atherosclerosis [127], but a later larger study showed no benefits although, unusually, regression was seen in the placebo group [128]. CETP inhibitors raise plasma HDL

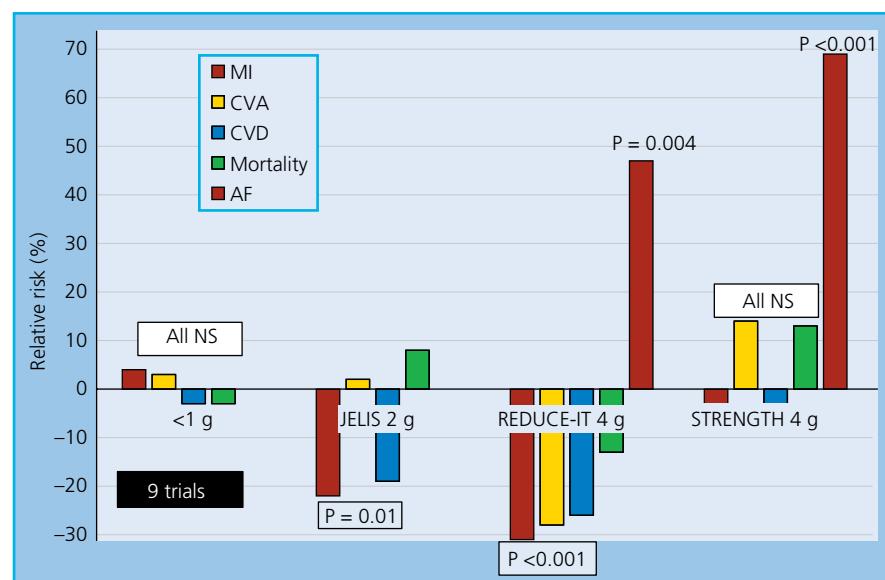

Figure 48.6 Effects of omega-3 fatty acid preparations on cardiovascular events and new-onset atrial fibrillation. AF, atrial fibrillation; CVA, stroke–cerebrovascular accident; CVD, cardiovascular disease; MI, myocardial infarction; NS, non-significant. Source: Data from Aung et al. 2018 [112].

cholesterol and reduce LDL cholesterol, but have lesser effects on HDL cholesterol turnover. Torcetrapib, the first CETP inhibitor to enter clinical trials, raised HDL cholesterol but also cardiovascular deaths due to off-target effects [129]. Further studies with other compounds of medium potency (dalcetrapib) and high potency (evacetrapib, anacetrapib) showed no benefits in large trials [130], except that anacetrapib produced a marginal reduction in MI but not total CVD events [131].

Cardiovascular risk guidelines

All CVD guidelines agree that aggressive lipid-lowering therapy is required in management of type 2 diabetes (Figure 48.7) [3, 4, 132]. These include prescription of high-dose high-efficacy statin therapy, consideration of use of ezetimibe in ACS, and PCSK9 inhibitors in individuals intolerant to statin therapy or with residual high LDL cholesterol. Most extrapolate these recommendations to type 1 diabetes based on a small amount of evidence and consensus. All guidelines suggest an LDL cholesterol target of <2 mmol/l, but the latest data indicate that <1.5 mmol/l might be appropriate, and the European guidelines are <0.8 mmol/l in ultra-high-risk individuals with ACS and additional risk factors including diabetes. Registry studies suggest that smoking cessation and optimized glucose management are still required in individuals with type 2 diabetes even if lipids are optimized [16], but the overall trends indicate that improvements in risk factor control are translating into reduced CVD events in both type 1 and type 2 diabetes [10].

Future drug developments and drug targets

Further developments in lipid lowering include longer-acting PCSK9 inhibitors such as inclisiran, with a six-monthly dosing schedule for short-interfering RNA therapy as opposed to fortnightly for antibody-based therapies [133]. Immunization against PCSK9 may also be possible. All are capable of 50% LDL cholesterol reductions. The alternative method to reduce LDL cholesterol is to inhibit hepatic adenosine triphosphate citrate-coenzyme A lyase with bempedoic acid, which reduces LDL cholesterol by 20–25% and is likely to be most frequently used in people who are intolerant of statins and have moderate dyslipidaemia [134]. Among TG-lowering drugs, CVD outcome studies will be published on

pemafibrate and on EPA derivatives. Little new is expected in HDL-raising therapies in the next few years, given the previous data on CETP inhibitors and the lack of benefit with the bromodomain and extraterminal domain (BET) inhibitor apabetalone.

Non-alcoholic fatty liver disease

There is a strong association between the presence of diabetes, especially type 2 diabetes and non-alcoholic fatty liver disease (NAFLD), and of NAFLD with CVD (Chapter 57) [135]. This reflects the role of insulin resistance and inflammation on the liver and the resultant oversynthesis and secretion of VLDL, leading to a mixed hyperlipidaemia in plasma. Many drugs used to treat insulin resistance and mixed hyperlipidaemia such as metformin, pioglitazone, or fibrates also have beneficial effects in reducing liver fat. New drugs are being developed for NAFLD and non-alcoholic steatohepatitis (NASH), with many being derived from compounds that affect the retinoid-X receptor (RXR) network [136]. Some of these drugs (e.g. obeticholic acid) have contrasting actions on plasma and liver lipid content. All these drugs require CVD outcomes trials, which will likely include individuals with type 2 diabetes and possibly some with type 1 diabetes. Table 48.1 shows the drug classes used or in development for treatment of NAFLD or NASH.

Conclusion

CVD is a very common complication of diabetes, and up to 80% of all people with diabetes will die from macrovascular complications. Lifestyle intervention is both effective and paramount to prevent and treat diabetes and its dyslipidaemia. Statins have revolutionized preventive cardiovascular medicine, and this has formed the foundation of therapeutic lipid intervention (Table 48.2). The abnormalities in lipids and lipoproteins represent only one factor among several that are responsible for the increased risk in persons with diabetes, and therefore multifactorial intervention (Figure 48.8) is required to reduce risk to that of the general population [16].

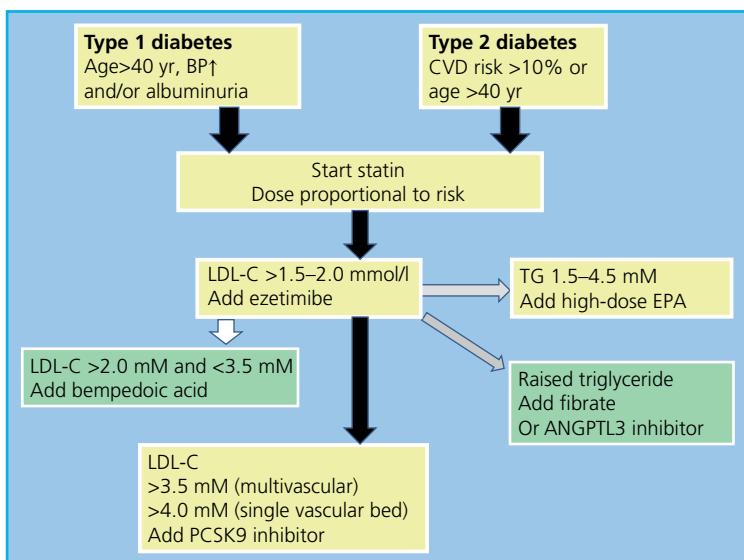

Figure 48.7 Pathways in clinical guidelines for management of lipids based on the American, European, and UK National Institute for Health and Care Excellence (NICE) recommendations. The potential position of novel therapies is indicated. The suggested cut-offs and targets may be modified to lower levels as guidelines evolve. ANGPTL3, angiopoietin-like protein 4; BP, blood pressure; CVD, cardiovascular disease; EPA, eicosapentanenoic acid; LDL-C, low-density lipoprotein cholesterol; PCSK9, proprotein convertase subtilisin kexin-9; TG, triglycerides.

Table 48.1 Drug classes used (**bold**) or in development for treatment of non-alcoholic fatty liver disease (NAFLD) or non-alcoholic steatohepatitis (NASH).

AMP kinase A agonists	PPAR agonists	Farnesoid-X receptor agonists	Weight-reducing agents	Anti-fibrotics
Metformin	PPAR-γ Pioglitazone PPAR- α/γ , e.g. sargagliptazar PPAR- α/δ , e.g. elafibrinor	Obeticholic acid FGF-19 agonists, e.g. aldafermin	GLP-1 receptor agonists, e.g. semaglutide CB1 agonists, e.g. rimonabant (withdrawn)	ASK-1 inhibitors, e.g. selonertib

ASK-1, apoptosis signal-regulated kinase-1; CB1, cannabinoid type 1; FGF-19, fibroblast growth factor 19; GLP-1, glucagon-like protein 1; PPAR, peroxisomal proliferator-activating receptor.

Table 48.2 Effects of different cardiovascular (CV) therapies on lipids and other CV risk factors and endpoint trial evidence of effects in prevention of diabetes and cardiovascular disease (CVD).

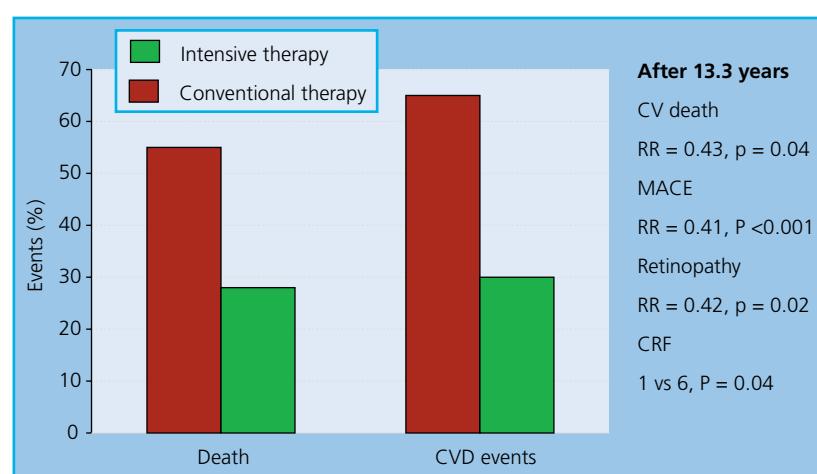

Drug/ treatment group	Component of the cardio-metabolic syndrome change (%)					Diabetes risk reduction (%)	CVD risk reduction (%)
	LDL-C decrease	HDL-C increase	TG decrease	SBP decrease	Glucose decrease		
Metformin	0–10	15	15	0–5	10	45–48	35
SU	0–5	0	0	3	0	?	20
TZD	(–5)–10	9	12	5	8	51–58	10–(+43)
GLP-1 agonist	5	(–2)	20	0	10	?	11
SGLT-2 inhibitor	(–5)	5	5	2	10–15	?	12
Statin	20–55	0–15	15–25	0	0	(–11)	20–55
Fibrate	0–10	2–16	15–24	0–8	0–6	0–23	10–34
Niacin	10–20	10–25	15–35	0	(–10)	?	22–31
Ezetimibe	20	3	8	0	0	?	6 ^a
PCSK-9 inhibitor	40–65	5–7	23	0	0	0	15–20 ^a
Orlistat	0–5	+3	1	1	4	43	?

Negative effects shown in brackets.

CVD, cardiovascular disease; GLP-1, glucagon-like peptide 1; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; PCSK-9, proprotein convertase subtilisin kexin-9; SBP, systolic blood pressure; SGLT-2, sodium–glucose cotransporter 2; SU, sulfonylurea; TG, triglycerides; TZD, thiazolidinedione.

^aData on ezetimibe and PCSK-9 inhibitors on cardiovascular events are only available in people already optimized on statin therapy. Effects are consistent with other LDL-C-lowering drugs in showing a relative risk reduction of 21% per 1 mmol/l LDL-C.

Figure 48.8 Effects of improved multiple risk factor intervention on mortality and cardiovascular events in diabetes. Steno-2: composite endpoint of death from cardiovascular causes, non-fatal myocardial infarction, coronary artery bypass graft, percutaneous coronary intervention, non-fatal stroke, amputation, or surgery for peripheral arterial disease. CRF, chronic renal failure; CV, cardiovascular; CVD, cardiovascular disease; MACE, major adverse cardiovascular events; RR, relative risk. Source: Data from Gaede et al. 2003 [137] and Gaede et al. 2008 [138].
